Cross-referencing the documentation

When reading this manual, you will find references to other Stata manuals, for example, [U] 27 Overview of Stata estimation commands; [R] regress; and [D] reshape. The first example is a reference to chapter 27, Overview of Stata estimation commands, in the User’s Guide; the second is a reference to the regress entry in the Base Reference Manual; and the third is a reference to the reshape entry in the Data Management Reference Manual.

All the manuals in the Stata Documentation have a shorthand notation:

- GSM: Getting Started with Stata for Mac
- GSU: Getting Started with Stata for Unix
- GSW: Getting Started with Stata for Windows
- U: Stata User’s Guide
- R: Stata Base Reference Manual
- BAYES: Stata Bayesian Analysis Reference Manual
- D: Stata Data Management Reference Manual
- ERM: Stata Extended Regression Models Reference Manual
- FN: Stata Functions Reference Manual
- LASSO: Stata Lasso Reference Manual
- XT: Stata Longitudinal-Data/Panel-Data Reference Manual
- META: Stata Meta-Analysis Reference Manual
- MI: Stata Multiple-Imputation Reference Manual
- PSS: Stata Power, Precision, and Sample-Size Reference Manual
- P: Stata Programming Reference Manual
- RPT: Stata Reporting Reference Manual
- SP: Stata Spatial Autoregressive Models Reference Manual
- SVY: Stata Survey Data Reference Manual
- ST: Stata Survival Analysis Reference Manual
- I: Stata Glossary and Index

viii
This entry describes the organization of the reference manuals.

The complete list of reference manuals is as follows:

[R]  *Stata Base Reference Manual*
[BAYES]  *Stata Bayesian Analysis Reference Manual*
[CM]  *Stata Choice Models Reference Manual*
[D]  *Stata Data Management Reference Manual*
[ERM]  *Stata Extended Regression Models Reference Manual*
[FMM]  *Stata Finite Mixture Models Reference Manual*
[FN]  *Stata Functions Reference Manual*
[IRT]  *Stata Item Response Theory Reference Manual*
[LASSO]  *Stata Lasso Reference Manual*
[XT]  *Stata Longitudinal-Data/Panel-Data Reference Manual*
[META]  *Stata Meta-Analysis Reference Manual*
[ME]  *Stata Multilevel Mixed-Effects Reference Manual*
[M]  *Stata Multiple-Imputation Reference Manual*
[MV]  *Stata Multivariate Statistics Reference Manual*
[PSS]  *Stata Power, Precision, and Sample-Size Reference Manual*
[P]  *Stata Programming Reference Manual*
[RPT]  *Stata Reporting Reference Manual*
[SP]  *Stata Spatial Autoregressive Models Reference Manual*
[SEM]  *Stata Structural Equation Modeling Reference Manual*
[SVY]  *Stata Survey Data Reference Manual*
[ST]  *Stata Survival Analysis Reference Manual*
[TS]  *Stata Time-Series Reference Manual*
[I]  *Stata Glossary and Index*
[M]  *Mata Reference Manual*
When we refer to “reference manuals”, we mean all manuals listed above.
When we refer to the specialty manuals, we mean all the manuals listed above except [R] and [I].

**Arrangement of the reference manuals**

Each manual contains the following sections:

- **Contents.**
  A table of contents can be found at the beginning of each manual.

- **Cross-referencing the documentation.**
  This entry lists all the manuals and explains how they are cross-referenced.

- **Introduction.**
  This entry—usually called intro—provides an overview of the manual. In the specialty manuals, this introduction suggests entries that you might want to read first and provides information about new features.

  Each specialty manual contains an overview of the commands described in it.

- **Entries.**
  Entries are arranged in alphabetical order. Most entries describe Stata commands, but some entries discuss concepts, and others provide overviews.

  Entries that describe estimation commands are followed by an entry discussing postestimation commands that are available for use after the estimation command. For example, the `xtlogit` entry in the [XT] manual is followed by the `xtlogit postestimation` entry.

- **Glossary.**
  A glossary is contained in all the specialty manuals.

  The *Glossary and Index*, [I], contains a subject table of contents for all the reference manuals and the *User’s Guide*, a acronym glossary, a vignette index, a combined author index, and a combined subject index for all the manuals.

  To find information and commands quickly, use Stata’s `search` command; see [R] `search` (see the entry `search` in the [R] manual).

**Arrangement of each entry**

Entries in most of the Stata reference manuals contain the following sections, which are explained below:

- **Description**
- **Quick start**
- **Menu**
- **Syntax**
- **Options**
- **Remarks and examples**
- **Stored results**
- **Methods and formulas**
- **Acknowledgments**
- **References**
- **Also see**
Description

The purpose of the command is briefly described here.

Quick start

A quick start lists common uses of the command and the corresponding syntax for each.

For details on the syntax elements shown in the Quick start examples and to further customize the examples shown, see the Syntax and Options sections of the entry.

If you prefer to use the GUI, see the Menu section of the entry.

For applied examples of the syntax, see Remarks and examples.

Menu

A menu indicates how the dialog box for the command may be accessed using the menu system.

Syntax

A command’s syntax diagram shows how to type the command, indicates all possible options, and gives the minimal allowed abbreviations for all the items in the command. For instance, the syntax diagram for the `summarize` command is

```
summarize [varlist] [if] [in] [weight] [, options]
```

<table>
<thead>
<tr>
<th>options</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>detail</code></td>
<td>display additional statistics</td>
</tr>
<tr>
<td><code>meanonly</code></td>
<td>suppress the display; calculate only the mean; programmer’s option</td>
</tr>
<tr>
<td><code>format</code></td>
<td>use variable’s display format</td>
</tr>
<tr>
<td><code>separator(#)</code></td>
<td>draw separator line after every # variables; default is separator(5)</td>
</tr>
<tr>
<td><code>display_options</code></td>
<td>control spacing and base and empty cells</td>
</tr>
</tbody>
</table>

`varlist` may contain factor variables; see [U] 11.4.3 Factor variables.

`varlist` may contain time-series operators; see [U] 11.4.4 Time-series varlists.

`by` is allowed; see [D] by.

`aweights`, `fweights`, and `iweights` are allowed. However, `iweights` may not be used with the `detail` option; see [U] 11.1.6 weight.

Items in the typewriter-style font should be typed exactly as they appear in the diagram, although they may be abbreviated. Underlining indicates the shortest abbreviations where abbreviations are allowed. For instance, `summarize` may be abbreviated `su`, `sum`, `summ`, etc., or it may be spelled out completely. Items in the typewriter font that are not underlined may not be abbreviated.

Square brackets denote optional items. In the syntax diagram above, `varlist`, `if`, `in`, `weight`, and the `options` are optional.

The `options` are listed in a table immediately following the diagram, along with a brief description of each.

Items typed in italics represent arguments for which you are to substitute variable names, observation numbers, and the like.
The diagrams use the following symbols:

- `#` Indicates a literal number, for example, 5; see [U] 12.2 Numbers.
- `[]` Anything enclosed in brackets is optional.
- `{}` At least one of the items enclosed in braces must appear.
- `|` The vertical bar separates alternatives.
- `%fmt` Any Stata format, for example, `%8.2f`; see [U] 12.5 Formats: Controlling how data are displayed.

- `depvar` The dependent variable in an estimation command; see [U] 20 Estimation and postestimation commands.
- `exp` Any algebraic expression, for example, `(5+myvar)/2`; see [U] 13 Functions and expressions.
- `filename` Any filename; see [U] 11.6 Filenaming conventions.
- `indepvars` The independent variables in an estimation command; see [U] 20 Estimation and postestimation commands.
- `newvar` A variable that will be created by the current command; see [U] 11.4.2 Lists of new variables.
- `numlist` A list of numbers; see [U] 11.1.8 numlist.
- `oldvar` A previously created variable; see [U] 11.4.1 Lists of existing variables.
- `options` A list of options; see [U] 11.1.7 options.
- `range` An observation range, for example, 5/20; see [U] 11.1.4 in range.
- `"string"` Any string of characters enclosed in double quotes; see [U] 12.4 Strings.
- `varlist` A list of variable names; see [U] 11.4 varname and varlists. If varlist allows factor variables, a note to that effect will be shown below the syntax diagram; see [U] 11.4.3 Factor variables. If varlist allows time-series operators, a note to that effect will be shown below the syntax diagram; see [U] 11.4.4 Time-series varlists.
- `varname` A variable name; see [U] 11.3 Naming conventions.
- `xvar` The variable to be displayed on the horizontal axis.
- `yvar` The variable to be displayed on the vertical axis.

The Syntax section will indicate whether factor variables or time-series operators may be used with a command. summarize allows factor variables and time-series operators.

If a command allows prefix commands, this will be indicated immediately following the table of options. summarize allows by.

If a command allows weights, the types of weights allowed will be specified, with the default weight listed first. summarize allows aweights, fweights, and iweights, and if the type of weight is not specified, the default is aweights.
Options

If the command allows any options, they are explained here, and for dialog users the location of the options in the dialog is indicated. For instance, in the `logistic` entry in this manual, the Options section looks like this:

<table>
<thead>
<tr>
<th>Model</th>
</tr>
</thead>
<tbody>
<tr>
<td>...</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>SE/Robust</th>
</tr>
</thead>
<tbody>
<tr>
<td>...</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Reporting</th>
</tr>
</thead>
<tbody>
<tr>
<td>...</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Maximization</th>
</tr>
</thead>
<tbody>
<tr>
<td>...</td>
</tr>
</tbody>
</table>

Remarks and examples

The explanations under Description and Options are exceedingly brief and technical; they are designed to provide a quick summary. The remarks explain in English what the preceding technical jargon means. Examples are used to illustrate the command.

Links to video examples posted on Stata’s YouTube channel are provided at the end of this section.

Stored results

Commands are classified as e-class, r-class, s-class, or n-class, according to whether they store calculated results in `e()`, `r()`, `s()`, or not at all. These results can then be used in subroutines by other programs (ado-files). Such stored results are documented here; see [U] 18.8 Accessing results calculated by other programs and [U] 18.9 Accessing results calculated by estimation commands.

Methods and formulas

The techniques and formulas used in obtaining the results are described here as tersely and technically as possible.

Acknowledgments

Some Stata commands began as community-contributed commands, or they were enhanced after suggestions by a Stata user. Here, we acknowledge these contributions.
Elizabeth L. ("Betty") Scott (1917–1988) was an astronomer and mathematician trained at the University of California at Berkeley. She published her first paper when she was just 22 years old, and her work was focused on comets for much of her early academic career. During World War II, Scott began working at the statistical laboratory at Berkeley, which had recently been established by Jerzy Neyman, sparking what would be a long and fruitful collaboration with him. After the war, she shifted her focus toward mathematics and statistics, partly because of limited career opportunities as an astronomer, though she still applied her research to astronomical topics. For example, in 1949 she published a paper using statistical techniques to analyze the distribution of binary star systems. She also published papers examining the distribution of galaxies, and she is the name behind the “Scott effect”, which helps determine the distances to galaxies. Later in her career, Scott applied her statistical knowledge to problems associated with ozone depletion and its effects on the incidence of skin cancer as well as weather modification. She was also a champion of equality for women graduate students and faculty.

Among Scott’s many awards and accomplishments, she was elected an honorary fellow of the Royal Statistical Society and was a fellow of the American Association for the Advancement of Science. In 1992, the Committee of Presidents of Statistical Societies established the Elizabeth L. Scott Award, a biannual award to recognize those who have strived to enhance the status of women within the statistics profession.

Janet Lippe Norwood (1923–2015) was born in Newark, New Jersey. She obtained her PhD from Tufts University and taught political science at Wellesley College. Norwood made significant contributions while she was the first female commissioner for the Bureau of Labor Statistics (BLS). She accomplished the goal of conducting the Consumer Expenditure Survey annually, a long-time goal of the BLS, and saved the National Longitudinal Survey from termination. As commissioner, she would present data on national unemployment before the Joint Economic Committee on a monthly basis, a duty that she performed with unwavering impartiality. Under her direction, the statistical quality of reported indicators improved, as did the cooperation of the BLS with the Census Bureau and the National Center for Health Statistics.

After her role as commissioner, she was the Chair of the Advisory Council on Unemployment Compensation, appointed by presidents George H. W. Bush and Bill Clinton. She also held a variety of other leadership positions, including president of the American Statistical Association, board member of the American Economic Association, and chair of a statistical committee for the OECD. Norwood was a trailblazer. In her honor, the University of Alabama at Birmingham created the Janet L. Norwood Award to recognize women in statistics.

### ado update — Update community-contributed packages

<table>
<thead>
<tr>
<th>Description</th>
<th>Quick start</th>
<th>Syntax</th>
<th>Options</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

### Description

*ado update* checks for available updates to community-contributed packages. To update packages, use *ado update, update*. By default, only packages in the PLUS directory are checked.

### Quick start

- List available updates for community-contributed packages
  
  ```
  ado update
  ```

- Install updates for community-contributed packages
  
  ```
  ado update, update
  ```

- Install updates from Statistical Software Components (SSC) archive only
  
  ```
  ado update, update ssconly
  ```

### Syntax

```
ado update [pkglist] [, options]
```

<table>
<thead>
<tr>
<th>options</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>update</td>
<td>perform update; default is to list packages that have updates, but not to update them</td>
</tr>
<tr>
<td>all</td>
<td>include packages that might have updates; default is to list or update only packages that are known to have updates</td>
</tr>
<tr>
<td>ssconly</td>
<td>check only packages obtained from SSC; default is to check all installed packages</td>
</tr>
<tr>
<td>dir(dir)</td>
<td>check packages installed in <em>dir</em>; default is to check those installed in PLUS</td>
</tr>
<tr>
<td>verbose</td>
<td>provide output to assist in debugging network problems</td>
</tr>
</tbody>
</table>
Options

Update specifies that packages with updates be updated. The default is simply to list the packages that could be updated without actually performing the update.

The first time you `ado update`, do not specify this option. Once you see `ado update` work, you will be more comfortable with it. Then type

```
    . ado update, update
```

The packages that can be updated will be listed and updated.

`all` is rarely specified. Sometimes, `ado update` cannot determine whether a package you previously installed has been updated. `ado update` can determine that the package is still available over the web but is unsure whether the package has changed. Usually, the package has not changed, but if you want to be certain that you are using the latest version, reinstall from the source.

Specifying `all` does this. Typing

```
    . ado update, all
```

adds such packages to the displayed list as needing updating but does not update them. Typing

```
    . ado update, update all
```

lists such packages and updates them.

`ssconly` specifies that `ado update` check only packages obtained from the Statistical Software Components (SSC) archive at Boston College, which is provided at http://repec.org. See [R] ssc for more information on the SSC.

`dir(dir)` specifies which installed packages be checked. The default is `dir(PLUS)`, and that is probably correct. If you are responsible for maintaining a large system, however, you may have previously installed packages in `dir(SITE)`, where they are shared across users. See [P] sysdir for an explanation of these directory codewords. You may also specify an actual directory name, such as `C:\mydir`.

`verbose` is specified when you suspect network problems. It provides more detailed output that may help you diagnose the problem.

Remarks and examples

Community-contributed additions to Stata are called packages and can add remarkable abilities to Stata. Community-contributed packages are updated by their developers, just as official Stata software is updated by StataCorp.

Do not confuse `ado update` with `update`. Use `ado update` to update community-contributed files. Use `update` to update the components (including ado-files) of the official Stata software. To use either command, you must be connected to the Internet.

Although Stata checks for updates automatically and can even be set to update automatically in Stata for Windows and Stata for Mac, you must remember to type `ado update`. Doing this regularly can help prevent errors that occur when accidentally running older versions of community-contributed packages.
Remarks are presented under the following headings:

*Using ado update*

*Notes for developers*

### Using ado update

The first time you try `ado update`, type

```
. ado update
```

`ado update` without the `update` option produces a report but does not update any files. The first time you run `ado update`, you may see messages such as

```
. ado update
  (note: package utx was installed more than once; older copy removed)
  (remaining output omitted)
```

Having the same packages installed multiple times can lead to confusion; `ado update` cleans that up.

To update all of your community-contributed packages that need updating, type

```
. ado update, update
```

You can also update a subset of your packages. You can specify one or many packages after the `ado update` command. You can even use wildcards such as `st*` to mean all packages that start with `st` or `st*8` to mean all packages that start with `st` and end with `8`. For example, if the report indicated package `st0008` had an update available, type the following to update that one package:

```
. ado update st0008, update
```

### Notes for developers

`ado update` reports whether an installed package is up to date by comparing its distribution date with that of the package available over the web.

If you are distributing software, include the line

```
  d Distribution-Date: date
```

somewhere in your `.pkg` file. The capitalization of `Distribution-Date` does not matter, but include the hyphen and the colon as shown. Code the date in either of two formats:

- all numeric: `yyyyymmdd`, for example, `20160701`
- Stata standard: `ddMONyyyy`, for example, `01ju12016`

### Stored results

`ado update` stores the following in `r()`:

- **Macros**
  - `r(pkglist)` a space-separated list of package names that need updating (`update` not specified) or that were updated (`update` specified)

ameans — Arithmetic, geometric, and harmonic means

Description

ameans computes the arithmetic, geometric, and harmonic means, with their corresponding confidence intervals, for each variable in varlist or for all the variables in the data if varlist is not specified. gmeans and hmeans are synonyms for ameans.

Quick start

Arithmetic, geometric, and harmonic means of variable v1

    ameans v1

As above but for variables v1, v2, and v3

    ameans v1 v2 v3

Means for all variables in the dataset

    ameans

Add n to each observation before calculating means

    ameans v1, add(n)

Add n to each observation only for variables with at least 1 nonpositive value

    ameans v1 v2 v3, add(n) only

Request 99% confidence intervals

    ameans v1, level(99)

Menu

Statistics > Summaries, tables, and tests > Summary and descriptive statistics > Arith./geometric/harmonic means
ameans — Arithmetic, geometric, and harmonic means

Syntax

```plaintext
ameans [varlist] [if] [in] [weight] [, options]
```

<table>
<thead>
<tr>
<th>options</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Main</td>
<td></td>
</tr>
<tr>
<td>add(#)</td>
<td>add # to each variable in <code>varlist</code></td>
</tr>
<tr>
<td>only</td>
<td>add # only to variables with nonpositive values</td>
</tr>
<tr>
<td>level(#)</td>
<td>set confidence level; default is <code>level(95)</code></td>
</tr>
</tbody>
</table>

by is allowed; see [D] by.
aweights and fweights are allowed; see [U] 11.1.6 weight.

Options

```plaintext
add(#) adds the value # to each variable in `varlist` before computing the means and confidence intervals. This option is useful when analyzing variables with nonpositive values.
```

```plaintext
only modifies the action of the `add(#)` option so that it adds # only to variables with at least one nonpositive value.
```

```plaintext
level(#) specifies the confidence level, as a percentage, for confidence intervals. The default is `level(95)` or as set by `set level`; see [U] 20.8 Specifying the width of confidence intervals.
```

Remarks and examples

Example 1

We have a dataset containing 8 observations on a variable named `x`. The eight values are 5, 4, -4, -5, 0, 0, missing, and 7.

```plaintext
. ameans x
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Type</th>
<th>Obs</th>

<td>6</td>
<td>1.795595 10.2044 *</td>
</tr>
<tr>
<td></td>
<td>Geometric</td>
<td>6</td>
<td>5.477226</td>
<td>2.1096 14.22071 *</td>
</tr>
<tr>
<td></td>
<td>Harmonic</td>
<td>6</td>
<td>3.540984</td>
<td>.        . *</td>
</tr>
</tbody>
</table>

(*) 5 was added to the variables prior to calculating the results. Missing values in confidence intervals for harmonic mean indicate that confidence interval is undefined for corresponding variables. Consult Reference Manual for details.
The number of observations displayed for the arithmetic mean is the number of nonmissing observations. The number of observations displayed for the geometric and harmonic means is the number of nonmissing, positive observations. Specifying the `add(5)` option produces 3 more positive observations. The confidence interval for the harmonic mean is not reported; see *Methods and formulas* below.

**Video example**

Descriptive statistics in Stata

**Stored results**

`ameans` stores the following in `r()`:

Scalars

- `r(N)` number of nonmissing observations; used for arithmetic mean
- `r(N_pos)` number of nonmissing positive observations; used for geometric and harmonic means
- `r(mean)` arithmetic mean
- `r(1b)` lower bound of confidence interval for arithmetic mean
- `r(ub)` upper bound of confidence interval for arithmetic mean
- `r(Var)` variance of untransformed data
- `r(mean_g)` geometric mean
- `r(1b_g)` lower bound of confidence interval for geometric mean
- `r(ub_g)` upper bound of confidence interval for geometric mean
- `r(Var_g)` variance of \( \ln x_i \)
- `r(mean_h)` harmonic mean
- `r(1b_h)` lower bound of confidence interval for harmonic mean
- `r(ub_h)` upper bound of confidence interval for harmonic mean
- `r(Var_h)` variance of \( 1/x_i \)
- `r(level)` confidence level of confidence interval

**Methods and formulas**

When restricted to the same set of values (that is, to positive values), the arithmetic mean (\( \bar{x} \)) is greater than or equal to the geometric mean, which in turn is greater than or equal to the harmonic mean. Equality holds only if all values within a sample are equal to a positive constant.

The arithmetic mean and its confidence interval are identical to those provided by `ci`; see [R] ci.

To compute the geometric mean, `ameans` first creates \( u_j = \ln x_j \) for all positive \( x_j \). The arithmetic mean of the \( u_j \) and its confidence interval are then computed as in `ci`. Let \( \bar{u} \) be the resulting mean, and let \([L, U]\) be the corresponding confidence interval. The geometric mean is then \( \exp(\bar{u}) \), and its confidence interval is \([\exp(L), \exp(U)]\).

The same procedure is followed for the harmonic mean, except that then \( u_j = 1/x_j \). The harmonic mean is then \( 1/\bar{u} \), and its confidence interval is \([1/U, 1/L]\) if \( L \) is greater than zero. If \( L \) is not greater than zero, this confidence interval is not defined, and missing values are reported.
When weights are specified, `ameans` applies the weights to the transformed values, $u_j = \ln x_j$ and $u_j = 1/x_j$, respectively, when computing the geometric and harmonic means. For details on how the weights are used to compute the mean and variance of the $u_j$, see \texttt{R} \texttt{summarize}. Without weights, the formula for the geometric mean reduces to

$$\exp\left\{\frac{1}{n} \sum_j \ln(x_j)\right\}$$

Without weights, the formula for the harmonic mean is

$$\frac{n}{\sum_j \frac{1}{x_j}}$$

**Acknowledgments**

This improved version of `ameans` is based on the `gmci` command (Carlin, Vidmar, and Ramalheira 1998) and was written by John Carlin of the Murdoch Children’s Research Institute and the University of Melbourne; Suzanna Vidmar of the University of Melbourne; and Carlos Ramalheira of Coimbra University Hospital, Portugal.

The `anova` command fits analysis-of-variance (ANOVA) and analysis-of-covariance (ANCOVA) models for balanced and unbalanced designs, including designs with missing cells; for repeated-measures ANOVA; and for factorial, nested, or mixed designs.

### Quick start

#### One-way ANOVA model of \( y \) for factor \( a \)

```bash
anova y a
```

#### Two-way full-factorial ANOVA for factors \( a \) and \( b \)

```bash
anova y a b a#b
```

Same as above

```bash
anova y a##b
```

#### ANCOVA model including continuous variable \( x \)

```bash
anova y a##b c.x
```

#### Factor \( b \) nested within \( a \)

```bash
anova y a / b\|a /
```

#### Repeated-measures ANOVA with repeated variable \( rvar \)

```bash
anova y a rvar, repeated(rvar)
```

#### Repeated-measures ANOVA with subjects, \( idvar \), observed at each level of \( rvar \)

```bash
anova y a / idvar\|a rvar rvar#a, repeated(rvar)
```

### Menu

Syntax

\texttt{anova varname [termlist] [if] [in] [weight] [ , options]}

where \texttt{termlist} is a factor-variable list (see [U] 11.4.3 Factor variables) with the following additional features:

- Variables are assumed to be categorical; use the \texttt{c.} factor-variable operator to override this.
- The | symbol (indicating nesting) may be used in place of the # symbol (indicating interaction).
- The / symbol is allowed after a term and indicates that the following term is the error term for the preceding terms.

<table>
<thead>
<tr>

<tr>
<td>\texttt{bseunit(varname)}</td>
<td>variable representing lowest unit in the between-subjects error term</td>
</tr>
<tr>
<td>\texttt{grouping(varname)}</td>
<td>grouping variable for computing pooled covariance matrix</td>
</tr>
</tbody>
</table>

bootstrap, by, fp, jackknife, and statsby are allowed; see [U] 11.1.10 Prefix commands.
Weights are not allowed with the bootstrap prefix; see [R] bootstrap.
aweights are not allowed with the jackknife prefix; see [R] jackknife.
aweights and fweights are allowed; see [U] 11.1.6 weight.
See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

Options

\texttt{repeated(varlist)} indicates the names of the categorical variables in the terms that are to be treated as repeated-measures variables in a repeated-measures ANOVA or ANCOVA.

\texttt{partial} presents the ANOVA table using partial (or marginal) sums of squares. This setting is the default. Also see the \texttt{sequential} option.

\texttt{sequential} presents the ANOVA table using sequential sums of squares.

\texttt{noconstant} suppresses the constant term (intercept) from the ANOVA or regression model.

\texttt{dropemptycells} drops empty cells from the design matrix. If \texttt{c(emptycells)} is set to keep (see [R] set emptycells), this option temporarily resets it to drop before running the ANOVA model. If \texttt{c(emptycells)} is already set to drop, this option does nothing.
anova — Analysis of variance and covariance

bse(term) indicates the between-subjects error term in a repeated-measures ANOVA. This option is needed only in the rare case when the anova command cannot automatically determine the between-subjects error term.

bseunit(varname) indicates the variable representing the lowest unit in the between-subjects error term in a repeated-measures ANOVA. This option is rarely needed because the anova command automatically selects the first variable listed in the between-subjects error term as the default for this option.

grouping(varname) indicates a variable that determines which observations are grouped together in computing the covariance matrices that will be pooled and used in a repeated-measures ANOVA. This option is rarely needed because the anova command automatically selects the combination of all variables except the first (or as specified in the bseunit() option) in the between-subjects error term as the default for grouping observations.

Remarks and examples

Remarks are presented under the following headings:

Introduction
One-way ANOVA
Two-way ANOVA
N-way ANOVA
Weighted data
ANCOVA
Nested designs
Mixed designs
Latin-square designs
Repeated-measures ANOVA
Video examples

Introduction

anova uses least squares to fit the linear models known as ANOVA or ANCOVA (henceforth referred to simply as ANOVA models).

If you want to fit one-way ANOVA models, you may find the oneway or loneway command more convenient; see [R] oneway and [R] loneway. If you are interested in MANOVA or MANCOVA, see [MV] manova.

Structural equation modeling provides a more general framework for fitting ANOVA models; see the Stata Structural Equation Modeling Reference Manual.

ANOVA was pioneered by Fisher. It features prominently in his texts on statistical methods and his design of experiments (1925, 1935). Many books discuss ANOVA; see, for instance, Altman (1991); van Belle et al. (2004); Cobb (1998); Snedecor and Cochran (1989); or Winer, Brown, and Michels (1991). For a classic source, see Scheffé (1959). Kennedy and Gentle (1980) discuss ANOVA’s computing problems. Edwards (1985) is concerned primarily with the relationship between multiple regression and ANOVA. Acock (2018, chap. 9) illustrates his discussion with Stata output. Repeated-measures ANOVA is discussed in Winer, Brown, and Michels (1991) and Milliken and Johnson (2009). Pioneering work in repeated-measures ANOVA can be found in Box (1954); Geisser and Greenhouse (1958); Huynh and Feldt (1976); and Huynh (1978). For a Stata-specific discussion of ANOVA contrasts, see Mitchell (2012, chap. 7–9; 2015, chap. 4–9).
One-way ANOVA

anova, entered without options, performs and reports standard ANOVA. For instance, to perform a one-way layout of a variable called endog on exog, you would type anova endog exog.

Example 1: One-way ANOVA

We run an experiment varying the amount of fertilizer used in growing apple trees. We test four concentrations, using each concentration in three groves of 12 trees each. Later in the year, we measure the average weight of the fruit.

If all had gone well, we would have had 3 observations on the average weight for each of the four concentrations. Instead, two of the groves were mistakenly leveled by a confused man on a large bulldozer. We are left with the following data:

```
. use https://www.stata-press.com/data/r16/apple
(Apple trees)
. list, abbrev(10) sepby(treatment)
+---------+------------+--------+
<table>
<thead>
<tr>
<th>treatment</th>
<th>weight</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>117.5</td>
</tr>
<tr>
<td>1</td>
<td>113.8</td>
</tr>
<tr>
<td>1</td>
<td>104.4</td>
</tr>
<tr>
<td>2</td>
<td>48.9</td>
</tr>
<tr>
<td>2</td>
<td>50.4</td>
</tr>
<tr>
<td>2</td>
<td>58.9</td>
</tr>
<tr>
<td>3</td>
<td>70.4</td>
</tr>
<tr>
<td>3</td>
<td>86.9</td>
</tr>
<tr>
<td>4</td>
<td>87.7</td>
</tr>
<tr>
<td>4</td>
<td>67.3</td>
</tr>
</tbody>
</table>
+---------+------------+--------+
```

To obtain one-way ANOVA results, we type

```
. anova weight treatment
```

```
Number of obs = 10 R-squared = 0.9147
Root MSE = 9.07002 Adj R-squared = 0.8721

Source | Partial SS | df | MS | F | Prob>F
----------|------------|----|----|---|-------
Model | 5295.5443 | 3  | 1765.1814 | 21.46 | 0.0013
treatment | 5295.5443 | 3  | 1765.1814 | 21.46 | 0.0013
Residual | 493.59167 | 6  | 82.265278 |
Total | 5789.136 | 9  | 643.23733 | |
```

We find significant (at better than the 1% level) differences among the four concentrations.

Although the output is a usual ANOVA table, let’s run through it anyway. Above the table is a summary of the underlying regression. The model was fit on 10 observations, and the root mean squared error (Root MSE) is 9.07. The $R^2$ for the model is 0.9147, and the adjusted $R^2$ is 0.8721.

The first line of the table summarizes the model. The sum of squares (Partial SS) for the model is 5295.5 with 3 degrees of freedom (df). This line results in a mean square (MS) of $5295.5/3 \approx 1765.2$. 
The corresponding \( F \) statistic is 21.46 and has a significance level of 0.0013. Thus the model appears to be significant at the 0.13\% level.

The next line summarizes the first (and only) term in the model, \textit{treatment}. Because there is only one term, the line is identical to that for the overall model.

The third line summarizes the residual. The residual sum of squares is 493.59 with 6 degrees of freedom, resulting in a mean squared error of 82.27. The square root of this latter number is reported as the Root MSE.

The model plus the residual sum of squares equals the total sum of squares, which is reported as 5789.1 in the last line of the table. This is the total sum of squares of weight after removal of the mean. Similarly, the model plus the residual degrees of freedom sum to the total degrees of freedom, 9. Remember that there are 10 observations. Subtracting 1 for the mean, we are left with 9 total degrees of freedom.

\section*{Technical note}

Rather than using the \texttt{anova} command, we could have performed this analysis by using the \texttt{oneway} command. \texttt{Example 1 in \texttt{R} oneway} repeats this same analysis. You may wish to compare the output.

The \texttt{regress} command (see \texttt{[R] regress}) is used to fit the underlying regression model corresponding to an \texttt{ANOVA} model fit using the \texttt{anova} command. Type \texttt{regress} after \texttt{anova} to see the coefficients, standard errors, etc., of the regression model for the last run of \texttt{anova}.

\section*{Example 2: Regression table from a one-way ANOVA}

Returning to the apple tree experiment, we found that the fertilizer concentration appears to significantly affect the average weight of the fruit. Although that finding is interesting, we next want to know which concentration appears to grow the heaviest fruit. One way to find out is by examining the underlying regression coefficients.

\begin{verbatim}
.regress, baselevels

Source |   SS    df   MS          Number of obs = 10
       |        |        |                  F(3, 6) = 21.46
Model  | 5295.54433 3  1765.18144  Prob > F = 0.0013
Residual | 493.591667 6  82.2652778  R-squared = 0.9147
       |        |        |                  Adj R-squared = 0.8721
Total  | 5789.136 9  643.237333  Root MSE = 9.07

weight | Coef. Std. Err.  t   P>|t|  [95% Conf. Interval]
       |        |        |        |        |                   
| treatment |       |        |        |        |                   
1 | 0 (base) |        |        |        |                   
2 | -59.16667  7.405641 -7.99  0.000 -77.28762 -41.04572
3 | -33.25  8.279758 -4.02  0.007 -53.50984 -12.99016
4 | -34.4  8.279758 -4.15  0.006 -54.65984 -14.14016
_cons | 111.9  5.236579 21.37  0.000  99.08655  124.7134
\end{verbatim}
See \[R\] \texttt{regress} for an explanation of how to read this table. The \texttt{baselevels} option of \texttt{regress} displays a row indicating the base category for our categorical variable, \texttt{treatment}. In summary, we find that concentration 1, the base (omitted) group, produces significantly heavier fruits than concentration 2, 3, and 4; concentration 2 produces the lightest fruits; and concentrations 3 and 4 appear to be roughly equivalent.

\section*{Example 3: ANOVA replay}

We previously typed \texttt{anova weight treatment} to produce and display the ANOVA table for our apple tree experiment. Typing \texttt{regress} displays the regression coefficients. We can redisplay the ANOVA table by typing \texttt{anova} without arguments:

\begin{verbatim}
   . anova
   Number of obs = 10  R-squared = 0.9147
   Root MSE = 9.07002  Adj R-squared = 0.8721

   Source     | Partial SS | df  | MS | F    | Prob>F
   treatment  | 5295.5443  | 3   | 1765.1814 | 21.46 | 0.0013
   Residual   | 493.59167  | 6   | 82.265278
   Total      | 5789.136   | 9   | 643.23733
\end{verbatim}

\section*{Two-way ANOVA}

You can include multiple explanatory variables with the \texttt{anova} command, and you can specify interactions by placing ‘\#’ between the variable names. For instance, typing \texttt{anova y a b} performs a two-way layout of \texttt{y} on \texttt{a} and \texttt{b}. Typing \texttt{anova y a b a\#b} performs a full two-way factorial layout. The shorthand \texttt{anova y a##b} does the same.

With the default partial sums of squares, when you specify interacted terms, the order of the terms does not matter. Typing \texttt{anova y a b a\#b} is the same as typing \texttt{anova y b a b\#a}.

\section*{Example 4: Two-way factorial ANOVA}

The classic two-way factorial ANOVA problem, at least as far as computer manuals are concerned, is a two-way ANOVA design from Afifi and Azen (1979).

Fifty-eight patients, each suffering from one of three different diseases, were randomly assigned to one of four different drug treatments, and the change in their systolic blood pressure was recorded. Here are the data:
Let’s assume that we have entered these data into Stata and stored the data as *systolic.dta*. Below we use the data, list the first 10 observations, summarize the variables, and tabulate the control variables:

```
. use https://www.stata-press.com/data/r16/systolic
(Systolic Blood Pressure Data)
. list in 1/10
    +---------+-----------+--------+
   | drug | disease | systolic |
   +---------+-----------+--------+
   |    1   |     1   |    42  |
   |    1   |     1   |    44  |
   |    1   |     1   |    36  |
   |    1   |     1   |    13  |
   |    1   |     1   |    19  |
   |    1   |     1   |    22  |
   |    1   |     2   |    33  |
   |    1   |     2   |    26  |
   |    1   |     2   |    33  |
   |    1   |     2   |    21  |
   +---------+-----------+--------+
. summarize
  Variable |    Obs |    Mean |  Std. Dev. |   Min |   Max
  +---------+--------+---------+------------+-------+-------
  drug     |   58   |     2.5 |       1.158493 |     1 |     4
  disease  |   58   |   2.017241 |      .8269873 |     1 |     3
  systolic |   58   | 18.87931 |      12.80087 |     -6 |    44
. tabulate drug disease
  Drug Used | Patient's Disease |     |     |     |
  +-----------+-----------------+-----+-----+-----+
  |           | Drug Used |  1 |  2 |  3 | Total |
  +-----------+-----------+-----+-----+-----+-------+
  | 1         |          |  6 |  4 |  5 |   15  |
  | 2         |          |  5 |  4 |  6 |   15  |
  | 3         |          |  3 |  5 |  4 |   12  |
  | 4         |          |  5 |  6 |  5 |   16  |
  +-----------+-----------+-----+-----+-----+-------+
  Total      |          | 19 | 19 | 20 |   58  |
```

Each observation in our data corresponds to one patient, and for each patient we record drug, disease, and the increase in the systolic blood pressure, systolic. The tabulation reveals that the data are not balanced—there are not equal numbers of patients in each drug–disease cell. Stata does not require that the data be balanced. We can perform a two-way factorial ANOVA by typing
. anova systolic drug disease drug#disease

<table>
<thead>
<tr>
<th>Source</th>
<th>Partial SS</th>
<th>df</th>
<th>MS</th>
<th>F</th>
<th>Prob&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>Model</td>
<td>4259.3385</td>
<td>11</td>
<td>387.21259</td>
<td>3.51</td>
<td>0.0013</td>
</tr>
<tr>
<td>drug</td>
<td>2997.4719</td>
<td>3</td>
<td>999.15729</td>
<td>9.05</td>
<td>0.0001</td>
</tr>
<tr>
<td>disease</td>
<td>415.87305</td>
<td>2</td>
<td>207.93652</td>
<td>1.88</td>
<td>0.1637</td>
</tr>
<tr>
<td>drug#disease</td>
<td>707.26626</td>
<td>6</td>
<td>117.87771</td>
<td>1.07</td>
<td>0.3958</td>
</tr>
<tr>
<td>Residual</td>
<td>5080.8167</td>
<td>46</td>
<td>110.45254</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Total</td>
<td>9340.1552</td>
<td>57</td>
<td>163.86237</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Although Stata's `table` command does not perform ANOVA, it can produce useful summary tables of your data (see `table`):

. table drug disease, c(mean systolic) row col f(%8.2f)

<table>
<thead>
<tr>
<th>Drug Used</th>
<th>Patient's Disease</th>
<th>1</th>
<th>2</th>
<th>3</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>29.33</td>
<td>28.25</td>
<td>20.40</td>
<td>26.07</td>
<td></td>
</tr>
<tr>
<td>2</td>
<td>28.00</td>
<td>33.50</td>
<td>18.17</td>
<td>25.53</td>
<td></td>
</tr>
<tr>
<td>3</td>
<td>16.33</td>
<td>4.40</td>
<td>8.50</td>
<td>8.75</td>
<td></td>
</tr>
<tr>
<td>4</td>
<td>13.60</td>
<td>12.83</td>
<td>14.20</td>
<td>13.50</td>
<td></td>
</tr>
<tr>
<td>Total</td>
<td>22.79</td>
<td>18.21</td>
<td>15.80</td>
<td>18.88</td>
<td></td>
</tr>
</tbody>
</table>

These are simple means and are not influenced by our anova model. More useful is the `margins` command (see `[R] margins`) that provides marginal means and adjusted predictions. Because drug is the only significant factor in our ANOVA, we now examine the adjusted marginal means for drug.

. margins drug, asbalanced

<table>
<thead>
<tr>
<th>Drug Used</th>
<th>Adjusted predictions</th>
<th>Number of obs = 58</th>
</tr>
</thead>
<tbody>
<tr>
<td>Expression: Linear prediction, predict() at: drug (asbalanced) disease (asbalanced)</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Delta-method</td>
<td>Margin</td>
<td>Std. Err.</td>
</tr>
<tr>
<td>drug</td>
<td></td>
<td></td>
</tr>
<tr>
<td>1</td>
<td>25.99444</td>
<td>2.751008</td>
</tr>
<tr>
<td>2</td>
<td>26.55556</td>
<td>2.751008</td>
</tr>
<tr>
<td>3</td>
<td>9.744444</td>
<td>3.100558</td>
</tr>
<tr>
<td>4</td>
<td>13.54444</td>
<td>2.637123</td>
</tr>
</tbody>
</table>

These adjusted marginal predictions are not equal to the simple drug means (see the total column from the table command); they are based upon predictions from our ANOVA model. The `asbalanced` option of `margins` corresponds with the interpretation of the F statistic produced by ANOVA—each cell is given equal weight regardless of its sample size (see the following three technical notes). You can omit the `asbalanced` option and obtain predictive margins that take into account the unequal sample sizes of the cells.
. margins drug
Predictive margins
Expression : Linear prediction, predict()
Number of obs = 58

|       | Delta-method | Margin | Std. Err. | t   | P>|t| | [95% Conf. Interval] |
|-------|--------------|--------|-----------|-----|------|----------------------|
| drug  |              |        |           |     |      |                      |
| 1     | 25.89799     | 2.750533 | 9.42     | 0.000 | 20.36145 | 31.43452 |
| 2     | 26.41092     | 2.742762 | 9.63     | 0.000 | 20.89003 | 31.93181 |
| 3     | 9.722989     | 3.099185 | 3.14     | 0.003 | 3.484652 | 15.96132 |
| 4     | 13.55755     | 2.640602 | 5.13     | 0.000 | 8.24049  | 18.871    |

⚠️ Technical note

How do you interpret the significance of terms like drug and disease in unbalanced data? If you are familiar with SAS, the sums of squares and the $F$ statistic reported by Stata correspond to SAS type III sums of squares. (Stata can also calculate sequential sums of squares, but we will postpone that topic for now.)

Let's think in terms of the following table:

<table>
<thead>
<tr>
<th></th>
<th>Disease 1</th>
<th>Disease 2</th>
<th>Disease 3</th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>Drug 1</td>
<td>$\mu_{11}$</td>
<td>$\mu_{12}$</td>
<td>$\mu_{13}$</td>
<td>$\mu_1$</td>
</tr>
<tr>
<td>Drug 2</td>
<td>$\mu_{21}$</td>
<td>$\mu_{22}$</td>
<td>$\mu_{23}$</td>
<td>$\mu_2$</td>
</tr>
<tr>
<td>Drug 3</td>
<td>$\mu_{31}$</td>
<td>$\mu_{32}$</td>
<td>$\mu_{33}$</td>
<td>$\mu_3$</td>
</tr>
<tr>
<td>Drug 4</td>
<td>$\mu_{41}$</td>
<td>$\mu_{42}$</td>
<td>$\mu_{43}$</td>
<td>$\mu_4$</td>
</tr>
<tr>
<td></td>
<td>$\mu_{..1}$</td>
<td>$\mu_{..2}$</td>
<td>$\mu_{..3}$</td>
<td>$\mu_{..}$</td>
</tr>
</tbody>
</table>

In this table, $\mu_{ij}$ is the mean increase in systolic blood pressure associated with drug $i$ and disease $j$, while $\mu_{i.}$ is the mean for drug $i$, $\mu_{.j}$ is the mean for disease $j$, and $\mu_{..}$ is the overall mean.

If the data are balanced, meaning that there are equal numbers of observations going into the calculation of each mean $\mu_{ij}$, the row means, $\mu_{i.}$, are given by

$$
\mu_{i.} = \frac{\mu_{i1} + \mu_{i2} + \mu_{i3}}{3}
$$

In our case, the data are not balanced, but we define the $\mu_{i.}$ according to that formula anyway. The test for the main effect of drug is the test that

$$
\mu_1 = \mu_2 = \mu_3 = \mu_4.
$$

To be absolutely clear, the $F$ test of the term drug, called the main effect of drug, is formally equivalent to the test of the three constraints:
In our data, we obtain a significant $F$ statistic of 9.05 and thus reject those constraints.

### Technical note

Stata can display the symbolic form underlying the test statistics it presents, as well as display other test statistics and their symbolic forms; see *Obtaining symbolic forms* in [R] _anova postestimation_. Here is the result of requesting the symbolic form for the main effect of _drug_ in our data:

```
. test drug, symbolic
   drug
    1   -(r2+r3+r4)
    2    r2
    3    r3
    4    r4
disease
    1    0
    2    0
    3    0
drug#disease
   1 1   -1/3  (r2+r3+r4)
   1 2   -1/3  (r2+r3+r4)
   1 3   -1/3  (r2+r3+r4)
   2 1    1/3  r2
   2 2    1/3  r2
   2 3    1/3  r2
   3 1    1/3  r3
   3 2    1/3  r3
   3 3    1/3  r3
   4 1    1/3  r4
   4 2    1/3  r4
   4 3    1/3  r4
_cons
   0
```

This says exactly what we said in the previous technical note.

### Technical note

Saying that there is no main effect of a variable is not the same as saying that it has no effect at all. Stata’s ability to perform ANOVA on unbalanced data can easily be put to ill use.
For example, consider the following table of the probability of surviving a bout with one of two diseases according to the drug administered to you:

<table>
<thead>
<tr>
<th></th>
<th>Disease 1</th>
<th>Disease 2</th>
</tr>
</thead>
<tbody>
<tr>
<td>Drug 1</td>
<td>1</td>
<td>0</td>
</tr>
<tr>
<td>Drug 2</td>
<td>0</td>
<td>1</td>
</tr>
</tbody>
</table>

If you have disease 1 and are administered drug 1, you live. If you have disease 2 and are administered drug 2, you live. In all other cases, you die.

This table has no main effects of either drug or disease, although there is a large interaction effect. You might now be tempted to reason that because there is only an interaction effect, you would be indifferent between the two drugs in the absence of knowledge about which disease infects you. Given an equal chance of having either disease, you reason that it does not matter which drug is administered to you—either way, your chances of surviving are 0.5.

You may not, however, have an equal chance of having either disease. If you knew that disease 1 was 100 times more likely to occur in the population, and if you knew that you had one of the two diseases, you would express a strong preference for receiving drug 1.

When you calculate the significance of main effects on unbalanced data, you must ask yourself why the data are unbalanced. If the data are unbalanced for random reasons and you are making predictions for a balanced population, the test of the main effect makes perfect sense. If, however, the data are unbalanced because the underlying populations are unbalanced and you are making predictions for such unbalanced populations, the test of the main effect may be practically—if not statistically—meaningless.

Example 5: ANOVA with missing cells

Stata can perform ANOVA not only on unbalanced populations, but also on populations that are so unbalanced that entire cells are missing. For instance, using our systolic blood pressure data, let’s refit the model eliminating the drug 1–disease 1 cell. Because anova follows the same syntax as all other Stata commands, we can explicitly specify the data to be used by typing the if qualifier at the end of the anova command. Here we want to use the data that are not for drug 1 and disease 1:

```
. anova systolic drug##disease if !(drug==1 & disease==1)
```

<table>
<thead>
<tr>
<th>Source</th>
<th>Partial SS</th>
<th>df</th>
<th>MS</th>
<th>F</th>
<th>Prob&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>Model</td>
<td>3527.959</td>
<td>10</td>
<td>352.7959</td>
<td>3.42</td>
<td>0.0025</td>
</tr>
<tr>
<td>drug</td>
<td>2686.5783</td>
<td>3</td>
<td>895.5261</td>
<td>8.67</td>
<td>0.0001</td>
</tr>
<tr>
<td>disease</td>
<td>327.7926</td>
<td>2</td>
<td>163.8963</td>
<td>1.59</td>
<td>0.2168</td>
</tr>
<tr>
<td>drug#disease</td>
<td>703.0076</td>
<td>5</td>
<td>140.6015</td>
<td>1.36</td>
<td>0.2586</td>
</tr>
<tr>
<td>Residual</td>
<td>4233.4833</td>
<td>41</td>
<td>103.2556</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Total</td>
<td>7761.4423</td>
<td>51</td>
<td>152.1851</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Here we used drug##disease as a shorthand for drug disease drug#disease.
The test of the main effect of drug in the presence of missing cells is more complicated than that for unbalanced data. Our underlying tableau now has the following form:

<table>
<thead>
<tr>
<th></th>
<th>Disease 1</th>
<th>Disease 2</th>
<th>Disease 3</th>
</tr>
</thead>
<tbody>
<tr>
<td>Drug 1</td>
<td>( \mu_{12} )</td>
<td>( \mu_{13} )</td>
<td></td>
</tr>
<tr>
<td>Drug 2</td>
<td>( \mu_{21} )</td>
<td>( \mu_{22} )</td>
<td>( \mu_{23} )</td>
</tr>
<tr>
<td>Drug 3</td>
<td>( \mu_{31} )</td>
<td>( \mu_{32} )</td>
<td>( \mu_{33} )</td>
</tr>
<tr>
<td>Drug 4</td>
<td>( \mu_{41} )</td>
<td>( \mu_{42} )</td>
<td>( \mu_{43} )</td>
</tr>
<tr>
<td></td>
<td>( \mu_2 )</td>
<td></td>
<td>( \mu_3 )</td>
</tr>
</tbody>
</table>

The hole in the drug 1–disease 1 cell indicates that the mean is unobserved. Considering the main effect of drug, the test is unchanged for the rows in which all the cells are defined:

\[
\mu_2 = \mu_3 = \mu_4.
\]

The first row, however, requires special attention. Here we want the average outcome for drug 1, which is averaged only over diseases 2 and 3, to be equal to the average values of all other drugs averaged over those same two diseases:

\[
\frac{\mu_{12} + \mu_{13}}{2} = \frac{\mu_{22} + \mu_{23}}{2} + \frac{\mu_{32} + \mu_{33}}{2} + \frac{\mu_{42} + \mu_{43}}{2}
\]

Thus the test contains three constraints:

\[
\frac{\mu_{21} + \mu_{22} + \mu_{23}}{3} = \frac{\mu_{31} + \mu_{32} + \mu_{33}}{3}
\]

\[
\frac{\mu_{21} + \mu_{22} + \mu_{23}}{3} = \frac{\mu_{41} + \mu_{42} + \mu_{43}}{3}
\]

\[
\frac{\mu_{12} + \mu_{13}}{2} = \frac{\mu_{22} + \mu_{23} + \mu_{32} + \mu_{33} + \mu_{42} + \mu_{43}}{6}
\]

Stata can calculate two types of sums of squares, partial and sequential. If you do not specify which sums of squares to calculate, Stata calculates partial sums of squares. The technical notes above have gone into great detail about the definition and use of partial sums of squares. Use the sequential option to obtain sequential sums of squares.

Before we illustrate sequential sums of squares, consider one more feature of the partial sums. If you know how such things are calculated, you may worry that the terms must be specified in some particular order, that Stata would balk or, even worse, produce different results if you typed, say, `anova drug#disease drug disease` rather than `anova drug disease drug#disease`. We assure you that is not the case.

When you type a model, Stata internally reorganizes the terms, forms the cross-product matrix, inverts it, converts the result to an upper-Hermite form, and then performs the hypothesis tests. As a final touch, Stata reports the results in the same order that you typed the terms.
Example 6: Sequential sums of squares

We wish to estimate the effects on systolic blood pressure of drug and disease by using sequential sums of squares. We want to introduce disease first, then drug, and finally, the interaction of drug and disease:

```
anova systolic disease drug disease#drug, sequential
```

<table>
<thead>
<tr>
<th>Source</th>
<th>Seq. SS</th>
<th>df</th>
<th>MS</th>
<th>F</th>
<th>Prob&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>Model</td>
<td>4259.3385</td>
<td>11</td>
<td>387.21259</td>
<td>3.51</td>
<td>0.0013</td>
</tr>
<tr>
<td>disease</td>
<td>488.63938</td>
<td>2</td>
<td>244.31969</td>
<td>2.21</td>
<td>0.1210</td>
</tr>
<tr>
<td>drug</td>
<td>3063.4329</td>
<td>3</td>
<td>1021.1443</td>
<td>9.25</td>
<td>0.0001</td>
</tr>
<tr>
<td>disease#drug</td>
<td>707.26626</td>
<td>6</td>
<td>117.87771</td>
<td>1.07</td>
<td>0.3958</td>
</tr>
<tr>
<td>Residual</td>
<td>5080.8167</td>
<td>46</td>
<td>110.45254</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Total</td>
<td>9340.1552</td>
<td>57</td>
<td>163.86237</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

The $F$ statistic on `disease` is now 2.21. When we fit this same model by using partial sums of squares, the statistic was 1.88.

N-way ANOVA

You may include high-order interaction terms, such as a third-order interaction between the variables A, B, and C, by typing `A#B#C`.

Example 7: Three-way factorial ANOVA

We wish to determine the operating conditions that maximize yield for a manufacturing process. There are three temperature settings, two chemical supply companies, and two mixing methods under investigation. Three observations are obtained for each combination of these three factors.

```
use https://www.stata-press.com/data/r16/manuf
describe
Contains data from https://www.stata-press.com/data/r16/manuf.dta
obs: 36  manufacturing process data
vars: 4  2 Jan 2018 13:28

storage  display  value
variable name type format label          variable label

  temperature byte %9.0g temp       machine temperature setting
  chemical   byte %9.0g supplier    chemical supplier
  method     byte %9.0g meth        mixing method
  yield      byte %9.0g            product yield
```

We wish to perform a three-way factorial ANOVA. We could type

```
anova yield temp chem temp#chem meth temp#meth chem#meth temp#chem#meth
```
but prefer to use the ## factor-variable operator for brevity.

```
. anova yield temp##chem##meth
```

```
Number of obs = 36    R-squared = 0.5474
Root MSE = 2.62996   Adj R-squared = 0.3399

                  Source |   Partial SS  df   MS      F    Prob>F
----------|-------------------------------------------
Model     |       200.75      11 18.25    2.64   0.0227
  temperature |       30.5        2 15.25    2.20   0.1321
  chemical   |       12.25       1 12.25   1.77   0.1958
  temperature#chemical |   24.5        2 12.25   1.77   0.1917
  method     |       42.25       1 42.25   6.11   0.0209
  temperature#method |    87.5        2 43.75   6.33   0.0062
  chemical#method |       0.25       1  0.25   0.04   0.8508
  temperature#chemical#method |    3.5        2  1.75   0.25   0.7785

  Total     |      366.75      35 10.478571
```

The interaction between temperature and method appears to be the important story in these data. A table of means for this interaction is given below.

```
. table method temp, c(mean yield) row col f(%8.2f)
```

```
     mixing method | machine temperature setting
             |  low  |  medium |  high | Total
          stir   | 7.50  |   6.00  |   6.00|  6.50
         fold   | 5.50  |   9.00  |  11.50|  8.67
     Total    | 6.50  |   7.50  |  8.75 |  7.58
```

Here our ANOVA is balanced (each cell has the same number of observations), and we obtain the same values as in the table above (but with additional information such as confidence intervals) by using the margins command. Because our ANOVA is balanced, using the asbalanced option with margins would not produce different results. We request the predictive margins for the two terms that appear significant in our ANOVA: temperature#method and method.
. margins temperature#method method

Predictive margins Number of obs = 36
Expression : Linear prediction, predict()

| Temperature#Method | Delta-method | Margin | Std. Err. | t     | P>|t|  | [95% Conf. Interval] |
|--------------------|--------------|--------|-----------|-------|------|---------------------|
| low#stir           | 7.5          | 1.073675 | 6.99      | 0.000 | 5.284044 | 9.715956           |
| low#fold           | 5.5          | 1.073675 | 5.12      | 0.000 | 3.284044 | 7.715956           |
| medium#stir        | 6            | 1.073675 | 5.59      | 0.000 | 3.784044 | 8.215956           |
| medium#fold        | 9            | 1.073675 | 8.38      | 0.000 | 6.784044 | 11.21596          |
| high#stir          | 6            | 1.073675 | 5.59      | 0.000 | 3.784044 | 8.215956           |
| high#fold          | 11.5         | 1.073675 | 10.71     | 0.000 | 9.284044 | 13.71596          |

We decide to use the folding method of mixing and a high temperature in our manufacturing process.

Weighted data

Like all estimation commands, `anova` can produce estimates on weighted data. See [U] 11.1.6 weight for details on specifying the weight.

Example 8: Three-way factorial ANOVA on grouped data

We wish to investigate the prevalence of byssinosis, a form of pneumoconiosis that can afflict workers exposed to cotton dust. We have data on 5,419 workers in a large cotton mill. We know whether each worker smokes, his or her race, and the dustiness of the work area. The variables are

- `smokes`: smoker or nonsmoker in the last five years
- `race`: white or other
- `workplace`: 1 (most dusty), 2 (less dusty), 3 (least dusty)

We wish to fit an ANOVA model explaining the prevalence of byssinosis according to a full factorial model of `smokes`, `race`, and `workplace`.

The data are unbalanced. Moreover, although we have data on 5,419 workers, the data are grouped according to the explanatory variables, along with some other variables, resulting in 72 observations. For each observation, we know the number of workers in the group (`pop`), the prevalence of byssinosis (`prob`), and the values of the three explanatory variables. Thus we wish to fit a three-way factorial model on grouped data.

We begin by showing a bit of the data, which are from Higgins and Koch (1977).
. use https://www.stata-press.com/data/r16/byssin
(Byssinosis incidence)

. list in 1/5, abbrev(10) divider

<table>
<thead>
<tr>
<th>smokes</th>
<th>race</th>
<th>workplace</th>
<th>pop</th>
<th>prob</th>
</tr>
</thead>
<tbody>
<tr>
<td>yes</td>
<td>white</td>
<td>most</td>
<td>40</td>
<td>.075</td>
</tr>
<tr>
<td>yes</td>
<td>white</td>
<td>less</td>
<td>74</td>
<td>0</td>
</tr>
<tr>
<td>yes</td>
<td>white</td>
<td>least</td>
<td>260</td>
<td>.0076923</td>
</tr>
<tr>
<td>yes</td>
<td>other</td>
<td>most</td>
<td>164</td>
<td>.152439</td>
</tr>
<tr>
<td>yes</td>
<td>other</td>
<td>less</td>
<td>88</td>
<td>0</td>
</tr>
</tbody>
</table>

The first observation in the data represents a group of 40 white workers who smoke and work in a “most” dusty work area. Of those 40 workers, 7.5% have byssinosis. The second observation represents a group of 74 white workers who also smoke but who work in a “less” dusty environment. None of those workers has byssinosis.

Almost every Stata command allows weights. Here we want to weight the data by pop. We can, for instance, make a table of the number of workers by their smoking status and race:

. tabulate smokes race [fw=pop]

<table>
<thead>
<tr>
<th>Smokes</th>
<th>Race other</th>
<th>white</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>no</td>
<td>799</td>
<td>1,431</td>
<td>2,230</td>
</tr>
<tr>
<td>yes</td>
<td>1,104</td>
<td>2,085</td>
<td>3,189</td>
</tr>
<tr>
<td>Total</td>
<td>1,903</td>
<td>3,516</td>
<td>5,419</td>
</tr>
</tbody>
</table>

The [fw=pop] at the end of the tabulate command tells Stata to count each observation as representing pop persons. When making the tally, tabulate treats the first observation as representing 40 workers, the second as representing 74 workers, and so on.
Similarly, we can make a table of the dustiness of the workplace:

```
.tabulate workplace [fw=pop]
```

<table>
<thead>
<tr>
<th>Dustiness of workplace</th>
<th>Freq.</th>
<th>Percent</th>
<th>Cum.</th>
</tr>
</thead>
<tbody>
<tr>
<td>least</td>
<td>3,450</td>
<td>63.66</td>
<td>63.66</td>
</tr>
<tr>
<td>less</td>
<td>1,300</td>
<td>23.99</td>
<td>87.65</td>
</tr>
<tr>
<td>most</td>
<td>669</td>
<td>12.35</td>
<td>100.00</td>
</tr>
<tr>
<td>Total</td>
<td>5,419</td>
<td>100.00</td>
<td></td>
</tr>
</tbody>
</table>

We can discover the average incidence of byssinosis among these workers by typing

```
.summarize prob [fw=pop]
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>prob</td>
<td>5,419</td>
<td>.0304484</td>
<td>.0567373</td>
<td>0</td>
<td>.287037</td>
</tr>
</tbody>
</table>

We discover that 3.04% of these workers have byssinosis. Across all cells, the byssinosis rates vary from 0 to 28.7%. Just to prove that there might be something here, let’s obtain the average incidence rates according to the dustiness of the workplace:

```
.table workplace smokes race [fw=pop], c(mean prob)
```

<table>
<thead>
<tr>
<th>Dustiness of workplace</th>
<th>Race and Smokes</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>other</td>
</tr>
<tr>
<td></td>
<td>no</td>
</tr>
<tr>
<td>least</td>
<td>.0107527</td>
</tr>
<tr>
<td>less</td>
<td>.02</td>
</tr>
<tr>
<td>most</td>
<td>.0820896</td>
</tr>
</tbody>
</table>

Let’s now fit the ANOVA model.

```
.anova prob workplace smokes race workplace#smokes workplace#race smokes#race workplace#smokes#race [aweight=pop]
```

```
Number of obs = 65   R-squared = 0.8300
Root MSE = .025902   Adj R-squared = 0.7948
            Source     Partial SS     df    MS      F     Prob>F
Model       .17364654     11  .01578605  23.53  0.0000
workplace   .09762518     2  .04881259  72.76  0.0000
smokes      .01303081     1  .01303081  19.42  0.0001
race        .00109472     1  .00109472  1.63  0.2070
workplace#smokes .01969034     2  .00984517  14.67  0.0000
workplace#race .00135252     2  .00067626  1.01  0.3718
smokes#race  .00166287     1  .00166287  2.48  0.1214
workplace#smokes#race .00095084     2  .00047542  0.71  0.4969
Residual    .03555777     53  .00067090          
Total       .2092043     64  .00326882          
```

Of course, if we want to see the underlying regression, we could type `regress`. 

Above we examined simple means of the cells of `workplace#smokes#race`. Our ANOVA shows `workplace`, `smokes`, and their interaction as being the only significant factors in our model. We now examine the predictive marginal mean byssinosis rates for these terms.

```
   . margins workplace#smokes workplace smokes

</table>

Smoking combined with the most dusty workplace produces the highest byssinosis rates.

---

Ronald Aylmer Fisher (1890–1962) (Sir Ronald from 1952) studied mathematics at Cambridge. Even before he finished his studies, he had published on statistics. He worked as a statistician at Rothamsted Experimental Station (1919–1933), as professor of eugenics at University College London (1933–1943), as professor of genetics at Cambridge (1943–1957), and in retirement at the CSIRO Division of Mathematical Statistics in Adelaide. His many fundamental and applied contributions to statistics and genetics mark him as one of the greatest statisticians of all time, including original work on tests of significance, distribution theory, theory of estimation, fiducial inference, and design of experiments.

---

**ANCOVA**

You can include multiple explanatory variables with the `anova` command, but unless you explicitly state otherwise by using the `c.` factor-variable operator, all the variables are interpreted as *categorical variables*. Using the `c.` operator, you can designate variables as *continuous* and thus perform ANCOVA.

---

**Example 9: ANCOVA (ANOVA with a continuous covariate)**

We have census data recording the death rate (`drate`) and median age (`age`) for each state. The dataset also includes the region of the country in which each state is located (`region`):
. use https://www.stata-press.com/data/r16/census2
(1980 Census data by state)
. summarize drate age region

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>drate</td>
<td>50</td>
<td>84.3</td>
<td>13.07318</td>
<td>40</td>
<td>107</td>
</tr>
<tr>
<td>age</td>
<td>50</td>
<td>29.5</td>
<td>1.752549</td>
<td>24</td>
<td>35</td>
</tr>
<tr>
<td>region</td>
<td>50</td>
<td>2.66</td>
<td>1.061574</td>
<td>1</td>
<td>4</td>
</tr>
</tbody>
</table>

age is coded in integral years from 24 to 35, and region is coded from 1 to 4, with 1 standing for the Northeast, 2 for the North Central, 3 for the South, and 4 for the West.

When we examine the data more closely, we discover large differences in the death rate across regions of the country:

. tabulate region, summarize(drate)

<table>
<thead>
<tr>
<th>Census</th>
<th>Summary of Death rate</th>
<th>Freq.</th>
</tr>
</thead>
<tbody>
<tr>
<td>NE</td>
<td>93.444444 7.0553368</td>
<td>9</td>
</tr>
<tr>
<td>N Cntrl</td>
<td>88.916667 5.5833899</td>
<td>12</td>
</tr>
<tr>
<td>South</td>
<td>88.3125 8.5457104</td>
<td>16</td>
</tr>
<tr>
<td>West</td>
<td>68.769231 13.342625</td>
<td>13</td>
</tr>
<tr>
<td>Total</td>
<td>84.3 13.073185</td>
<td>50</td>
</tr>
</tbody>
</table>

Naturally, we wonder if these differences might not be explained by differences in the median ages of the populations. To find out, we fit a regression model (via anova) of drate on region and age. In the anova example below, we treat age as a categorical variable.

. anova drate region age

<table>

<td>49</td>
<td>170.90816</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

We have the answer to our question: differences in median ages do not eliminate the differences in death rates across the four regions. The ANOVA table summarizes the two terms in the model, region and age. The region term contains 3 degrees of freedom, and the age term contains 8 degrees of freedom. Both are significant at better than the 1% level.

The age term contains 8 degrees of freedom. Because we did not explicitly indicate that age was to be treated as a continuous variable, it was treated as categorical, meaning that unique coefficients were estimated for each level of age. The only clue of this labeling is that the number of degrees of freedom associated with the age term exceeds 1. The labeling becomes more obvious if we review the regression coefficients:
The *regress* command displayed the *anova* model as a regression table. We used the *baselevels* option to display the dropped level (or base) for each term.

If we want to treat *age* as a continuous variable, we must prepend *c.* to *age* in our *anova.*
The age term now has 1 degree of freedom. The regression coefficients are

\begin{verbatim}

Total explained

461.52

\end{verbatim}

Although we started analyzing these data to explain the regional differences in death rate, let’s focus on the effect of age for a moment. In our first model, each level of age had a unique death rate associated with it. For instance, the predicted death rate in a north central state with a median age of 28 was

\[0.44 + 12.66 + 68.37 \approx 81.47\]

whereas the predicted death rate from our current model is

\[1.79 + 3.92 \times 28 - 28.60 \approx 82.95\]

Our previous model had an \(R^2\) of 0.7927, whereas our current model has an \(R^2\) of 0.7203. This “small” loss of predictive power accompanies a gain of 7 degrees of freedom, so we suspect that the continuous-age model is as good as the discrete-age model.

\[\checkmark\]

Technical note

There is enough information in the two ANOVA tables to attach a statistical significance to our suspicion that the loss of predictive power is offset by the savings in degrees of freedom. Because the continuous-age model is nested within the discrete-age model, we can perform a standard Chow test. For those of us who know such formulas off the top of our heads, the \(F\) statistic is

\[
\frac{(2342.41746 - 1735.63471)/7}{45.6745977} = 1.90
\]

There is, however, a better way.

We can find out whether our continuous model is as good as our discrete model by putting age in the model twice: once as a continuous variable and once as a categorical variable. The categorical variable will then measure deviations around the straight line implied by the continuous variable, and the \(F\) test for the significance of the categorical variable will test whether those deviations are jointly zero.
We find that the \( F \) test for the significance of the (categorical) \( \text{age} \) variable is 1.90, just as we calculated above. It is significant at the 9.7% level. If we hold to a 5% significance level, we cannot reject the null hypothesis that the effect of \( \text{age} \) is linear.

Example 10: Interaction of continuous and categorical variables

In our census data, we still find significant differences across the regions after controlling for the median age of the population. We might now wonder whether the regional differences are differences in level—indeed of age—or are instead differences in the regional effects of age. Just as we can interact categorical variables with other categorical variables, we can interact categorical variables with continuous variables.

The \( \text{region}\#\text{c.age} \) term in our model measures the differences in slopes across the regions. We cannot reject the null hypothesis that there are no such differences. The \( \text{region} \) effect is now “insignificant”. This status does not mean that there are no regional differences in death rates because each test is a marginal or partial test. Here, with \( \text{region}\#\text{c.age} \) included in the model, \( \text{region} \) is being tested at the point where \( \text{age} \) is zero. Apart from this value not existing in the dataset, it is also a long way from the mean value of \( \text{age} \), so the test of \( \text{region} \) at this point is meaningless (although it is valid if you acknowledge what is being tested).
To obtain a more sensible test of region, we can subtract the mean from the age variable and use this in the model.

```stata
. quietly summarize age
. generate mage = age - r(mean)
. anova drate region c.mage region#c.mage
```

```

region is significant when tested at the mean of the age variable.

Remember that we can specify interactions by typing `varname#varname`. We have seen examples of interacting categorical variables with categorical variables and, in the examples above, a categorical variable (region) with a continuous variable (age or mage).

We can also interact continuous variables with continuous variables. To include an age² term in our model, we could type `c.age#c.age`. If we also wanted to interact the categorical variable region with the age² term, we could type `region#c.age#c.age` (or even `c.age#region#c.age`).

### Nested designs

In addition to specifying interaction terms, nested terms can also be specified in an ANOVA. A vertical bar is used to indicate nesting: `A|B` is read as A nested within B. `A|B|C` is read as A nested within B, which is nested within C. `A|B#C` is read as A is nested within the interaction of B and C. `A#B|C` is read as the interaction of A and B, which is nested within C.

Different error terms can be specified for different parts of the model. The forward slash is used to indicate that the next term in the model is the error term for what precedes it. For instance, `anova y A / B|A` indicates that the $F$ test for A is to be tested by using the mean square from B|A in the denominator. Error terms (terms following the slash) are generally not tested unless they are themselves followed by a slash. Residual error is the default error term.

For example, consider `A / B / C`, where A, B, and C may be arbitrarily complex terms. Then `anova` will report A tested by B and B tested by C. If we add one more slash on the end to form `A / B / C /`, then `anova` will also report C tested by the residual error.

**Example 11: Simple nested ANOVA**

We have collected data from a manufacturer that is evaluating which of five different brands of machinery to buy to perform a particular function in an assembly line. Twenty assembly-line employees were selected at random for training on these machines, with four employees assigned to learn a particular machine. The output from each employee (operator) on the brand of machine for which he trained was measured during four trial periods. In this example, the operator is nested
within machine. Because of sickness and employee resignations, the final data are not balanced. The following table gives the mean output and sample size for each machine and operator combination.

```
use https://www.stata-press.com/data/r16/machine, clear
(machine data)
.table machine operator, c(mean output n output) col f(%8.2f)
```

Assuming that `operator` is random (that is, we wish to infer to the larger population of possible operators) and `machine` is fixed (that is, only these five machines are of interest), the typical test for `machine` uses `operator` nested within `machine` as the error term. `operator` nested within `machine` can be tested by residual error. Our earlier warning concerning designs with either unplanned missing cells or unbalanced cell sizes, or both, also applies to interpreting the ANOVA results from this unbalanced nested example.

`operator|machine` is preceded by a slash, indicating that it is the error term for the terms before it (here `machine`). `operator|machine` is also followed by a slash that indicates it should be tested with residual error. The output lists the `operator|machine` term twice, once as the error term for `machine`, and again as a term tested by residual error. A line is placed in the ANOVA table to separate the two. In general, a dividing line is placed in the output to separate the terms into groups that are tested with the same error term. The overall model is tested by residual error and is separated from the rest of the table by a blank line at the top of the table.
The results indicate that the machines are not all equal and that there are significant differences between operators.

Example 12: ANOVA with multiple levels of nesting

Your company builds and operates sewage treatment facilities. You want to compare two particulate solutions during the particulate reduction step of the sewage treatment process. For each solution, two area managers are randomly selected to implement and oversee the change to the new treatment process in two of their randomly chosen facilities. Two workers at each of these facilities are trained to operate the new process. A measure of particulate reduction is recorded at various times during the month at each facility for each worker. The data are described below.

```
. use https://www.stata-press.com/data/r16/sewage
(Sewage treatment)
. describe
Contains data from https://www.stata-press.com/data/r16/sewage.dta
obs: 64
vars: 5
  9 May 2018 12:43
storage  display value
variable name   type format label variable label
particulate    byte %9.0g particulate reduction
solution       byte %9.0g 2 particulate solutions
manager        byte %9.0g 2 managers per solution
facility       byte %9.0g 2 facilities per manager
worker         byte %9.0g 2 workers per facility
```

You want to determine if the two particulate solutions provide significantly different particulate reduction. You would also like to know if manager, facility, and worker are significant effects. solution is a fixed factor, whereas manager, facility, and worker are random factors.

In the following anova command, we use abbreviations for the variable names, which can sometimes make long ANOVA model statements easier to read.
While `solution` is not declared significant at the 5% significance level, it is near enough to that threshold to warrant further investigation (see example 3 in [R] `anova postestimation` for a continuation of the analysis of these data).

### Technical note

Why did we use the `dropemptycells` option with the previous `anova`? By default, Stata retains empty cells when building the design matrix and currently treats | and # the same in how it determines the possible number of cells. Retaining empty cells in an ANOVA with nested terms can cause your design matrix to become too large. In example 12, there are $1024 = 2 \times 4 \times 8 \times 16$ cells that are considered possible for the `worker|facility|manager|solution` term because the `worker`, `facility`, and `manager` variables are uniquely numbered. With the `dropemptycells` option, the `worker|facility|manager|solution` term requires just 16 columns in the design matrix (corresponding to the 16 unique workers).

Why did we not use the `dropemptycells` option in example 11, where `operator` is nested in `machine`? If you look at the table presented at the beginning of that example, you will see that `operator` is compactly instead of uniquely numbered (you need both `operator` number and `machine` number to determine the `operator`). Here the `dropemptycells` option would have only reduced our design matrix from 26 columns down to 24 columns (because there were only 3 operators instead of 4 for machines 3 and 5).

We suggest that you specify `dropemptycells` when there are nested terms in your ANOVA. You could also use the `set emptycells drop` command to accomplish the same thing; see [R] `set`. 

```plaintext

Mixed designs

An ANOVA can consist of both nested and crossed terms. A split-plot ANOVA design provides an example.

Example 13: Split-plot ANOVA

Two reading programs and three skill-enhancement techniques are under investigation. Ten classes of first-grade students were randomly assigned so that five classes were taught with one reading program and another five classes were taught with the other. The 30 students in each class were divided into six groups with 5 students each. Within each class, the six groups were divided randomly so that each of the three skill-enhancement techniques was taught to two of the groups within each class. At the end of the school year, a reading assessment test was administered to all the students. In this split-plot ANOVA, the whole-plot treatment is the two reading programs, and the split-plot treatment is the three skill-enhancement techniques.

```
. use https://www.stata-press.com/data/r16/reading
(Reading experiment data)
. describe
Contains data from https://www.stata-press.com/data/r16/reading.dta

Sorted by:
```

In this split-plot ANOVA, the error term for program is class nested within program. The error term for skill and the program by skill interaction is the class by skill interaction nested within program. Other terms are also involved in the model and can be seen below.

Our `anova` command is too long to fit on one line of this manual. Where we have chosen to break the command into multiple lines is arbitrary. If we were typing this command into Stata, we would just type along and let Stata automatically wrap across lines, as necessary.

Because our ANOVA involves nested terms, we used the within() option of margins; see [R] margins.

Skill 2 produces a low score when combined with program 1 and a high score when combined with program 2, demonstrating the interaction between the reading program and the skill-enhancement technique. You might conclude that the first reading program and the first skill-enhancement technique perform best when combined. However, notice the overlapping confidence interval for the first reading program and the third skill-enhancement technique.

Technical note

There are several valid ways to write complicated anova terms. In the reading experiment example (example 13), we had a term group\class\skill\program. This term can be read as group nested within both class and skill and further nested within program. You can also write this term as group\class\skill\program or group\program\class\skill or group\skill\class\program, etc. All variations will produce the same result. Some people prefer having only one ‘|’ in a term and would use group\class\skill\program, which is read as group nested within class, skill, and program.
Gertrude Mary Cox (1900–1978) was born on a farm near Dayton, Iowa. Initially intending to become superintendent of an orphanage, she enrolled at Iowa State College. There she majored in mathematics and attained the college’s first Master’s degree in statistics. After working on her PhD in psychological statistics for two years at the University of California–Berkeley, she decided to go back to Iowa State to work with George W. Snedecor. There she pursued her interest in and taught a course in design of experiments. That work led to her collaboration with W. G. Cochran, which produced a classic text. In 1940, when Snedecor shared with her his list of men he was nominating to head the statistics department at North Carolina State College, she wanted to know why she had not been included. He added her name, she won the position, and she built an outstanding department at North Carolina State. Cox retired early so she could work at the Research Triangle Institute in North Carolina. She consulted widely, served as editor of *Biometrics*, and was elected to the National Academy of Sciences.

Latin-square designs

You can use `anova` to analyze a Latin-square design. Consider the following example, published in *Snedecor and Cochran* (1989).

> Example 14: Latin-square ANOVA

Data from a Latin-square design are as follows:

<table>
<thead>
<tr>
<th>Row</th>
<th>Column 1</th>
<th>Column 2</th>
<th>Column 3</th>
<th>Column 4</th>
<th>Column 5</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>257(B)</td>
<td>230(E)</td>
<td>279(A)</td>
<td>287(C)</td>
<td>202(D)</td>
</tr>
<tr>
<td>2</td>
<td>245(D)</td>
<td>283(A)</td>
<td>245(E)</td>
<td>280(B)</td>
<td>260(C)</td>
</tr>
<tr>
<td>3</td>
<td>182(E)</td>
<td>252(B)</td>
<td>280(C)</td>
<td>246(D)</td>
<td>250(A)</td>
</tr>
<tr>
<td>4</td>
<td>203(A)</td>
<td>204(C)</td>
<td>227(D)</td>
<td>193(E)</td>
<td>259(B)</td>
</tr>
<tr>
<td>5</td>
<td>231(C)</td>
<td>271(D)</td>
<td>266(B)</td>
<td>334(A)</td>
<td>338(E)</td>
</tr>
</tbody>
</table>

In Stata, the data might appear as follows:

```stata
use https://www.stata-press.com/data/r16/latinsq
list
```

<table>
<thead>
<tr>
<th>row</th>
<th>c1</th>
<th>c2</th>
<th>c3</th>
<th>c4</th>
<th>c5</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>257</td>
<td>230</td>
<td>279</td>
<td>287</td>
<td>202</td>
</tr>
<tr>
<td>2</td>
<td>245</td>
<td>283</td>
<td>245</td>
<td>280</td>
<td>260</td>
</tr>
<tr>
<td>3</td>
<td>182</td>
<td>252</td>
<td>280</td>
<td>246</td>
<td>250</td>
</tr>
<tr>
<td>4</td>
<td>203</td>
<td>204</td>
<td>227</td>
<td>193</td>
<td>259</td>
</tr>
<tr>
<td>5</td>
<td>231</td>
<td>271</td>
<td>266</td>
<td>334</td>
<td>338</td>
</tr>
</tbody>
</table>

Before `anova` can be used on these data, the data must be organized so that the outcome measurement is in one column. `reshape` is inadequate for this task because there is information about the treatments in the sequence of these observations. `pkshape` is designed to reshape this type of data; see [R] `pkshape`.

These methods will work with any type of Latin-square design, including those with replicated measurements. For more information, see [R] pk, [R] pkcross, and [R] pkshape.
Repeated-measures ANOVA

One approach for analyzing repeated-measures data is to use multivariate ANOVA (MANOVA); see \[ MV \] manova. In this approach, the data are placed in wide form (see \[ D \] reshape), and the repeated measures enter the MANOVA as dependent variables.

A second approach for analyzing repeated measures is to use anova. However, one of the underlying assumptions for the $F$ tests in ANOVA is independence of observations. In a repeated-measures design, this assumption is almost certainly violated. In a repeated-measures ANOVA, the subjects (or whatever the experimental units are called) are observed for each level of one or more of the other categorical variables in the model. These variables are called the repeated-measure variables. Observations from the same subject are likely to be correlated, though this is only a problem if the observations violate compound symmetry or the sphericity condition.

The approach used in repeated-measures ANOVA to correct for violation of compound symmetry or sphericity is to apply correction to the degrees of freedom of the $F$ test for terms in the model that involve repeated measures. This correction factor, $\epsilon$, lies between the reciprocal of the degrees of freedom for the repeated term and 1. Box (1954) provided the pioneering work in this area. Milliken and Johnson (2009) refer to the lower bound of this correction factor as Box’s conservative correction factor. Winer, Brown, and Michels (1991) call it simply the conservative correction factor.

Geisser and Greenhouse (1958) provide an estimate for the correction factor called the Greenhouse–Geisser $\epsilon$. This value is estimated from the data. Huynh and Feldt (1976) show that the Greenhouse–Geisser $\epsilon$ tends to be conservatively biased. They provide a revised correction factor called the Huynh–Feldt $\epsilon$. When the Huynh–Feldt $\epsilon$ exceeds 1, it is set to 1. Thus there is a natural ordering for these correction factors:

$$
\text{Box’s conservative } \epsilon \leq \text{Greenhouse–Geisser } \epsilon \leq \text{Huynh–Feldt } \epsilon \leq 1
$$

A correction factor of 1 is the same as no correction.

anova with the repeated() option computes these correction factors and displays the revised test results in a table that follows the standard ANOVA table. In the resulting table, H-F stands for Huynh–Feldt, G-G stands for Greenhouse–Geisser, and Box stands for Box’s conservative $\epsilon$.

Example 15: Repeated-measures ANOVA

This example is taken from table 4.3 of Winer, Brown, and Michels (1991). The reaction time for five subjects each tested with four drugs was recorded in the variable score. Here is a table of the data (see \[ P \] tabdisp if you are unfamiliar with tabdisp):

```
. use https://www.stata-press.com/data/r16/t43, clear
(T4.3 -- Winer, Brown, Michels)
. tabdisp person drug, cellvar(score)

<table>
<thead>
<tr>
<th>person</th>
<th>1</th>
<th>2</th>
<th>3</th>
<th>4</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>30</td>
<td>28</td>
<td>16</td>
<td>34</td>
</tr>
<tr>
<td>2</td>
<td>14</td>
<td>18</td>
<td>10</td>
<td>22</td>
</tr>
<tr>
<td>3</td>
<td>24</td>
<td>20</td>
<td>18</td>
<td>30</td>
</tr>
<tr>
<td>4</td>
<td>38</td>
<td>34</td>
<td>20</td>
<td>44</td>
</tr>
<tr>
<td>5</td>
<td>26</td>
<td>28</td>
<td>14</td>
<td>30</td>
</tr>
</tbody>
</table>
```

drug is the repeated variable in this simple repeated-measures ANOVA example. The ANOVA is specified as follows:
anova — Analysis of variance and covariance

```
.anova score person drug, repeated(drug)
```

```
Number of obs = 20 R-squared = 0.9244
Root MSE = 3.06594 Adj R-squared = 0.8803

Source | Partial SS | df | MS | F | Prob>F
-------------------------------------------------------------------------------
Model | 1379 | 7 | 197 | 20.96 | 0.0000
person | 680.8 | 4 | 170.2 | 18.11 | 0.0001
drug | 698.2 | 3 | 232.73333 | 24.76 | 0.0000
Residual | 112.8 | 12 | 9.4 | | |
Total | 1491.8 | 19 | 78.515789 | | |

| Between-subjects error term: person
| Levels: 5 (4 df)
| Lowest b.s.e. variable: person

Repeated variable: drug

Huynh-Feldt epsilon = 1.0789
*Huynh-Feldt epsilon reset to 1.0000
Greenhouse-Geisser epsilon = 0.6049
Box’s conservative epsilon = 0.3333

```

Here the Huynh–Feldt $\epsilon$ is 1.0789, which is larger than 1. It is reset to 1, which is the same as making no adjustment to the standard test computed in the main ANOVA table. The Greenhouse–Geisser $\epsilon$ is 0.6049, and its associated $p$-value is computed from an $F$ ratio of 24.76 using $1.8147 (= 3\epsilon)$ and 7.2588 ($= 12\epsilon$) degrees of freedom. Box’s conservative $\epsilon$ is set equal to the reciprocal of the degrees of freedom for the repeated term. Here it is 1/3, so Box’s conservative test is computed using 1 and 4 degrees of freedom for the observed $F$ ratio of 24.76.

Even for Box’s conservative $\epsilon$, drug is significant with a $p$-value of 0.0076. The following table gives the predictive marginal mean score (that is, response time) for each of the four drugs:

```
.margins drug
Predictive margins Number of obs = 20
Expression : Linear prediction, predict()

| Delta-method | Margin | Std. Err. | t | P>|t| | [95% Conf. Interval] |
|-------------|--------|-----------|---|-------|-------------------|
| drug | 1 | 26.4 | 1.371131 | 19.25 | 0.000 | 23.41256 | 29.38744 |
| | 2 | 25.6 | 1.371131 | 18.67 | 0.000 | 22.61256 | 28.58744 |
| | 3 | 15.6 | 1.371131 | 11.38 | 0.000 | 12.61256 | 18.58744 |
| | 4 | 32 | 1.371131 | 23.34 | 0.000 | 29.01256 | 34.98744 |
```

The ANOVA table for this example provides an $F$ test for person, but you should ignore it. An appropriate test for person would require replication (that is, multiple measurements for person and drug combinations). Also, without replication there is no test available for investigating the interaction between person and drug.
Example 16: Repeated-measures ANOVA with nesting

Table 7.7 of Winer, Brown, and Michels (1991) provides another repeated-measures ANOVA example. There are four dial shapes and two methods for calibrating dials. Subjects are nested within calibration method, and an accuracy score is obtained. The data are shown below.

```
use https://www.stata-press.com/data/r16/t77
(T7.7 -- Winer, Brown, Michels)
tabdisp shape subject calib, cell(score)
```

<table>
<thead>
<tr>
<th>4 dial shapes</th>
<th>2 methods for calibrating dials and subject nested in calib</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>1</td>
</tr>
<tr>
<td>1</td>
<td>0</td>
</tr>
<tr>
<td>2</td>
<td>0</td>
</tr>
<tr>
<td>3</td>
<td>5</td>
</tr>
<tr>
<td>4</td>
<td>3</td>
</tr>
</tbody>
</table>

The calibration method and dial shapes are fixed factors, whereas subjects are random. The appropriate test for calibration method uses the nested subject term as the error term. Both the dial shape and the interaction between dial shape and calibration method are tested with the dial shape by subject interaction nested within calibration method. Here we drop this term from the `anova` command, and it becomes residual error. The dial shape is the repeated variable because each subject is tested with all four dial shapes. Here is the `anova` command that produces the desired results:

```
anova score calib / subject|calib shape calib#shape, repeated(shape)
```

```
 Number of obs = 24   R-squared = 0.8925
 Root MSE = 1.11181   Adj R-squared = 0.7939

 Source | Partial SS  df       MS       F        Prob>F 
---------|-------------|---------|---------|---------|---------|
 Model   | 123.125     11     11.193182  9.06 0.0003 
 calib   | 51.041667   1      51.041667  11.89 0.0261 
 subject|calib       | 17.166667  4      4.2916667  
 shape   | 47.458333   3      15.819444  12.80 0.0005 
 calib#shape | 7.4583333   3      2.4861111  2.01 0.1662 
 Residual | 14.833333   12     1.2361111   
 Total   | 137.95833   23     5.9981884   

Between-subjects error term: subject|calib
Levels: 6 (4 df)
Lowest b.s.e. variable: subject
Covariance pooled over: calib (for repeated variable)
Repeate variable: shape

Huynh-Feldt epsilon = 0.8483
Greenhouse-Geisser epsilon = 0.4751
Box’s conservative epsilon = 0.3333

 Source | df  F Regular H-F G-G Box Prob > F
---------|-----|-----|-----|-----|-----|-----|
 shape   | 3   | 12.80 | 0.0005 | 0.0011 | 0.0099 | 0.0232 
 calib#shape | 3   | 2.01  | 0.1662 | 0.1791 | 0.2152 | 0.2291 
 Residual | 12  |       |       |       |       |       |
The repeated-measure $\epsilon$ corrections are applied to any terms that are tested in the main ANOVA table and have the repeated variable in the term. These $\epsilon$ corrections are given in a table below the main ANOVA table. Here the repeated-measures tests for shape and calib#shape are presented.

Calibration method is significant, as is dial shape. The interaction between calibration method and dial shape is not significant. The repeated-measure $\epsilon$ corrections do not change these conclusions, but they do change the significance level for the tests on shape and calib#shape. Here, though, unlike in the example 15, the Huynh–Feldt $\epsilon$ is less than 1.

Here are the predictive marginal mean scores for calibration method and dial shapes. Because the interaction was not significant, we request only the calib and shape predictive margins.

```
   . margins, within(calib)
Predictive margins          Number of obs  =  24
Expression : Linear prediction, predict()
within     : calib

```

Technical note

The computation of the Greenhouse–Geisser and Huynh–Feldt epsilons in a repeated-measures ANOVA requires the number of levels and degrees of freedom for the between-subjects error term, as well as a value computed from a pooled covariance matrix. The observations are grouped based on all but the lowest-level variable in the between-subjects error term. The covariance over the repeated variables is computed for each resulting group, and then these covariance matrices are pooled. The dimension of the pooled covariance matrix is the number of levels of the repeated variable (or combination of levels for multiple repeated variables). In example 16, there are four levels of the repeated variable (shape), so the resulting covariance matrix is $4 \times 4$.

The `anova` command automatically attempts to determine the between-subjects error term and the lowest-level variable in the between-subjects error term to group the observations for computation of the pooled covariance matrix. `anova` issues an error message indicating that the `bse()` or `bseunit()` option is required when `anova` cannot determine them. You may override the default selections of
anova by specifying the `bse()`, `bseunit()`, or `grouping()` option. The term specified in the `bse()` option must be a term in the ANOVA model.

The default selection for the between-subjects error term (the `bse()` option) is the interaction of the nonrepeated categorical variables in the ANOVA model. The first variable listed in the between-subjects error term is automatically selected as the lowest-level variable in the between-subjects error term but can be overridden with the `bseunit(varname)` option. `varname` is often a term, such as subject or subsample within subject, and is most often listed first in the term because of the nesting notation of ANOVA. This term makes sense in most repeated-measures ANOVA designs when the terms of the model are written in standard form. For instance, in example 16, there were three categorical variables (subject, calib, and shape), with shape being the repeated variable. Here anova looked for a term involving only subject and calib to determine the between-subjects error term. It found `subject|calib` as the term with six levels and 4 degrees of freedom. anova then picked subject as the default for the `bseunit()` option (the lowest variable in the between-subjects error term) because it was listed first in the term.

The grouping of observations proceeds, based on the different combinations of values of the variables in the between-subjects error term, excluding the lowest level variable (as found by default or as specified with the `bseunit()` option). You may specify the `grouping()` option to change the default grouping used in computing the pooled covariance matrix.

The between-subjects error term, number of levels, degrees of freedom, lowest variable in the term, and grouping information are presented after the main ANOVA table and before the rest of the repeated-measures output.

Example 17: Repeated-measures ANOVA with two repeated variables

Data with two repeated variables are given in table 7.13 of Winer, Brown, and Michels (1991). The accuracy scores of subjects making adjustments to three dials during three different periods are recorded. Three subjects are exposed to a certain noise background level, whereas a different set of three subjects is exposed to a different noise background level. Here is a table of accuracy scores for the noise, subject, period, and dial variables:

<table>
<thead>
<tr>
<th>noise background and subject nested in noise</th>
<th>10 minute time periods and type of dial</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>1</td>
</tr>
<tr>
<td></td>
<td>1</td>
</tr>
<tr>
<td>1</td>
<td>45</td>
</tr>
<tr>
<td>2</td>
<td>35</td>
</tr>
<tr>

</tr>
<tr>
<td>2</td>
<td>50</td>
</tr>
<tr>
<td>2</td>
<td>42</td>
</tr>
<tr>
<td>3</td>
<td>56</td>
</tr>
</tbody>
</table>

noise, period, and dial are fixed, whereas subject is random. Both period and dial are repeated variables. The ANOVA for this example is specified next.
anova — Analysis of variance and covariance

```
. anova score noise / subject|noise period noise#period /
   > period#subject|noise dial noise#dial /
   > dial#subject|noise period#dial noise#period#dial, repeated(period dial)

Number of obs = 54  R-squared = 0.9872
Root MSE = 2.81859  Adj R-squared = 0.9576

For each repeated variable and for each combination of interactions of repeated variables, there are different $\epsilon$ correction values. The *anova* command produces tables for each applicable combination.

The two most significant factors in this model appear to be dial and period. The noise by period interaction may also be significant, depending on the correction factor you use. Below is a table of predictive margins for the accuracy score for dial, period, and noise by period.

</tbody>
</table>

**predict**

predict after anova follows the same syntax as predict after regress and can provide predictions, residuals, standardized residuals, Studentized residuals, the standard error of the residuals, the standard error of the prediction, the diagonal elements of the projection (hat) matrix, and Cook’s $D$. See [R] regress postestimation for details.

**margins**

margins after anova follows the same syntax as margins after regress. See [R] regress postestimation for details.
test

Description for test

In addition to the standard syntax of test (see [R] test), test after anova has three additionally allowed syntaxes; see below. test performs Wald tests of expressions involving the coefficients of the underlying regression model. Simple and composite linear hypotheses are possible.

Menu for test

Statistics > Linear models and related > ANOVA/MANOVA > Test linear hypotheses after anova

Syntax for test

```
test, test(matname) [mtest[(opt)] matvlc(matname)] syntax a
test, showorder syntax b
test [term [term ...]] [/ term [term ...]] [,, symbolic] syntax c
```

syntax a  test expression involving the coefficients of the underlying regression model; you provide information as a matrix
syntax b  show underlying order of design matrix, which is useful when constructing `matname` argument of the `test()` option
syntax c  test effects and show symbolic forms

Options for test

`test(matname)` is required with syntax a of test. The rows of `matname` specify linear combinations of the underlying design matrix of the ANOVA that are to be jointly tested. The columns correspond to the underlying design matrix (including the constant if it has not been suppressed). The column and row names of `matname` are ignored.

A listing of the constraints imposed by the `test()` option is presented before the table containing the tests. You should examine this table to verify that you have applied the linear combinations you desired. Typing `test, showorder` allows you to examine the ordering of the columns for the design matrix from the ANOVA.

`mtest[(opt)]` specifies that tests are performed for each condition separately. `opt` specifies the method for adjusting p-values for multiple testing. Valid values for `opt` are

```
bonferroni    Bonferroni’s method
holm          Holm’s method
sidak         Šidák’s method
noadjust      no adjustment is to be made
```

Specifying `mtest` with no argument is equivalent to `mtest(noadjust)`.

`matvlc(matname)`, a programmer’s option, saves the variance–covariance matrix of the linear combinations involved in the suite of tests. For the test $Lb = c$, what is returned in `matname` is $LVL'$, where $V$ is the estimated variance–covariance matrix of $b.$
showorder causes test to list the definition of each column in the design matrix. showorder is not allowed with any other option.

symbolic requests the symbolic form of the test rather than the test statistic. When this option is specified with no terms (test, symbolic), the symbolic form of the estimable functions is displayed.

**Remarks and examples**

Remarks are presented under the following headings:

- **Testing effects**
- **Obtaining symbolic forms**
- **Testing coefficients and contrasts of margins**
- **Video example**

See examples 4, 7, 8, 13, 15, 16, and 17 in [R] anova for examples that use the margins command.

### Testing effects

After fitting a model using anova, you can test for the significance of effects in the ANOVA table, as well as for effects that are not reported in the ANOVA table, by using the test or contrast command. You follow test or contrast by the list of effects that you wish to test. By default, these commands use the residual mean squared error in the denominator of the $F$ ratio. You can specify other error terms by using the slash notation, just as you would with anova. See [R] contrast for details on this command.

#### Example 1: Testing effects

Recall our byssinosis example (example 8) in [R] anova:

```
. anova prob workplace smokes race workplace#smokes workplace#race smokes#race
    > workplace#smokes#race [aweight=pop]
    (sum of wgt is 5.4190e+03)

Number of obs = 65       R-squared = 0.8300
Root MSE = .025902       Adj R-squared = 0.7948

Source       Partial SS  df       MS       F       Prob>F
------------- ----------- ------- ------- ------- --------
Model        .17364654  11   .01578605  23.53    0.0000
workplace    .09762518  2   .04881259  72.76    0.0000
smokes       .01303081  1   .01303081  19.42    0.0001
race         .00109472  1   .00109472  1.63     0.2070
workplace#smokes .01969034  2   .00984517  14.67    0.0000
workplace#race .00135252  2   .00067626  1.01     0.3718
smokes#race   .00166287  1   .00166287  2.48     0.1214
workplace#smokes#race .00095084  2   .00047542  0.71     0.4969
Residual     .03555777  53   .0006709
Total        .2092043   64   .00326882
```
We can easily obtain a test on a particular term from the ANOVA table. Here are two examples:

```plaintext
.test smokes
Source | Partial SS | df | MS | F    | Prob>F
-------|------------|----|----|------|-------
smokes  | .01303081  | 1  | .01303081 | 19.42 | 0.0001
Residual| .03555777  | 53 | .0006709   |
.test smokes#race
Source | Partial SS | df | MS | F    | Prob>F
-------|------------|----|----|------|-------
smokes#race | .00166287  | 1  | .00166287 | 2.48  | 0.1214
Residual | .03555777  | 53 | .0006709   |
```

Both of these tests use residual error by default and agree with the ANOVA table produced earlier.

We could have performed these same tests with `contrast`:

```plaintext
. contrast smokes
Contrasts of marginal linear predictions
Margins : asbalanced
<table>
<thead>
<tr>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
</table>
smokes| 1    | 19.42 | 0.0001
Denominator | 53   |       |
```

```plaintext
. contrast smokes#race
Contrasts of marginal linear predictions
Margins : asbalanced
<table>
<thead>
<tr>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
</table>
smokes#race | 1    | 2.48  | 0.1214
Denominator | 53   |       |
```

### Technical note

After `anova`, you can use the ‘/’ syntax in `test` or `contrast` to perform tests with a variety of non-$\sigma^2 I$ error structures. However, in most unbalanced models, the mean squares are not independent and do not have equal expectations under the null hypothesis. Also, be warned that you assume responsibility for the validity of the test statistic.

### Example 2: Testing effects with different error terms

We return to the nested ANOVA example (example 11) in [R] `anova`, where five brands of machinery were compared in an assembly line. We can obtain appropriate tests for the nested terms using `test`, even if we had run the `anova` command without initially indicating the proper error terms.
In this ANOVA table, `machine` is tested with residual error. With this particular nested design, the appropriate error term for testing `machine` is `operator` nested within `machine`, which is easily obtained from `test`.

This result from `test` matches what we obtained from our `anova` command.

### Example 3: Pooling terms when testing effects

The other nested ANOVA example (example 12) in [R] `anova` was based on the sewage data. The ANOVA table is presented here again. As before, we will use abbreviations of variable names in typing the commands.
. use https://www.stata-press.com/data/r16/sewage
(Sewage treatment)
. anova particulate s / m|s / f|m|s / w|f|m|s /, dropemptycells

Number of obs = 64  R-squared = 0.6338

</tbody>
</table>

In practice, it is often beneficial to pool nonsignificant nested terms to increase the power of tests on remaining terms. One rule of thumb is to allow the pooling of a term whose p-value is larger than 0.25. In this sewage example, the p-value for the test of manager is 0.6166. This value indicates that the manager effect is negligible and might be ignored. Currently, solution is tested by manager|solution, which has only 2 degrees of freedom. If we pool the manager and facility terms and use this pooled estimate as the error term for solution, we would have a term with 6 degrees of freedom.

Below are two tests: a test of solution with the pooled manager and facility terms and a test of this pooled term by worker.

. test s / m|s f|m|s

</tr>
</tbody>
</table>

In the first test, we included two terms after the forward slash (m|s and f|m|s). test after anova allows multiple terms both before and after the slash. The terms before the slash are combined and are then tested by the combined terms that follow the slash (or residual error if no slash is present).
The \( p \)-value for \textit{solution} using the pooled term is 0.0159. Originally, it was 0.0536. The increase in the power of the test is due to the increase in degrees of freedom for the pooled error term.

We can get identical results if we drop \textit{manager} from the \textit{anova} model. (This dataset has unique numbers for each facility so that there is no confusion of facilities when \textit{manager} is dropped.)

```stata
.anova particulate s/f s/w f/, dropemptycells
```

</tbody>
</table>

This output agrees with our earlier test results.

In the following example, two terms from the \textit{anova} are jointly tested (pooled).

\textbf{Example 4: Obtaining overall significance of a term using \textit{contrast}}

In \textit{example 10} of \textquote{R} \textit{anova}, we fit the model \textit{anova drate region c.mage region#c.mage}. Now we use the \textit{contrast} command to test for the overall significance of \textit{region}.

```stata
.contrast region region#c.mage, overall
```

<table>
<thead>
<tr>
<th>Margins : asbalanced</th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>region</td>
<td>3</td>
<td>7.40</td>
<td>0.0004</td>
</tr>
<tr>
<td>region#c.mage</td>
<td>3</td>
<td>0.86</td>
<td>0.4689</td>
</tr>
<tr>
<td>Overall</td>
<td>6</td>
<td>5.65</td>
<td>0.0002</td>
</tr>
<tr>
<td>Denominator</td>
<td>42</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

The overall \( F \) statistic associated with the \textit{region} and \textit{region#c.mage} terms is 5.65, and it is significant at the 0.02% level.

In the ANOVA output, the \textit{region} term, by itself, had a sum of squares of 1166.15, which, based on 3 degrees of freedom, yielded an \( F \) statistic of 7.40 and a significance level of 0.0004. This is the same test that is reported by \textit{contrast} in the row labeled \textit{region}. Likewise, the test from the ANOVA output for the \textit{region#c.mage} term is reproduced in the second row of the \textit{contrast} output.
Obtaining symbolic forms

test can produce the symbolic form of the estimable functions and symbolic forms for particular tests.

Example 5: Symbolic form of the estimable functions

After fitting an ANOVA model, we type test, symbolic to obtain the symbolic form of the estimable functions. For instance, returning to our blood pressure data introduced in example 4 of [R] anova, let’s begin by reestimating systolic on drug, disease, and drug#disease:

```
use https://www.stata-press.com/data/r16/systolic, clear
(Systolic Blood Pressure Data)
.anova systolic drug disease drug#disease
```

```
<table>

<td>0.0013</td>
</tr>
<tr>
<td>drug</td>
<td>2997.4719</td>
<td>3</td>
<td>999.15729</td>
<td>9.05</td>
<td>0.0001</td>
</tr>
<tr>
<td>disease</td>
<td>415.87305</td>
<td>2</td>
<td>207.93652</td>
<td>1.88</td>
<td>0.1637</td>
</tr>
<tr>
<td>drug#disease</td>
<td>707.26626</td>
<td>6</td>
<td>117.87771</td>
<td>1.07</td>
<td>0.3958</td>
</tr>
<tr>
<td>Residual</td>
<td>5080.8167</td>
<td>46</td>
<td>110.45254</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Total</td>
<td>9340.1552</td>
<td>57</td>
<td>163.86237</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
```

To obtain the symbolic form of the estimable functions, type

```
.test, symbolic
drug
  1  -(r2+r3+r4-r0)
  2  r2
  3  r3
  4  r4
disease
  1  -(r6+r7-r0)
  2  r6
  3  r7
drug#disease
  1  1  -(r2+r3+r4+r6+r7-r12-r13-r15-r16-r18-r19-r0)
  1  2  r6 - (r12+r15+r18)
  1  3  r7 - (r13+r16+r19)
  2  1  r2 - (r12+r13)
  2  2  r12
  2  3  r13
  3  1  r3 - (r15+r16)
  3  2  r15
  3  3  r16
  4  1  r4 - (r18+r19)
  4  2  r18
  4  3  r19
_cons
  r0
```
Example 6: Symbolic form for a particular test

To obtain the symbolic form for a particular test, we type `test term [term ...], symbolic`. For instance, the symbolic form for the test of the main effect of `drug` is

```
.test drug, symbolic
  drug
  1  -(r2+r3+r4)
  2  r2
  3  r3
  4  r4
disease
  1  0
  2  0
  3  0
drug#disease
  1 1  -1/3 (r2+r3+r4)
  1 2  -1/3 (r2+r3+r4)
  1 3  -1/3 (r2+r3+r4)
  2 1  1/3 r2
  2 2  1/3 r2
  2 3  1/3 r2
  3 1  1/3 r3
  3 2  1/3 r3
  3 3  1/3 r3
  4 1  1/3 r4
  4 2  1/3 r4
  4 3  1/3 r4
_cons 0
```

If we omit the `symbolic` option, we instead see the result of the test:

```
.test drug

<table>
<thead>
<tr>

<td>2997.4719</td>
<td>3</td>
<td>999.15729</td>
<td>9.05</td>
<td>0.0001</td>
</tr>
<tr>
<td>Residual</td>
<td>5080.8167</td>
<td>46</td>
<td>110.45254</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
```

Testing coefficients and contrasts of margins

The `test` command allows you to perform tests directly on the coefficients of the underlying regression model. For instance, the coefficient on the third `drug` and the second `disease` is referred to as `3.drug#2.disease`. This could also be written as `i3.drug#i2.disease`, or `_b[3.drug#2.disease]`, or even `_coef[i3.drug#i2.disease]; see [U] 13.5 Accessing coefficients and standard errors.

Example 7: Testing linear combinations of coefficients

Let's begin by testing whether the coefficient on the third `drug` is equal to the coefficient on the fourth in our blood pressure data. We have already fit the model `anova systolic drug##disease` (equivalent to `anova systolic drug disease drug#disease`), and you can see the results of that estimation in example 5. Even though we have performed many tasks since we fit the model, Stata still remembers, and we can perform tests at any time.
We find that the two coefficients are not significantly different, at least at any significance level smaller than 73%.

For more complex tests, the `contrast` command often provides a more concise way to specify the test we are interested in and prevents us from having to write the tests in terms of the regression coefficients. With `contrast`, we instead specify our tests in terms of differences in the marginal means for the levels of a particular factor. For example, if we want to compare the third and fourth drugs, we can test the difference in the mean impact on systolic blood pressure separately for each disease using the `@` operator. We also use the reverse adjacent operator, `ar`, to compare the fourth level of drug with the previous level.

```
. contrast ar4.drug@disease
Contrasts of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>drug@disease</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>(4 vs 3) 1</td>
<td>1</td>
<td>0.13</td>
<td>0.7234</td>
</tr>
<tr>
<td>(4 vs 3) 2</td>
<td>1</td>
<td>1.76</td>
<td>0.1917</td>
</tr>
<tr>
<td>(4 vs 3) 3</td>
<td>1</td>
<td>0.65</td>
<td>0.4230</td>
</tr>
<tr>
<td>Joint</td>
<td>3</td>
<td>0.85</td>
<td>0.4761</td>
</tr>
<tr>
<td>Denominator</td>
<td></td>
<td>46</td>
<td></td>
</tr>
</tbody>
</table>
```

None of the individual contrasts shows significant differences between the third drug and the fourth drug. Likewise, the overall $F$ statistic is 0.85, which is hardly significant. We cannot reject the hypothesis that the third drug has the same effect as the fourth drug.

**Technical note**

Alternatively, we could have specified these tests based on the coefficients of the underlying regression model using the `test` command. We would have needed to perform tests on the coefficients for `drug` and for the coefficients on `drug` interacted with `disease` in order to test for differences in the means mentioned above. To do this, we start with our previous `test` command:

```
. test 3.drug = 4.drug
( 1) 3.drug - 4.drug = 0
    F( 1, 46) = 0.13
    Prob > F = 0.7234
```

Notice that the $F$ statistic for this test is equivalent to the test labeled `(4 vs 3) 1` in the `contrast` output. Let’s now add the constraint that the coefficient on the third drug interacted with the third disease is equal to the coefficient on the fourth drug, again interacted with the third disease. We do that by typing the new constraint and adding the `accumulate` option:
So far, our test includes the equality of the two drug coefficients, along with the equality of the two drug coefficients when interacted with the third disease. Now we add two more equations, one for each of the remaining two diseases:

\[
\begin{align*}
\text{. test 3.drug#2.disease = 4.drug#2.disease, accumulate} \\
(1) & \quad 3.\text{drug} - 4.\text{drug} = 0 \\
(2) & \quad 3.\text{drug#3.disease} - 4.\text{drug#3.disease} = 0 \\
(3) & \quad 3.\text{drug#2.disease} - 4.\text{drug#2.disease} = 0 \\
F( & \quad 3, \quad 46) = 0.85 \\
\text{Prob} > F & = 0.4761
\end{align*}
\]

The overall \( F \) statistic reproduces the one from the joint test in the \texttt{contrast} output.

You may notice that we also got the message “Constraint 4 dropped”. For the technically inclined, this constraint was unnecessary, given the normalization of the model. If we specify all the constraints involved in our test or use \texttt{contrast}, we need not worry about the normalization because Stata handles this automatically.

The \texttt{test()} option of \texttt{test} provides another alternative for testing coefficients. Instead of spelling out each coefficient involved in the test, a matrix representing the test provides the needed information. \texttt{test, showorder} shows the order of the terms in the ANOVA corresponding to the order of the columns for the matrix argument of \texttt{test()}.

\textbf{Example 8: Another way to test linear combinations of coefficients}

We repeat the last test of \textbf{example 7} above with the \texttt{test()} option. First, we view the definition and order of the columns underlying the ANOVA performed on the systolic data.
. test, showorder

Order of columns in the design matrix
1: (drug==1)
2: (drug==2)
3: (drug==3)
4: (drug==4)
5: (disease==1)
6: (disease==2)
7: (disease==3)
8: (drug==1)*(disease==1)
9: (drug==1)*(disease==2)
10: (drug==1)*(disease==3)
11: (drug==2)*(disease==1)
12: (drug==2)*(disease==2)
13: (drug==2)*(disease==3)
14: (drug==3)*(disease==1)
15: (drug==3)*(disease==2)
16: (drug==3)*(disease==3)
17: (drug==4)*(disease==1)
18: (drug==4)*(disease==2)
19: (drug==4)*(disease==3)
20: _cons

Columns 1–4 correspond to the four levels of drug. Columns 5–7 correspond to the three levels of disease. Columns 8–19 correspond to the interaction of drug and disease. The last column corresponds to _cons, the constant in the model.

We construct the matrix `dr3vs4` with the same four constraints as the last test shown in example 7 and then use the `test(dr3vs4)` option to perform the test.

```
. matrix dr3vs4 = (0,0,1,-1, 0,0,0, 0,0,0,0,0,0,0,0,0,0,0,0, 0, 0, 0, 0 \\
> 0,0,0, 0,0,0, 0,0,0,0,0,0,0,0,0,0,1, 0, 0,-1, 0, 0 \\
> 0,0,0, 0,0,0, 0,0,0,0,0,0,0,1,0, 0,-1, 0, 0, 0 \\
> 0,0,0, 0,0,0, 0,0,0,0,0,0,1,0,0,-1, 0, 0, 0)
. test, test(dr3vs4)
( 1)  3.drug - 4.drug = 0
( 2)  3.drug#3.disease - 4.drug#3.disease = 0
( 3)  3.drug#2.disease - 4.drug#2.disease = 0
( 4) 3o.drug#1b.disease - 4o.drug#1b.disease = 0
  Constraint 4 dropped
  F(  3,  46) =  0.85
  Prob > F =  0.4761
```

Here the effort involved with spelling out the coefficients is similar to that of constructing a matrix and using it in the `test()` option. When the test involving coefficients is more complicated, the `test()` option may be more convenient than specifying the coefficients directly in `test`. However, as previously demonstrated, `contrast` may provide an even simpler method for testing the same hypothesis.

After fitting an ANOVA model, various contrasts (1-degree-of-freedom tests comparing different levels of a categorical variable) are often of interest. `contrast` can perform each 1-degree-of-freedom test in addition to the combined test, even in cases in which the contrasts do not correspond to one of the contrast operators.
Example 9: Testing particular contrasts of interest

Rencher and Schaalje (2008) illustrate 1-degree-of-freedom contrasts for an ANOVA comparing the net weight of cans filled by five machines (labeled A–E). The data were originally obtained from Ostle and Mensing (1975). Rencher and Schaalje use a cell-means ANOVA model approach for this problem. We could do the same by using the noconstant option of anova; see [R] anova. Instead, we obtain the same results by using the standard overparameterized ANOVA approach (that is, we keep the constant in the model).

```
use https://www.stata-press.com/data/r16/canfill

All the above tests appear to be significant. In addition to presenting the 1-degree-of-freedom tests, the combined tests for \( A \) and \( B \) are produced and agree with the original ANOVA results.

Now we explore the interaction between \( A \) and \( B \).

. contrast \texttt{p.A#p1.B}, noeffects

The 2-degrees-of-freedom test of the interaction of \( A \) with the linear components of \( B \) is significant at the 0.0011 level. But, when we examine the two 1-degree-of-freedom tests that compose this result,
the significance is due to the linear A by linear B contrast (significance level of 0.0003). A significance value of 0.7893 for the quadratic A by linear B indicates that this factor is not significant for these data.

```

[U] 20 Estimation and postestimation commands
areg — Linear regression with a large dummy-variable set

Description

areg fits a linear regression absorbing one categorical factor. areg is designed for datasets with many groups, but not a number of groups that increases with the sample size. See the xtreg, fe command in [XT] xtreg for an estimator that handles the case in which the number of groups increases with the sample size.

Quick start

Linear regression of y on x, absorbing an indicator variable for each level of cvar
  areg y x, absorb(cvar)

As above, but add categorical variable a
  areg y x i.a, absorb(cvar)

With cluster-robust standard errors
  areg y x i.a, absorb(cvar) vce(cluster cvar2)

Using svyset data
  svy: areg y x i.a, absorb(cvar)

Menu

Statistics > Linear models and related > Other > Linear regression absorbing one cat. variable
Syntax

\texttt{areg depvar [indevars] [if] [in] [weight], absorb(varname) [options]}

\texttt{options} \hspace{1cm} \text{Description}

\textbf{Model}

\texttt{*absorb(varname)} \hspace{2cm} \text{categorical variable to be absorbed}

\textbf{SE/Robust}

\texttt{vce(vcetype)} \hspace{2cm} \text{vcetype may be ols, robust, cluster clustvar, bootstrap, or jackknife}

\textbf{Reporting}

\texttt{level(#)} \hspace{2cm} \text{set confidence level; default is level(95)}

\texttt{display_options} \hspace{2cm} \text{control columns and column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling}

\texttt{coeflegend} \hspace{2cm} \text{display legend instead of statistics}

*\texttt{absorb(varname)} is required.

\texttt{indevars} may contain factor variables; see \texttt{[U] 11.4.3 Factor variables.}

\texttt{depvar} and \texttt{indevars} may contain time-series operators; see \texttt{[U] 11.4.4 Time-series varlists.}

\texttt{bootstrap}, \texttt{by}, \texttt{fp}, \texttt{jackknife}, \texttt{mi estimate}, \texttt{rolling}, and \texttt{stataby} are allowed; see \texttt{[U] 11.1.10 Prefix commands.}

\texttt{vce(bootstrap)} and \texttt{vce(jackknife)} are not allowed with the \texttt{mi estimate} prefix; see \texttt{[MI] mi estimate.}

Weights are not allowed with the \texttt{bootstrap} prefix; see \texttt{[R] bootstrap.}

\texttt{aweights} are not allowed with the \texttt{jackknife} prefix; see \texttt{[R] jackknife.}

\texttt{aweights}, \texttt{fweights}, and \texttt{pweights} are allowed; see \texttt{[U] 11.1.6 weight.}

\texttt{coeflegend} does not appear in the dialog box.

See \texttt{[U] 20 Estimation and postestimation commands} for more capabilities of estimation commands.

\textbf{Options}

\texttt{absorb(varname)} specifies the categorical variable, which is to be included in the regression as if it were specified by dummy variables. \texttt{absorb()} is required.

\texttt{vce(vcetype)} specifies the type of standard error reported, which includes types that are derived from asymptotic theory (\texttt{ols}), that are robust to some kinds of misspecification (\texttt{robust}), that allow for intragroup correlation (\texttt{cluster clustvar}), and that use bootstrap or jackknife methods (\texttt{bootstrap}, \texttt{jackknife}); see \texttt{[R] vce_option.}

\texttt{vce(ols)}, the default, uses the standard variance estimator for ordinary least-squares regression.

Exercise caution when using the \texttt{vce(cluster clustvar)} option with \texttt{areg}. The effective number of degrees of freedom for the robust variance estimator is \( n_g - 1 \), where \( n_g \) is the number of clusters. Thus the number of levels of the \texttt{absorb()} variable should not exceed the number of clusters.
level(#)\); see \[R\] Estimation options.

display_options: noci, nopvalues, noomitted, vsquish, noemptycells, baselevels, allbaselevels, noflabel, fvwrap(#), fvwrapon(style), cformat(\%fmt), pformat(\%fmt), sformat(\%fmt), and nolstretch; see \[R\] Estimation options.

The following option is available with \texttt{areg} but is not shown in the dialog box:
coeflegend; see \[R\] Estimation options.

**Remarks and examples**

Suppose that you have a regression model that includes among the explanatory variables a large number, \(k\), of mutually exclusive and exhaustive dummies:

\[
y = X\beta + d_1\gamma_1 + d_2\gamma_2 + \cdots + d_k\gamma_k + \epsilon
\]

For instance, the dummy variables, \(d_i\), might indicate countries in the world or states of the United States. One solution would be to fit the model with \texttt{regress}, but this solution is possible only if \(k\) is small enough so that the total number of variables (the number of columns of \(X\) plus the number of \(d_i\)'s plus one for \(y\)) is sufficiently small—meaning that it can fit in a Stata matrix (see \[R\] Limits). If you have more variables than can fit in a Stata matrix, \texttt{regress} will not work. \texttt{areg} provides a way of obtaining estimates of \(\beta\)—but not the \(\gamma_i\)'s—in these cases. The effects of the dummy variables are said to be absorbed.

**Example 1**

So that we can compare the results produced by \texttt{areg} with Stata’s other regression commands, we will fit a model in which \(k\) is small. \texttt{areg}'s real use, however, is when \(k\) is large.

In our automobile data, we have a variable called \texttt{rep78} that is coded 1, 2, 3, 4, and 5, where 1 means poor and 5 means excellent. Let’s assume that we wish to fit a regression of \texttt{mpg} on \texttt{weight}, \texttt{gear_ratio}, and \texttt{rep78} (parameterized as a set of dummies).
. use https://www.stata-press.com/data/r16/auto2
(1978 Automobile Data)
. regress mpg weight gear_ratio b5.rep78

| Source | SS     | df | MS       | Number of obs = 69

| _cons   | 34.05889 | 7.056383 | 4.83  | 0.000   | 19.95338 48.1644 |

F test of absorbed indicators: F(4, 62) = 1.117 Prob > F = 0.356

Both regress and areg display the same $R^2$ values, root mean squared error, and—for weight and gear_ratio—the same parameter estimates, standard errors, $t$ statistics, significance levels, and confidence intervals. areg, however, does not report the coefficients for rep78, and, in fact, they are not even calculated. This computational trick makes the problem manageable when $k$ is large. areg reports a test that the coefficients associated with rep78 are jointly zero. Here this test has a significance level of 35.6%. This $F$ test for rep78 is the same that we would obtain after regress if we were to specify test 1.rep78 2.rep78 3.rep78 4.rep78; see [R] test.

The model $F$ tests reported by regress and areg also differ. The regress command reports a test that all coefficients except that of the constant are equal to zero; thus, the dummies are included in this test. The areg output shows a test that all coefficients excluding the dummies and the constant are equal to zero. This is the same test that can be obtained after regress by typing test weight gear_ratio.
Technical note

areg is designed for datasets with many groups, but not a number that grows with the sample size. Consider two different samples from the U.S. population. In the first sample, we have 10,000 individuals and we want to include an indicator for each of the 50 states, whereas in the second sample we have 3 observations on each of 10,000 individuals and we want to include an indicator for each individual. areg was designed for datasets similar to the first sample in which we have a fixed number of groups, the 50 states. In the second sample, the number of groups, which is the number of individuals, grows as we include more individuals in the sample. For an estimator designed to handle the case in which the number of groups grows with the sample size, see the xtreg, fe command in [XT] xtreg.

Although the point estimates produced by areg and xtreg, fe are the same, the estimated VCEs differ when vce(cluster clustvar) is specified because the commands make different assumptions about whether the number of groups increases with the sample size.

Technical note

The intercept reported by areg deserves some explanation because, given \( k \) mutually exclusive and exhaustive dummies, it is arbitrary. areg identifies the model by choosing the intercept that makes the prediction calculated at the means of the independent variables equal to the mean of the dependent variable: \( \bar{Y} = \bar{x} \hat{\beta} \).

```
. predict yhat
   (option xb assumed; fitted values)
. summarize mpg yhat if rep78 != .
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>mpg</td>
<td>69</td>
<td>21.28986</td>
<td>5.866408</td>
<td>12</td>
<td>41</td>
</tr>
<tr>
<td>yhat</td>
<td>69</td>
<td>21.28986</td>
<td>4.383224</td>
<td>11.58643</td>
<td>28.07367</td>
</tr>
</tbody>
</table>

We had to include if rep78 < . in our summarize command because we have missing values in our data. areg automatically dropped those missing values (as it should) in forming the estimates, but predict with the xb option will make predictions for cases with missing rep78 because it does not know that rep78 is really part of our model.

These predicted values do not include the absorbed effects (that is, the \( d_i \gamma_i \)). For predicted values that include these effects, use the xbd option of predict (see [R] areg postestimation) or see [XT] xtreg.

Example 2

areg, vce(robust) is a Huberized version of areg; see [P] _robust. Just as areg is equivalent to using regress with dummies, areg, vce(robust) is equivalent to using regress, vce(robust) with dummies. You can use areg, vce(robust) when you expect heteroskedastic or nonnormal errors. areg, vce(robust), like ordinary regression, assumes that the observations are independent, unless the vce(cluster clustvar) option is specified. If the vce(cluster clustvar) option is specified, this independence assumption is relaxed and only the clusters identified by equal values of clustvar are assumed to be independent.
Assume that we were to collect data by randomly sampling 10,000 doctors (from 100 hospitals) and then sampling 10 patients of each doctor, yielding a total dataset of 100,000 patients in a cluster sample. If in some regression we wished to include effects of the hospitals to which the doctors belonged, we would want to include a dummy variable for each hospital, adding 100 variables to our model. `areg` could fit this model by

```
. areg depvar patient_vars, absorb(hospital) vce(cluster doctor)
```

## Stored results

`areg` stores the following in `e()`:

### Scalars

- `e(N)`: number of observations
- `e(k_absorb)`: number of absorbed categories
- `e(mss)`: model sum of squares
- `e(tss)`: total sum of squares
- `e(df_m)`: model degrees of freedom
- `e(rss)`: residual sum of squares
- `e(df_r)`: residual degrees of freedom
- `e(r2)`: $R^2$
- `e(r2_a)`: adjusted $R^2$
- `e(df_a)`: degrees of freedom for absorbed effect
- `e(ll)`: log likelihood
- `e(ll_0)`: log likelihood, constant-only model
- `e(N_clust)`: number of clusters
- `e(F)`: $F$ statistic
- `e(F_absorb)`: $F$ statistic for absorbed effect (when `vce(robust)` is not specified)
- `e(p)`: $p$-value for model $F$ test
- `e(p_absorb)`: $p$-value for $F$ test of absorbed effect
- `e(rank)`: rank of `e(V)`

### Macros

- `e(cmd)`: `areg`
- `e(cmdline)`: command as typed
- `e(depvar)`: name of dependent variable
- `e(absvar)`: name of `absorb` variable
- `e(wtype)`: weight type
- `e(wexp)`: weight expression
- `e(title)`: title in estimation output
- `e(clustvar)`: name of cluster variable
- `e(vce)`: `vcetype` specified in `vce()`
- `e(vcetype)`: title used to label Std. Err.
- `e(datasignature)`: the checksum
- `e(datasignaturevars)`: variables used in calculation of checksum
- `e(properties)`: `b V`
- `e(predict)`: program used to implement `predict`
- `e(footnote)`: program used to implement the footnote display
- `e(marginsnotok)`: predictions disallowed by `margins`
- `e(asbalanced)`: factor variables `fvset` as `asbalanced`
- `e(asobserved)`: factor variables `fvset` as `asobserved`

### Matrices

- `e(b)`: coefficient vector
- `e(V)`: variance–covariance matrix of the estimators
- `e(V_modelbased)`: model-based variance

### Functions

- `e(sample)`: marks estimation sample
Methods and formulas

areg begins by recalculating depvar and indepvars to have mean 0 within the groups specified by absorb(). The overall mean of each variable is then added back in. The adjusted depvar is then regressed on the adjusted indepvars with regress, yielding the coefficient estimates. The degrees of freedom of the variance–covariance matrix of the coefficients is then adjusted to account for the absorbed variables—this calculation yields the same results (up to numerical roundoff error) as if the matrix had been calculated directly by the formulas given in [R] regress.

areg with vce(robust) or vce(cluster clustvar) works similarly, calling _robust after regress to produce the Huber/White/sandwich estimator of the variance or its clustered version. See [P] _robust, particularly Introduction and Methods and formulas. The model $F$ test uses the robust variance estimates. There is, however, no simple computational means of obtaining a robust test of the absorbed dummies; thus this test is not displayed when the vce(robust) or vce(cluster clustvar) option is specified.

The number of groups specified in absorb() are included in the degrees of freedom used in the finite-sample adjustment of the cluster–robust VCE estimator. This statement is only valid if the number of groups is small relative to the sample size. (Technically, the number of groups must remain fixed as the sample size grows.) For an estimator that allows the number of groups to grow with the sample size, see the xtreg, fe command in [XT] xtreg.

<td>( d_{\text{absorbvar}} )</td>
</tr>
<tr>
<td>*residuals</td>
<td>residual</td>
</tr>
<tr>
<td>*score</td>
<td>score; equivalent to residuals</td>
</tr>
</tbody>
</table>

Unstarred statistics are available both in and out of sample; type \text{predict} \ ... \text{if e(sample)} \ ... if wanted only for the estimation sample. Starred statistics are calculated only for the estimation sample, even when \text{if e(sample)} is not specified.

Options for predict

xb, the default, calculates the prediction of \( x_j b \), the fitted values, by using the average effect of the absorbed variable. Also see xbd below.

stdp calculates the standard error of \( x_j b \).

dresiduals calculates \( y_j - x_j b \), which are the residuals plus the effect of the absorbed variable.

xd calculates \( x_j b + d_{\text{absorbvar}} \), which are the fitted values including the individual effects of the absorbed variable.

d calculates \( d_{\text{absorbvar}} \), the individual coefficients for the absorbed variable.

residuals calculates the residuals, that is, \( y_j - (x_j b + d_{\text{absorbvar}}) \).

score is a synonym for residuals.
margins

Description for margins

margins estimates margins of response for fitted values.

Menu for margins

Statistics > Postestimation

Syntax for margins

margins [marginlist] [, options]
margins [marginlist], predict(statistic ...) [options]

<table>
<thead>

</tr>
</tbody>
</table>

Statistics not allowed with margins are functions of stochastic quantities other than $e(b)$.

For the full syntax, see [R] margins.

Remarks and examples

Example 1

Continuing with example 1 of [R] areg, we refit the model with robust standard errors and then obtain linear predictions and standard errors for those linear predictions.

```
. use https://www.stata-press.com/data/r16/auto2
   (1978 Automobile Data)
. areg mpg weight gear_ratio, absorb(rep78) vce(robust)
   (output omitted)
. predict xb_ar
   (option xb assumed; fitted values)
. predict stdp_ar, stdp
```

We can obtain the same linear predictions by fitting the model with xtreg, fe, but we would first need to specify the panel structure by using xtset.
The predicted \(xb\) values above are the same for \texttt{areg} and \texttt{xtreg}, \texttt{fe}, but the standard errors for those linear predictions are different. The assumptions for these two estimators lead to different formulations for their standard errors. The robust variance estimates with \texttt{areg} are equivalent to the robust variance estimates using \texttt{regress}, including the panel dummies. The consistent robust variance estimates with \texttt{xtreg} are equivalent to those obtained by specifying \texttt{vce(cluster panelvar)} with that estimation command. For a theoretical discussion, see Wooldridge (2020), Stock and Watson (2008), and Arellano (2003); also see the technical note after example 3 of [XT] \texttt{xtreg}.

\section*{Example 2}

We would like to use \texttt{linktest} to check whether the dependent variable for our model is correctly specified:

\begin{verbatim}
. use https://www.stata-press.com/data/r16/auto2, clear
(1978 Automobile Data)
. areg mpg weight gear_ratio, absorb(rep78) (output omitted)
. linktest, absorb(rep78)
Linear regression, absorbing indicators Absorbed variable: \texttt{rep78}  
Number of obs = 69  
No. of categories = 5  
F( 2, 62) = 46.50  
Prob > F = 0.0000  
R-squared = 0.6939  
Adj R-squared = 0.6643  
Root MSE = 3.3990  

mpg  Coef.  Std. Err.  t  P>|t|  [95% Conf. Interval]
_\_hat -0.9305602 0.9537856 -0.98 0.333 -2.83715 .9760302 
_\_hatsq 0.0462785 .0227219 2.04 0.046 .0008582 .0916989 
_\_cons 19.24899 9.725618 1.98 0.052 -.1922457 38.69022 

F test of absorbed indicators: F(4, 62) = 1.278  
Prob > F = 0.288
\end{verbatim}

The squared residuals are significant in the regression for \texttt{mpg} on the linear and squared residuals; therefore, the test indicates that our dependent variable does not seem to be well specified. Let’s transform the dependent variable into energy consumption, gallons per mile, fit the alternative model, and check the link test again.
. generate gpm = 1/mpg
. areg gpm weight gear_ratio, absorb(rep78)
(output omitted)
. linktest, absorb(rep78)

Linear regression, absorbing indicators
Absorbed variable: rep78

[U] 20 Estimation and postestimation commands
**Description**

*betareg* estimates the parameters of a beta regression model. This model accommodates dependent variables that are greater than 0 and less than 1, such as rates, proportions, and fractional data.

**Quick start**

Beta regression of \( y \) on \( x_1 \) and \( x_2 \)

\[
\text{betareg } y \ x_1 \ x_2
\]

Add categorical variable \( a \) using *factor-variable* syntax

\[
\text{betareg } y \ x_1 \ x_2 \ i.a
\]

Add covariates for scale

\[
\text{betareg } y \ x_1 \ x_2 \ i.a, \ scale(x_1 \ z_1)
\]

As above, but use probit link for conditional mean and square-root link for conditional scale

\[
\text{betareg } y \ x_1 \ x_2 \ i.a, \ scale(x_1 \ z_1) \ link(probit) \ slink(root)
\]

Beta regression of \( y \) on \( x_1 \) and \( x_2 \) with robust standard errors

\[
\text{betareg } y \ x_1 \ x_2, \ vce(robust)
\]

**Menu**

Statistics > Fractional outcomes > Beta regression
Syntax

betareg depvar indepvars [if] [in] [weight] [, options]

options Description

Model

noconstant suppress constant term
scale(varlist[, noconstant]) specify independent variables for scale
link(linkname) specify link function for the conditional mean; default is link(logit)
slink(slinkname) specify link function for the conditional scale; default is slink(log)
constraints(constraints) apply specified linear constraints

SE/Robust

vce(vcetype) vcetype may be oim, robust, cluster clustvar, bootstrap, or jackknife

Reporting

level(#) set confidence level; default is level(95)
nocnsreport do not display constraints
display_options control columns and column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling

Maximization

maximize_options control the maximization process; seldom used

coefflegend display legend instead of statistics

linkname Description

logit logit
probit probit
cloglog complementary log-log
loglog log-log

slinkname Description

log log
root square root
identity identity

indepvars and varlist specified in scale() may contain factor variables; see [U] 11.4.3 Factor variables.
bayes, bootstrap, by, fmm, fp, jackknife, nestreg, rolling, statsby, stepwise, and svy are allowed; see [U] 11.1.10 Prefix commands. For more details, see [BAYES] bayes: betareg and [FMM] fmm: betareg.
Weights are not allowed with the bootstrap prefix; see [R] bootstrap.
vce() and weights are not allowed with the svy prefix; see [SVY] svy.
aweights, iweights, and pweights are allowed; see [U] 11.1.6 weight.
coefflegend does not appear in the dialog box.
See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.
Options

Model

noconstant; see [R] Estimation options.

scale(varlist[, noconstant]) specifies the independent variables used to model the scale.

noconstant suppresses the constant term in the scale model. A constant term is included by default.

link(linkname) specifies the link function used for the conditional mean. linkname may be logit, probit, cloglog, or loglog. The default is link(logit).

slink(slinkname) specifies the link function used for the conditional scale. slinkname may be log, root, or identity. The default is slink(log).

constraints(constraints); see [R] Estimation options.

SE/Robust

vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.

Reporting

level(#), nocnsreport; see [R] Estimation options.

display_options: noci, nopvalues, nolabel, noomitted, vsquish, noemptycells, baselevels, allbaselevels,nofvlabel, fvwrap(#), fvwrapon(style), cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch; see [R] Estimation options.

Maximization

maximize_options: difficult, technique(algorithm_spec), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(init_specs); see [R] Maximize. These options are seldom used.

The following option is available with betareg but is not shown in the dialog box:

coeflegend; see [R] Estimation options.

Remarks and examples

Dependent variables such as rates, proportions, and fractional data are frequently greater than 0 and less than 1. There are a variety of methods to model such variables, including beta regression and fractional logistic regression.

Beta regression is widely used because of its flexibility for modeling variables between 0 and 1 and because its predictions are confined to the same range. However, beta regression models are not appropriate for dependent variables with some observations exactly equal to 0 or 1. See [R] fracreg for models when the dependent variable can equal 0 or 1 that also make predictions over the same range. The predictions from linear regression models are not constrained to the 0 to 1 interval; thus they are not widely used for these variables.
These models have applications in a variety of disciplines, such as economics, the social sciences, and health science. For example, Castellani, Pattitoni, and Scorcu (2012) use beta regression to estimate Gini index values for the prices of art by famous and nonfamous artists. In political science, Paolino (2001) explores the advantages of beta regression and reviewed its applicability for a variety of research topics such as the proportion of minority applicants deemed eligible for the Rural Housing Loans program and the proportion of a state’s gay and lesbian population that is covered by antidiscrimination laws. In psychology, Smithson, Deady, and Gracik (2007) analyzed the relationship between how jurors judged the probability of a defendant’s guilt and the verdict in a trial. Finally, beta regression has been used to model quality-adjusted life years in health-economics outcome studies (Hubben et al. [2008]; Basu and Manca [2012]).

Ferrari and Cribari-Neto (2004) and Smithson and Verkuilen (2006) derived the beta regression estimators implemented in \texttt{betareg}. Basu and Manca (2012) also discuss quasimaximum likelihood inference for these estimators. These estimators augment the inherent flexibility of the beta distribution with functional form choices, known as links.

Beta regression is a model of the mean of the dependent variable \( y \) conditional on covariates \( x \), which we denote by \( \mu_x \). Because \( y \) is in \((0, 1)\), we must ensure that \( \mu_x \) is also in \((0, 1)\). We do this by using the link function for the conditional mean, denoted \( g(\cdot) \). This is necessary because linear combinations of the covariates are not otherwise restricted to \((0, 1)\).

Algebraically,
\[
g(\mu_x) = x\beta
\]
or, equivalently,
\[
\mu_x = g^{-1}(x\beta)
\]
where \( g^{-1}(\cdot) \) is the inverse function of \( g(\cdot) \). For example, the default logit link implies that
\[
\ln\{\mu_x/(1 - \mu_x)\} = x\beta
\]
and that
\[
\mu_x = \exp(x\beta)/(1 + \exp(x\beta))
\]
Using a link function to keep the conditional-mean model inside an interval is common in the statistical literature; see \texttt{R glm} for additional applications of link functions.

The conditional variance of the beta distribution is
\[
\text{Var}(y|x) = \{\mu_x(1 - \mu_x)\}/(1 + \psi)
\]
The parameter \( \psi \) is known as the scale factor because it rescales the conditional variance. We use the scale link to ensure that \( \psi > 0 \).

**Example 1: Beta regression model of a rate**

Suppose we wish to know whether offering a summer instruction program increases a school’s pass rate for a mandatory state exam administered to students. The school-wide pass rate must be between 0 and 1. It is unlikely that any school will have either no students pass or all students pass, so we consider estimating the effect of the summer instruction program using beta regression.

The dataset \texttt{sprogram} contains fictional data on the pass rate of 1,000 schools (prate). We begin by reading in the data and verifying that \texttt{prate} contains no 0s or 1s.
prate ranges from 0.299 to 0.997, so we proceed with our choice of a beta regression model.

We model prate as a function of a binary indicator for whether the school offered voluntary, half-day instruction to students during the past two summers (summer). The summer program should raise the scores of disadvantaged children who otherwise would not have access to programs that maintain their skills through the summer, thereby increasing the total proportion of students who pass the exam the next year.

We include the fraction of students receiving free or reduced-price meals (freemeals) and the sum of parents’ monetary donations to the school two years earlier (pdonations) as additional covariates that measure affluence of the students’ parents. We estimate the parameters of this model using the default logit link for the conditional mean and log link for the conditional scale.

The output table reports the estimated coefficients of the covariates and an estimated scale parameter. The coefficient of the factor variable for \texttt{summer==1}, shown as \texttt{yes} under \texttt{summer}, is significant and positive. Thus we conclude that the summer program was effective at increasing a school’s pass rate.

However, we cannot determine the magnitude of the effect from these results. In general, when you use \texttt{betareg}, the best way to obtain interpretable effect sizes for the covariates is by using \texttt{margins}. See example 1 in \texttt{[R] betareg postestimation} for more information.
Technical note

The results displayed in example 1 can be written concisely in algebraic form. Because we used the default logit link, the estimated conditional mean is

\[
\hat{\mu}_x = \frac{\exp(x\hat{\beta})}{1 + \exp(x\hat{\beta})}
\]

where the estimated \(x\hat{\beta}\) is

\[
x\hat{\beta} = -0.456 \times \text{freemeals} + 0.045 \times \text{pdonations} + 0.556 \times (\text{summer}==1) + 1.18
\]

The estimated \(\psi\) with the default log link for the scale is \(\hat{\psi} = \exp(2.38) = 10.80\), which is simply substituted into the formula given above to express the conditional variance.

See Methods and formulas for the functional forms of the other links implemented in betareg for the conditional mean and scale.

Example 2: Modeling conditional variance

Some processes require that we model the scale parameter as a function of covariates. For example, we might believe that the proportion of students with free or reduced meals influences the variance of the estimated mean.

We augment example 1 by modeling the scale parameter as a function of freemeals.

```
. betareg prate i.summer freemeals pdonations, scale(freemeals)
(output omitted)
```

Beta regression

```
Number of obs = 1,000
LR chi2(4) = 169.38
Prob > chi2 = 0.0000

Link function : g(u) = log(u/(1-u)) [Logit]
Slink function : g(u) = log(u) [Log]
Log likelihood = 895.41544

prate | Coef. Std. Err. z P>|z| [95% Conf. Interval]
------------- | --------------------------------------------------
prate | .5571133 .0480378 11.60 0.000 .4629609 .6512658
summer | .5571133 .0480378 11.60 0.000 .4629609 .6512658
yes | -.5291892 .0896511 -5.90 0.000 -.7049021 -.3534762

pdonations | 1.209179 .0649585 18.61 0.000 1.081863 1.336495
_cons | 2.547047 .0882327 28.87 0.000 2.374114 2.71998

scale | Coef. Std. Err. z P>|z| [95% Conf. Interval]
------------------ | --------------------------------------------------
freemeals | -.3598137 .1644214 -2.19 0.029 -.6820737 -.0375536
_cons | 2.547047 .0882327 28.87 0.000 2.374114 2.71998
```

Again, we conclude that having a summer program increases the pass rate. The effect of an increase in the proportion of students receiving free meals on the conditional variance is ambiguous because it is in both equations. We can use margins to estimate the effect of the program on the conditional mean or the conditional variance.
The estimators in `betareg` are consistent and efficient when the model is correctly specified. Smithson and Verkuilen (2006) discuss model selection for beta regression and note that selecting the model that minimizes the Bayesian information criterion (BIC) will select the correct model in large samples. Selecting the model that minimizes the BIC is a general approach to model selection; see Cameron and Trivedi (2005) for more details.

Example 3: Model selection

We fit the models `quietly` and use `estimates store` to store the results under the names `model1`, `model2`, `model3`, and `model4`.

```
. quietly betareg prate i.summer freemeals pdonations, scale(freemeals)
. estimates store model1
. quietly betareg prate i.summer freemeals pdonations, scale(freemeals)
> link(cloglog)
. estimates store model2
. quietly betareg prate i.summer freemeals pdonations, scale(freemeals)
> slink(root)
. estimates store model3
. quietly betareg prate i.summer freemeals pdonations, scale(freemeals)
> link(cloglog) slink(root)
. estimates store model4
```

Next, we use `estimates table` to display the coefficients, standard errors, and the BIC for each model.

```
. estimates table model1 model2 model3 model4, stats(bic) se

We select `model4`, the model with the complementary log-log link for the conditional mean and the square-root link for the conditional variance, because it has the lowest BIC.
Stored results

`betareg` stores the following in `e()`:

Scalars
- `e(N)` number of observations
- `e(k)` number of parameters
- `e(k_eq)` number of equations in `e(b)`
- `e(k_eq_model)` number of equations in overall model test
- `e(k_dv)` number of dependent variables
- `e(df_m)` model degrees of freedom
- `e(ll)` log likelihood
- `e(ll_0)` log likelihood, constant-only model
- `e(N_clust)` number of clusters
- `e(chi2)` $\chi^2$
- `e(p)` $p$-value for model test
- `e(rank)` rank of `e(V)`
- `e(ic)` number of iterations
- `e(rc)` return code
- `e(converged)` 1 if converged, 0 otherwise

Macros
- `e(cmd)` `betareg`
- `e(cmdline)` command as typed
- `e(depvar)` name of dependent variable
- `e(wtype)` weight type
- `e(wexp)` weight expression
- `e(title)` title in estimation output
- `e(linkt)` link title in the conditional mean equation
- `e(linkf)` link function in the conditional mean equation
- `e(slinkt)` link title in the conditional scale equation
- `e(slinkf)` link function in the conditional scale equation
- `e(clustvar)` name of cluster variable
- `e(chi2type)` Wald or LR; type of model $\chi^2$ test
- `e(vce)` vcetype specified in `vce()`
- `e(vcetype)` title used to label Std. Err.
- `e(opt)` type of optimization
- `e(which)` max or min; whether optimizer is to perform maximization or minimization
- `e(ml_method)` type of ml method
- `e(user)` name of likelihood-evaluator program
- `e(technique)` maximization technique
- `e(properties)` `b` `V`
- `e(predict)` program used to implement `predict`
- `e(marginsok)` predictions allowed by `margins`
- `e(marginsnotok)` predictions disallowed by `margins`
- `e(asbalanced)` factor variables `fvset` as `asbalanced`
- `e(asobserved)` factor variables `fvset` as `asobserved`

Matrices
- `e(b)` coefficient vector
- `e(Cns)` constraints matrix
- `e(ilog)` iteration log (up to 20 iterations)
- `e(gradient)` gradient vector
- `e(V)` variance–covariance matrix of the estimators
- `e(V_modelbased)` model-based variance

Functions
- `e(sample)` marks estimation sample

Methods and formulas

Beta regression models were proposed by Ferrari and Cribari-Neto (2004) and extended by Smithson and Verkuilen (2006) to allow the scale parameter to depend on covariates.
Beta regression is only appropriate for a dependent variable that is strictly greater than 0 and strictly less than 1 because the beta distribution only has support on the interval \((0, 1)\). The density of a beta-distributed dependent variable \(y\) conditional on covariates \(x\) can be written as

\[
f(y; \mu_x, \psi_x) = \frac{\Gamma(\psi_x)}{\Gamma(\mu_x \psi_x) \Gamma((1 - \mu_x) \psi_x)} y^{\mu_x \psi_x - 1} (1 - y)^{(1 - \mu_x) \psi_x - 1}
\]

where \(\mu_x = \mathbb{E}(y|x)\), \(\mu_x\) is linked to the covariates by the link function \(g(\mu_x) = x\beta\), \(\psi_x\) scales the conditional variance according to

\[
\text{Var}(y|x) = \mu_x (1 - \mu_x) / (1 + \psi_x)
\]

and \(\psi_x\) is linked to the covariates by link function \(h(\psi_x) = x\gamma\).

This parameterization yields a log-likelihood function of

\[
\sum_{i=1}^{N} \omega_i \left( \ln \{ \Gamma(\psi_{x,i}) \} - \ln \{ \Gamma(\mu_{x,i} \psi_{x,i}) \} - \ln \{ (1 - \mu_{x,i}) \psi_{x,i} \} \right) + (\mu_{x,i} \psi_{x,i} - 1) \ln(y_i) + \{(1 - \mu_{x,i}) \psi_{x,i} - 1\} \ln(1 - y_i)
\]

The definitions of the link functions are

<table>

These statistics are available both in and out of sample; type predict ... if e(sample) ... if wanted only for the estimation sample.

Options for predict

- **cmean**, the default, calculates the conditional mean of the dependent variable.
- **cvariance** calculates the conditional variance of the dependent variable.
- **xb** calculates the linear prediction for the conditional-mean equation.
- **xbscale** calculates the linear prediction for the conditional-scale equation.
- **stdp** calculates the standard error of the linear prediction for the conditional mean equation.
- **scores** calculates equation-level score variables. The first new variable will contain the derivative of the log likelihood with respect to the conditional-mean equation, and the second new variable will contain the derivative of the log likelihood with respect to the conditional-scale equation.
margins

Description for margins

margins estimates margins of response for conditional means, conditional variances, and linear predictions.

</tr>
<tr>
<td>scores</td>
<td>not allowed with margins</td>
</tr>
</tbody>
</table>

Statistics not allowed with margins are functions of stochastic quantities other than e(b).

For the full syntax, see [R] margins.

Remarks and examples

Example 1

In example 3 in [R] betareg, we selected a model for school-level data on the fraction of students passing a state-required exam. In that example, we were interested in whether a voluntary summer program increased schools’ pass rates. We continue that example to estimate an average treatment effect (ATE) of the program.

After reading in the data and fitting the model, we use margins to estimate the ATE.

. use https://www.stata-press.com/data/r16/sprogram (Fictional summer program data)
. betareg prate freemeals pdonations i.summer, scale(freemeals) link(cloglog) > slink(root) vce(robust)
(output omitted)

We specify vce(robust) with the estimation command and vce(unconditional) with the margins command to obtain standard errors for a population ATE instead of a sample ATE.
. margins r.summer, contrast(nowald) vce(unconditional)

Contrasts of predictive margins
Expression : Conditional mean of prate, predict()

Number of obs = 1,000

<table>
<thead>
<tr>
<th>Contrast</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>summer (yes vs no)</td>
<td>0.0890851</td>
<td>0.008626 0.0721784 0.1059918</td>
</tr>
</tbody>
</table>

The average pass rate would be about 9% higher when all schools offered the program than when no school offered the program.

[U] 20 Estimation and postestimation commands
This entry discusses a statistical issue that arises when using the Bayesian information criterion (BIC) to compare models.

Stata calculates BIC using $N = e(N)$, unless $e(N_{ic})$ has been set; in that instance, it uses $N = e(N_{ic})$. For example, choice-model `cm` commands set $e(N_{ic})$ to the number of cases because these commands use a data arrangement in which multiple Stata observations represent a single statistical observation, which is called a case.

Sometimes, it would be better if a different $N$ than $e(N)$ were used. Commands that calculate BIC have an `n()` option, allowing you to specify the $N$ to be used.

In summary,

1. If you are comparing results estimated by the same estimation command, using the default BIC calculation is probably fine. There is an issue, but most researchers would ignore it.
2. If you are comparing results estimated by different estimation commands, you need to be on your guard.
   a. If the different estimation commands share the same definitions of observations, independence, and the like, you are back in case 1.
   b. If they differ in these regards, you need to think about the value of $N$ that should be used. For example, `logit` and `xtlogit` differ in that the former assumes independent observations and the latter, independent panels.
   c. If estimation commands differ in the events being used over which the likelihood function is calculated, the information criteria may not be comparable at all. We say information criteria because this would apply equally to the Akaike information criterion (AIC), as well as to BIC. For instance, `streg` and `stcox` produce such incomparable results. The events used by `streg` are the actual survival times, whereas the events used by `stcox` are failures within risk pools, conditional on the times at which failures occurred.

Remarks and examples

Remarks are presented under the following headings:

- Background
- The problem of determining $N$
- The problem of conformable likelihoods
- The first problem does not arise with AIC; the second problem does
- Calculating BIC correctly
Background

The AIC and the BIC are two popular measures for comparing maximum likelihood models. AIC and BIC are defined as

\[
\text{AIC} = -2 \times \ln(\text{likelihood}) + 2 \times k \\
\text{BIC} = -2 \times \ln(\text{likelihood}) + \ln(N) \times k
\]

where

\[k = \text{number of parameters estimated} \]
\[N = \text{number of observations}\]

We are going to discuss AIC along with BIC because AIC has some of the problems that BIC has, but not all.

AIC and BIC can be viewed as measures that combine fit and complexity. Fit is measured negatively by \(-2 \times \ln(\text{likelihood})\); the larger the value, the worse the fit. Complexity is measured positively, either by \(2 \times k\) (AIC) or \(\ln(N) \times k\) (BIC).

Given two models fit on the same data, the model with the smaller value of the information criterion is considered to be better.

There is substantial literature on these measures: see Akaike (1974); Raftery (1995); Sakamoto, Ishiguro, and Kitagawa (1986); and Schwarz (1978).

When Stata calculates the above measures, it uses the rank of \(e(V)\) for \(k\) and it uses \(e(N)\) for \(N\). \(e(V)\) and \(e(N)\) are Stata notation for results stored by the estimation command. \(e(V)\) is the variance–covariance matrix of the estimated parameters, and \(e(N)\) is the number of observations in the dataset used in calculating the result.

The problem of determining \(N\)

The difference between AIC and BIC is that AIC uses the constant 2 to weight \(k\), whereas BIC uses \(\ln(N)\).

Determining what value of \(N\) should be used is problematic. Despite appearances, the definition “\(N\) is the number of observations” is not easy to make operational. \(N\) does not appear in the likelihood function itself, \(N\) is not the output of a standard statistical formula, and what is an observation is often subjective.

Example 1

Often what is meant by \(N\) is obvious. Consider a simple logit model. What is meant by \(N\) is the number of observations that are statistically independent and that corresponds to \(M\), the number of observations in the dataset used in the calculation. We will write \(N = M\).

But now assume that the same dataset has a grouping variable and the data are thought to be clustered within group. To keep the problem simple, let’s pretend that there are \(G\) groups and \(m\) observations within group, so that \(M = G \times m\). Because you are worried about intragroup correlation, you fit your model with \texttt{xtlogit}, grouping on the grouping variable. Now you wish to calculate BIC. What is the \(N\) that should be used? \(N = M\) or \(N = G\)?
That is a deep question. If the observations really are independent, then you should use \( N = M \). If the observations within group are not just correlated but are duplicates of one another, and they had to be so, then you should use \( M = G \). Between those two extremes, you should probably use a number between \( N \) and \( G \), but determining what that number should be from measured correlations is difficult. Using \( N = M \) is conservative in that, if anything, it overweights complexity. Conservativeness, however, is subjective, too: using \( N = G \) could be considered more conservative in that fewer constraints are being placed on the data.

When the estimated correlation is high, our reaction would be that using \( N = G \) is probably more reasonable. Our first reaction, however, would be that using BIC to compare models is probably a misuse of the measure.

Stata uses \( N = M \). An informal survey of web-based literature suggests that \( N = M \) is the popular choice.

There is another reason, not so good, to choose \( N = M \). It makes across-model comparisons more likely to be valid when performed without thinking about the issue. Say that you wish to compare the \texttt{logit} and \texttt{xtlogit} results. Thus you need to calculate

\[
\text{BIC}_p = -2 \times \ln(\text{likelihood}_p) + \ln(N_p) \times k \\
\text{BIC}_x = -2 \times \ln(\text{likelihood}_x) + \ln(N_x) \times k
\]

Whatever \( N \) you use, you must use the same \( N \) in both formulas. Stata’s choice of \( N = M \) at least meets that test.

\[\text{Example 2}\]

In the above example, using \( N = M \) is reasonable. Now let’s look at when using \( N = M \) is wrong, even if popular.

Consider a model fit by \texttt{stcox}. Using \( N = M \) is certainly wrong if for no other reason than \( M \) is not even a well-defined number. The same data can be represented by different datasets with different numbers of observations. For example, in one dataset, there might be 1 observation per subject. In another, the same subjects could have two records each, the first recording the first half of the time at risk and the second recording the remaining part. All statistics calculated by Stata on either dataset would be the same, but \( M \) would be different.

Deciding on the right definition, however, is difficult. Viewed one way, \( N \) in the Cox regression case should be the number of risk pools, \( R \), because the Cox regression calculation is made on the basis of the independent risk pools. Viewed another way, \( N \) should be the number of subjects, \( N_{\text{subj}} \), because, even though the likelihood function is based on risk pools, the parameters estimated are at the subject level.

You can decide which argument you prefer.

For parametric survival models, in single-record data, \( N = M \) is unambiguously correct. For multirecord data, there is an argument for \( N = M \) and for \( N = N_{\text{subj}} \).
The problem of conformable likelihoods

The problem of conformable likelihoods does not concern \( N \). Researchers sometimes use information criteria such as BIC and AIC to make comparisons across models. For that to be valid, the likelihoods must be conformable; that is, the likelihoods must all measure the same thing.

It is common to think of the likelihood function as the \( \Pr(\text{data} | \text{parameters}) \), but in fact, the likelihood is

\[
\Pr(\text{particular events in the data} | \text{parameters})
\]

You must ensure that the events are the same.

For instance, they are not the same in the semiparametric Cox regression and the various parametric survival models. In Cox regression, the events are, at each failure time, that the subjects observed to fail in fact failed, given that failures occurred at those times. In the parametric models, the events are that each subject failed exactly when the subject was observed to fail.

The formula for AIC and BIC is

\[
\text{measure} = -2 \times \ln(\text{likelihood}) + \text{complexity}
\]

When you are comparing models, if the likelihoods are measuring different events, even if the models obtain estimates of the same parameters, differences in the information measures are irrelevant.

The first problem does not arise with AIC; the second problem does

Regardless of model, the problem of defining \( N \) never arises with AIC because \( N \) is not used in the AIC calculation. AIC uses a constant 2 to weight complexity as measured by \( k \), rather than \( \ln(N) \).

For both AIC and BIC, however, the likelihood functions must be conformable; that is, they must be measuring the same event.

Calculating BIC correctly

When using BIC to compare results, and especially when using BIC to compare results from different models, you should think carefully about how \( N \) should be defined. Then specify that number by using the \( n() \) option:

```
. estimates stats full sub, n(74)
```

Akaike’s information criterion and Bayesian information criterion

<table>
<thead>
<tr>
<th>Model</th>
<th>Obs</th>
<th>ll(null)</th>
<th>ll(model)</th>
<th>df</th>
<th>AIC</th>
<th>BIC</th>
</tr>
</thead>
<tbody>
<tr>
<td>full</td>
<td>74</td>
<td>-45.03321</td>
<td>-20.59083</td>
<td>4</td>
<td>49.18167</td>
<td>58.39793</td>
</tr>
<tr>
<td>sub</td>
<td>74</td>
<td>-45.03321</td>
<td>-27.17516</td>
<td>3</td>
<td>60.35031</td>
<td>67.26251</td>
</tr>
</tbody>
</table>

Note: \( N=74 \) used in calculating BIC.

Both estimates stats and estat ic allow the \( n() \) option; see \([R]\) estimates stats and \([R]\) estat ic.
Methods and formulas

AIC and BIC are defined as

\[
\text{AIC} = -2 \times \ln(\text{likelihood}) + 2 \times k
\]

\[
\text{BIC} = -2 \times \ln(\text{likelihood}) + \ln(N) \times k
\]

where \( k \) is the model degrees of freedom calculated as the rank of variance–covariance matrix of the parameters \( e(V) \) and \( N \) is the number of observations used in estimation or, more precisely, the number of independent terms in the likelihood. Operationally, \( N \) is defined as \( e(N) \) unless the \( n() \) option is specified.

Description

`binreg` fits generalized linear models for the binomial family. It estimates odds ratios, risk ratios, health ratios, and risk differences. The available links are

<table>
<thead>
<tr>
<th>Option</th>
<th>Implied link</th>
<th>Parameter</th>
</tr>
</thead>
<tbody>
<tr>
<td>or</td>
<td>logit</td>
<td>odds ratios = exp(β)</td>
</tr>
<tr>
<td>rr</td>
<td>log</td>
<td>risk ratios = exp(β)</td>
</tr>
<tr>
<td>hr</td>
<td>log complement</td>
<td>health ratios = exp(β)</td>
</tr>
<tr>
<td>rd</td>
<td>identity</td>
<td>risk differences = β</td>
</tr>
</tbody>
</table>

Estimates of odds, risk, and health ratios are obtained by exponentiating the appropriate coefficients. The `or` option produces the same results as Stata’s `logistic` command, and `or` coefficients yields the same results as the `logit` command. When no link is specified, `or` is assumed.

Quick start

Report odds ratios from a model of `y` on `x1` and `x2` using a logit link

```
binreg y x1 x2, or
```

Use the log link and report risk ratios

```
binreg y x1 x2, rr
```

Use the identity link and report risk differences

```
binreg y x1 x2, rd
```

As above, but with data stored as the number of successes, `ys`, out of `n` trials

```
binreg ys x1 x2, rd n(n)
```

Options

<table>
<thead>
<tr>
<th>Model</th>
</tr>
</thead>
<tbody>
<tr>
<td>noconstant; see [R] Estimation options.</td>
</tr>
<tr>
<td>or requests the logit link and results in odds ratios if coefficients is not specified.</td>
</tr>
<tr>
<td>rr requests the log link and results in risk ratios if coefficients is not specified.</td>
</tr>
<tr>
<td>hr requests the log-complement link and results in health ratios if coefficients is not specified.</td>
</tr>
<tr>
<td>rd requests the identity link and results in risk differences.</td>
</tr>
<tr>
<td>n(#)varname) specifies either a constant integer to use as the denominator for the binomial family or a variable that holds the denominator for each observation.</td>
</tr>
<tr>
<td>exposure(varname), offset(varname), constraints(constants); see [R] Estimation options.</td>
</tr>
<tr>
<td>constraints(constants) is not allowed with irls.</td>
</tr>
<tr>
<td>mu(varname) specifies varname containing an initial estimate for the mean of depvar. This option can be useful if you encounter convergence difficulties. init(varname) is a synonym.</td>
</tr>
<tr>
<td>SE/Robust</td>
</tr>
<tr>
<td>[R] vce_option.</td>
</tr>
<tr>
<td>[R] vce(eim), the default, uses the expected information matrix (EIM) for the variance estimator.</td>
</tr>
<tr>
<td>binreg also allows the following:</td>
</tr>
<tr>
<td>[R] vce(hac kernel [#]) specifies that a heteroskedasticity- and autocorrelation-consistent (HAC) variance estimate be used. HAC refers to the general form for combining weighted matrices to form the variance estimate. There are three kernels built into binreg. kernel is a user-written program or one of</td>
</tr>
<tr>
<td>nwest</td>
</tr>
<tr>
<td>If # is not specified, N − 2 is assumed.</td>
</tr>
<tr>
<td>[R] vce(jackknife1) specifies that the one-step jackknife estimate of variance be used.</td>
</tr>
<tr>
<td>[R] vce(unbiased) specifies that the unbiased sandwich estimate of variance be used.</td>
</tr>
</tbody>
</table>
t(varname) specifies the variable name corresponding to time; see [TS] tsset. binreg does not always need to know t(), though it does if vce(hac ...) is specified. Then you can either specify the time variable with t(), or you can tsset your data before calling binreg. When the time variable is required, binreg assumes that the observations are spaced equally over time.

vfactor(#) specifies a scalar by which to multiply the resulting variance matrix. This option allows users to match output with other packages, which may apply degrees of freedom or other small-sample corrections to estimates of variance.

disp(#) multiplies the variance of depvar by # and divides the deviance by #. The resulting distributions are members of the quasilikelihood family. This option is not allowed with option ml.

scale(x2 | dev | #) overrides the default scale parameter. This option is allowed only with Hessian (information matrix) variance estimates.

By default, scale(1) is assumed for the discrete distributions (binomial, Poisson, and negative binomial), and scale(x2) is assumed for the continuous distributions (Gaussian, gamma, and inverse Gaussian).

scale(x2) specifies that the scale parameter be set to the Pearson chi-squared (or generalized chi-squared) statistic divided by the residual degrees of freedom, which is recommended by McCullagh and Nelder (1989) as a good general choice for continuous distributions.

scale(dev) sets the scale parameter to the deviance divided by the residual degrees of freedom. This option provides an alternative to scale(x2) for continuous distributions and overdispersed or underdispersed discrete distributions. This option is not allowed with option ml.

scale(#) sets the scale parameter to #.

level(#), noconstant; see [R] Estimation options.

coefficients displays the nonexponentiated coefficients and corresponding standard errors and confidence intervals. This option has no effect when the rd option is specified, because it always presents the nonexponentiated coefficients.

nocnsreport; see [R] Estimation options.

display_options: noci, nopvalues, noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(#), fvwrapon(style), cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch; see [R] Estimation options.

Maximization

irls requests iterated, reweighted least-squares (IRLS) optimization of the deviance instead of Newton–Raphson optimization of the log likelihood. This option is the default.

ml requests that optimization be carried out by using Stata’s ml command; see [R] ml.

maximize_options: difficult, technique(algorithm_spec), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(init_specs); see [R] Maximize. These options are seldom used.

Setting the optimization method to ml, with technique() set to something other than BHHH, changes the vcetype to vce(om). Specifying technique(bhhh) changes vcetype to vce(opg).

Unless option ml is specified, only maximize_options iterate(), nolog, trace, and ltolerance() are allowed. With IRLS optimization, the convergence criterion is satisfied when the
absolute change in deviance from one iteration to the next is less than or equal to 1 tolerance(), where 1 tolerance(1e-6) is the default.

fisher(#) specifies the number of Newton–Raphson steps that should use the Fisher scoring Hessian or EIM before switching to the observed information matrix (OIM). This option is available only if ml is specified and is useful only for Newton–Raphson optimization.

search specifies that the command search for good starting values. This option is available only if ml is specified and is useful only for Newton–Raphson optimization.

The following options are available with binreg but are not shown in the dialog box: collinear, coeflegend; see [R] Estimation options. collinear is not allowed with irls.

Remarks and examples

Wacholder (1986) suggests methods for estimating risk ratios and risk differences from prospective binomial data. These estimates are obtained by selecting the proper link functions in the generalized linear-model framework. (See Methods and formulas for details; also see [R] glm.)

Example 1

Wacholder (1986) presents an example, using data from Wright et al. (1983), of an investigation of the relationship between alcohol consumption and the risk of a low-birthweight baby. Covariates examined included whether the mother smoked (yes or no), mother’s social class (three levels), and drinking frequency (light, moderate, or heavy). The data for the 18 possible categories determined by the covariates are illustrated below.

Let’s first describe the data and list a few observations.

. use https://www.stata-press.com/data/r16/binreg
. list

Each observation corresponds to one of the 18 covariate structures. The number of low-birthweight babies from n_women in each category is given by the n_lbw_babies variable.
We begin by estimating risk ratios:

```
. binreg n_lbw_babies i.soc i.alc i.smo, n(n_women) rr
Iteration 1:  deviance =  14.2879
Iteration 2:  deviance =  13.607
Iteration 3:  deviance =  13.60503
Iteration 4:  deviance =  13.60503
```

Generalized linear models

- Number of obs = 18
- Optimization : MQL Fisher scoring (IRLS EIM)
- Scale parameter = 1
- Deviance = 13.6050268 (1/df) Deviance = 1.133752
- Pearson = 11.51517095 (1/df) Pearson = .9595976
- Variance function: V(u) = u*(1-u/n_women) [Binomial]
- Link function : g(u) = ln(u/n_women) [Log]

BIC = -21.07943

</table>
```

Note: _cons estimates baseline risk.

By default, Stata reports the risk ratios (the exponentiated regression coefficients) estimated by the model. We can see that the risk ratio comparing heavy drinkers with light drinkers, after adjusting for smoking and social class, is 1.974078. That is, mothers who drink heavily during their pregnancy have approximately twice the risk of delivering low-birthweight babies as mothers who are light drinkers.
The nonexponentiated coefficients can be obtained with the `coefficients` option:

```
. binreg n_lbw_babies i.soc i.alc i.smo, n(n_women) rr coefficients
```

**Iteration 1:**
- Deviance = 14.2879

**Iteration 2:**
- Deviance = 13.607

**Iteration 3:**
- Deviance = 13.60503

**Iteration 4:**
- Deviance = 13.60503

Generalized linear models

Note: _cons estimates baseline health (probability of no disease).

To see the nonexponentiated coefficients, we can specify the coefficients option.
binreg, irls stores the following in e():

 Scalars

- `e(N)` number of observations
- `e(k)` number of parameters
- `e(k_eq_model)` number of equations in overall model test
- `e(df_m)` model degrees of freedom
- `e(df)` residual degrees of freedom
- `e(phi)` model scale parameter
- `e(disp)` dispersion parameter
- `e(bic)` model BIC
- `e(N_clust)` number of clusters
- `e(deviance)` deviance
- `e(deviance_s)` scaled deviance
- `e(deviance_p)` Pearson deviance
- `e(deviance_ps)` scaled Pearson deviance
- `e(dispers)` dispersion
- `e(dispers_s)` scaled dispersion
- `e(dispers_p)` Pearson dispersion
- `e(dispers_ps)` scaled Pearson dispersion
- `e(vf)` factor set by `vfactor()`, 1 if not set
- `e(rank)` rank of `e(V)`
- `e(rc)` return code

 Macros

- `e(cmd)` `binreg`
- `e(cmdline)` command as typed
- `e(depvar)` name of dependent variable
- `e(eform)` `eform()` option implied by `or`, `rr`, `hr`, or `rd`
- `e(varfunc)` program to calculate variance function
- `e(varfunct)` variance title
- `e(varfuncf)` variance function
- `e(link)` program to calculate link function
- `e(linkt)` link title
- `e(linkf)` link function
- `e(m)` number of binomial trials
- `e(wtype)` weight type
- `e(wexp)` weight expression
- `e(title)` title in estimation output
- `e(title_f1)` family–link title
- `e(clustvar)` name of cluster variable
- `e(offset)` linear offset variable
- `e(cons)` noconstant or not set
- `e(hac_kernel)` HAC kernel
- `e(hac_lag)` HAC lag
- `e(vce)` `vcetype` specified in `vce()`
- `e(vcetype)` title used to label Std. Err.
- `e(opt)` type of optimization
- `e(opt1)` optimization title, line 1
- `e(opt2)` optimization title, line 2
- `e(properties)` \( b \ V \)
- `e(predict)` program used to implement `predict`
- `e(marginsok)` predictions allowed by `margins`
- `e(marginsnotok)` predictions disallowed by `margins`
- `e(asbalanced)` factor variables `fvset` as `asbalanced`
- `e(asobserved)` factor variables `fvset` as `asobserved`
Matrices
- `e(b)` coefficient vector
- `e(V)` variance–covariance matrix of the estimators
- `e(V_modelbased)` model-based variance

Functions
- `e(sample)` marks estimation sample

**binreg, ml** stores the following in `e()`:

**Scalars**
- `e(N)` number of observations
- `e(k)` number of parameters
- `e(k_eq)` number of equations in `e(b)`
- `e(k_eq_model)` number of equations in overall model test
- `e(k_dv)` number of dependent variables
- `e(df_m)` model degrees of freedom
- `e(df)` residual degrees of freedom
- `e(phi)` model scale parameter
- `e(aic)` model AIC, if `ml`
- `e(bic)` model BIC
- `e(ll)` log likelihood, if `ml`
- `e(N_clust)` number of clusters
- `e(chi2)` $\chi^2$
- `e(p)` $p$-value for model test
- `e(deviance)` deviance
- `e(deviance_s)` scaled deviance
- `e(deviance_p)` Pearson deviance
- `e(deviance_ps)` scaled Pearson deviance
- `e(dispers)` dispersion
- `e(dispers_s)` scaled dispersion
- `e(dispers_p)` Pearson dispersion
- `e(dispers_ps)` scaled Pearson dispersion
- `e(vf)` factor set by `vfactor()`, 1 if not set
- `e(rank)` rank of `e(V)`
- `e(ic)` number of iterations
- `e(rc)` return code
- `e(converged)` 1 if converged, 0 otherwise

**Macros**
- `e(cmd)` `binreg`
- `e(cmdline)` command as typed
- `e(depvar)` name of dependent variable
- `e(eform)` `eform()` option implied by `or`, `rr`, `hr`, or `rd`
- `e(varfunc)` program to calculate variance function
- `e(varfuncf)` variance function
- `e(link)` program to calculate link function
- `e(linkt)` link title
- `e(linkf)` link function
- `e(m)` number of binomial trials
- `e(wtype)` weight type
- `e(wexp)` weight expression
- `e(title)` title in estimation output
- `e(title_f1)` family–link title
- `e(clustvar)` name of cluster variable
- `e(offset)` linear offset variable
- `e(cons)` noconstant or not set
- `e(hac_kernel)` HAC kernel
- `e(hac_lag)` HAC lag
- `e(chi2type)` Wald; type of model $\chi^2$ test
- `e(vce)` vcetype specified in `vce()`
- `e(vcetype)` title used to label Std. Err.
Methods and formulas

Let $\pi_i$ be the probability of success for the $i$th observation, $i = 1, \ldots, N$, and let $X\beta$ be the linear predictor. The link function relates the covariates of each observation to its respective probability through the linear predictor.

In logistic regression, the logit link is used:
\[
\ln\left(\frac{\pi}{1 - \pi}\right) = X\beta
\]

The regression coefficient $\beta_k$ represents the change in the logarithm of the odds associated with a one-unit change in the value of the $X_k$ covariate; thus $\exp(\beta_k)$ is the ratio of the odds associated with a change of one unit in $X_k$.

For risk differences, the identity link $\pi = X\beta$ is used. The regression coefficient $\beta_k$ represents the risk difference associated with a change of one unit in $X_k$. When using the identity link, you can obtain fitted probabilities outside the interval $(0, 1)$. As suggested by Wacholder, at each iteration, fitted probabilities are checked for range conditions (and put back in range if necessary). For example, if the identity link results in a fitted probability that is smaller than 1e–4, the probability is replaced with 1e–4 before the link function is calculated.

A similar adjustment is made for the logarithmic link, which is used for estimating the risk ratio, $\ln(\pi) = X\beta$, where $\exp(\beta_k)$ is the risk ratio associated with a change of one unit in $X_k$, and for the log-complement link used to estimate the probability of no disease or health, where $\exp(\beta_k)$ represents the “health ratio” associated with a change of one unit in $X_k$.

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using vce(robust) and vce(cluster clustvar), respectively. See [P] _robust, particularly Maximum likelihood estimators and Methods and formulas.

</tr>
</tbody>
</table>

`*` `estat ic` and `lrtest` are not appropriate after `binreg, irls`.

`†` `forecast` is not appropriate with `mi` estimation results.
predict

Description for predict

predict creates a new variable containing predictions such as expected values, linear predictions, standard errors, residuals, Cook’s distance, diagonals, weighted averages, differences, and first derivatives.

</tbody>
</table>

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.
Options for predict

- **mu**, the default, specifies that predict calculate the expected value of $y$, equal to $g^{-1}(\hat{x}\beta) [ng^{-1}(\hat{x}\beta)]$ for the binomial family.
- **xb** calculates the linear prediction $\eta = x\hat{\beta}$.
- **eta** is a synonym for xb.
- **stdp** calculates the standard error of the linear prediction.
- **anscombe** calculates the Anscombe (1953) residuals to produce residuals that closely follow a normal distribution.
- **cooksd** calculates Cook’s distance, which measures the aggregate change in the estimated coefficients when each observation is left out of the estimation.
- **deviance** calculates the deviance residuals, which are recommended by McCullagh and Nelder (1989) and others as having the best properties for examining goodness of fit of a GLM. They are approximately normally distributed if the model is correct and may be plotted against the fitted values or against a covariate to inspect the model’s fit. Also see the **pearson** option below.
- **hat** calculates the diagonals of the “hat” matrix, analogous to linear regression.
- **likelihood** calculates a weighted average of the standardized deviance and standardized Pearson (described below) residuals.
- **pearson** calculates the Pearson residuals, which often have markedly skewed distributions for nonnormal family distributions. Also see the **deviance** option above.
- **response** calculates the differences between the observed and fitted outcomes.
- **score** calculates the equation-level score, $\partial \ln L / \partial (x_j\beta)$.
- **working** calculates the working residuals, which are response residuals weighted according to the derivative of the link function.

Options

- **nooffset** is relevant only if you specified offset(varname) for **binreg**. It modifies the calculations made by predict so that they ignore the offset variable; the linear prediction is treated as $x_j\beta$ rather than as $x_j\beta + \text{offset}_j$.
- **adjusted** adjusts the deviance residual to make the convergence to the limiting normal distribution faster. The adjustment deals with adding to the deviance residual a higher-order term depending on the variance function family. This option is allowed only when **deviance** is specified.
- **standardized** requests that the residual be multiplied by the factor $(1 - h)^{-1/2}$, where $h$ is the diagonal of the hat matrix. This step is done to take into account the correlation between depvar and its predicted value.
- **studentized** requests that the residual be multiplied by one over the square root of the estimated scale parameter.
- **modified** requests that the denominator of the residual be modified to be a reasonable estimate of the variance of depvar. The base residual is multiplied by the factor $(k/w)^{-1/2}$, where $k$ is either one or the user-specified dispersion parameter and $w$ is the specified weight (or one if left unspecified).
margins

Description for margins

margins estimates margins of response for expected values and linear predictions.

Menu for margins

Statistics > Postestimation

Syntax for margins

margins [marginlist] [, options]
margins [marginlist], predict(statistic ...) [predict(statistic ...) ...] [options]

<table>

[U] 20 Estimation and postestimation commands
Description

biprobit fits maximum-likelihood two-equation probit models—either a bivariate probit or a seemingly unrelated probit (limited to two equations).

Quick start

Bivariate probit regression of \(y_1\) and \(y_2\) on \(x_1\)
\[\text{biprobit } y_1 \ y_2 \ x_1\]

Bivariate probit regression of \(y_1\) and \(y_2\) on \(x_1\), \(x_2\), and \(x_3\)
\[\text{biprobit } y_1 \ y_2 \ x_1 \ x_2 \ x_3\]

Constrain the coefficients for \(x_1\) to equality in both equations
\[\text{constraint define 1 } \_b[y_1:x1] = \_b[y2:x1]\]
\[\text{biprobit } y_1 \ y_2 \ x_1 \ x_2 \ x_3, \text{ constraints(1)}\]

Seemingly unrelated bivariate probit regression
\[\text{biprobit } (y_1 = x_1 \ x_2 \ x_3) (y_2 = x_1 \ x_2)\]

With robust standard errors
\[\text{biprobit } (y_1 = x_1 \ x_2 \ x_3) (y_2 = x_1 \ x_2), \text{ vce(robust)}\]

Poirier partial observability model with difficult option
\[\text{biprobit } (y_1 = x_1 \ x_2) (y_2 = x_2 \ x_3), \text{ partial difficult}\]

su_options | Description
---|---
**Model**
partia**l** specs the partial observability model. This particular model commonly has poor convergence properties, so we recommend that you use the difficult option if you want to fit the Poirier partial observability model; see [R] Maximize.

This model computes the product of the two dependent variables so that you do not have to replace each with the product.

**SE/Robust**
vcetype may be oim, robust, cluster clustvar, opg, bootstrap, or jackknife

**Reporting**
set confidence level; default is level(95)
do not display constraints
control columns and column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling

**Maximization**
control the maximization process; seldom used
keep collinear variables
display legend instead of statistics

indepvars may contain factor variables; see [U] 11.4.3 Factor variables.
depvar1, depvar2, indepvars, and depvar may contain time-series operators; see [U] 11.4.4 Time-series varlists.
bayes, bootstrap, by, fp, jackknife, rolling, statsby, and svy are allowed; see [U] 11.1.10 Prefix commands.
Weights are not allowed with the bootstrap prefix; see [R] bootstrap.
vce(), lrmodel, and weights are not allowed with the svy prefix; see [SVY] svy.
pweights, fweights, and iweights are allowed; see [U] 11.1.6 weight.
collinear and coeflegend do not appear in the dialog box.
See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

**Options**
---|---
**Model**
noconstant; see [R] Estimation options.
partial specifies that the partial observability model be fit. This particular model commonly has poor convergence properties, so we recommend that you use the difficult option if you want to fit the Poirier partial observability model; see [R] Maximize.

This model computes the product of the two dependent variables so that you do not have to replace each with the product.

offset1(varname), offset2(varname), constraints(constraints); see [R] Estimation options.
vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim, opg), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.

Reporting

level(#), lrmodel, nocnsreport; see [R] Estimation options.
display_options: noci, nopvalues, noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabels, fvwrap(#), fvwrapon(style), cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch; see [R] Estimation options.

Maximization

maximize_options: difficult, technique(algorithm_spec), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), 1rtolerance(#), nonrtolerance(#), nonrtolerance, and from(init_specs); see [R] Maximize. These options are seldom used.

Setting the optimization type to technique(bhhh) resets the default vcetype to vce(opg).

The following options are available with biprobit but are not shown in the dialog box: collinear, coeflegend; see [R] Estimation options.

Remarks and examples

Example 1

We use the data from Pindyck and Rubinfeld (1998, 332). In this dataset, the variables are whether children attend private school (private), number of years the family has been at the present residence (years), log of property tax (logptax), log of income (loginc), and whether the head of the household voted for an increase in property taxes (vote).

We wish to model the bivariate outcomes of whether children attend private school and whether the head of the household voted for an increase in property tax based on the other covariates.
The output shows several iteration logs. The first iteration log corresponds to running the univariate probit model for the first equation, and the second log corresponds to running the univariate probit for the second model. If $\rho = 0$, the sum of the log likelihoods from these two models will equal the log likelihood of the bivariate probit model; this sum is printed in the iteration log as the comparison log likelihood.

The final iteration log is for fitting the full bivariate probit model. A likelihood-ratio test of the log likelihood for this model and the comparison log likelihood is presented at the end of the output. If we had specified the `vce(robust)` option, this test would be presented as a Wald test instead of as a likelihood-ratio test.

We could have fit the same model by using the seemingly unrelated syntax as

```
. biprobit (private=years logptax loginc) (vote=years logptax loginc)
```
biprobit — Bivariate probit regression

Stored results

biprobit stores the following in e():

Scalars
- e(N) number of observations
- e(k) number of parameters
- e(k_eq) number of equations in e(b)
- e(k_aux) number of auxiliary parameters
- e(k_eq_model) number of equations in overall model test
- e(k_dv) number of dependent variables
- e(ll) log likelihood
- e(ll_0) log likelihood, constant-only model (lrmodel only)
- e(ll_c) log likelihood, comparison model
- e(N_clust) number of clusters
- e(chi2) \( \chi^2 \)
- e(chi2_c) \( \chi^2 \) for comparison test
- e(p) p-value for model test
- e(rho) \( \rho \)
- e(rank) rank of e(V)
- e(rank0) rank of e(V) for constant-only model
- e(ic) number of iterations
- e(rc) return code
- e(converged) 1 if converged, 0 otherwise

Macros
- e(cmd) biprobit
- e(cmdline) command as typed
- e(depvar) names of dependent variables
- e(wtype) weight type
- e(wexp) weight expression
- e(title) title in estimation output
- e(clustvar) name of cluster variable
- e(offset1) offset for first equation
- e(offset2) offset for second equation
- e(chi2type) Wald or LR; type of model \( \chi^2 \) test
- e(chi2_ct) Wald or LR; type of model \( \chi^2 \) test corresponding to e(chi2_c)
- e(vce) vcetype specified in vce()
- e(vcetype) title used to label Std. Err.
- e(opt) type of optimization
- e(which) max or min; whether optimizer is to perform maximization or minimization
- e(ml_method) type of ml method
- e(user) name of likelihood-evaluator program
- e(technique) maximization technique
- e(properties) b V
- d(predict) program used to implement predict
- e(marginsok) predictions allowed by margins
- e(marginsnotok) predictions disallowed by margins
- e(asbalanced) factor variables fvset as asbalanced
- e(asobserved) factor variables fvset as asobserved

Matrices
- e(b) coefficient vector
- e(Cns) constraints matrix
- e(lllog) iteration log (up to 20 iterations)
- e(gradient) gradient vector
- e(V) variance–covariance matrix of the estimators
- e(V_modelbased) model-based variance

Functions
- e(sample) marks estimation sample
Methods and formulas

The log likelihood, \( \ln L \), is given by

\[
\begin{align*}
\xi_j^\beta &= x_j \beta + \text{offset}_j^\beta \\
\xi_j^\gamma &= z_j \gamma + \text{offset}_j^\gamma \\
q_{1j} &= \begin{cases} 
1 & \text{if } y_{1j} \neq 0 \\
-1 & \text{otherwise}
\end{cases} \\
q_{2j} &= \begin{cases} 
1 & \text{if } y_{2j} \neq 0 \\
-1 & \text{otherwise}
\end{cases} \\
\rho_j^* &= q_{1j} q_{2j} \rho \\
\ln L &= \sum_{j=1}^{n} w_j \ln \Phi_2 \left( q_{1j} \xi_j^\beta, q_{2j} \xi_j^\gamma, \rho_j^* \right)
\end{align*}
\]

where \( \Phi_2() \) is the cumulative bivariate normal distribution function (with mean \([0 \ 0]\)') and \( w_j \) is an optional weight for observation \( j \). This derivation assumes that

\[
\begin{align*}
y_{1j}^* &= x_j \beta + \epsilon_{1j} + \text{offset}_j^\beta \\
y_{2j}^* &= z_j \gamma + \epsilon_{2j} + \text{offset}_j^\gamma \\
E(\epsilon_1) &= E(\epsilon_2) = 0 \\
\text{Var}(\epsilon_1) &= \text{Var}(\epsilon_2) = 1 \\
\text{Cov}(\epsilon_1, \epsilon_2) &= \rho
\end{align*}
\]

where \( y_{1j}^* \) and \( y_{2j}^* \) are the unobserved latent variables; instead, we observe only \( y_{ij} = 1 \text{ if } y_{ij}^* > 0 \) and \( y_{ij} = 0 \) otherwise (for \( i = 1, 2 \)).

In the maximum likelihood estimation, \( \rho \) is not directly estimated, but \( \text{atanh} \rho \) is

\[
\text{atanh} \rho = \frac{1}{2} \ln \left( \frac{1 + \rho}{1 - \rho} \right)
\]

From the form of the likelihood, if \( \rho = 0 \), then the log likelihood for the bivariate probit models is equal to the sum of the log likelihoods of the two univariate probit models. A likelihood-ratio test may therefore be performed by comparing the likelihood of the full bivariate model with the sum of the log likelihoods for the univariate probit models.

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using \texttt{vce(robust)} and \texttt{vce(cluster clustvar)}, respectively. See \[P\] \_\texttt{robust}, particularly \texttt{Maximum likelihood estimators} and \texttt{Methods and formulas}.

\texttt{biprobit} also supports estimation with survey data. For details on VCEs with survey data, see \[SVY\] \texttt{Variance estimation}.

</tbody>
</table>

where $\Phi(\cdot)$ is the standard normal-distribution function and $\Phi_2(\cdot)$ is the bivariate standard normal-distribution function.

These statistics are available both in and out of sample; type predict ... if e(sample) ... if wanted only for the estimation sample.

Options for predict

- **p11**, the default, calculates the bivariate predicted probability $Pr(y_{1j} = 1, y_{2j} = 1)$.
- **p10** calculates the bivariate predicted probability $Pr(y_{1j} = 1, y_{2j} = 0)$.
- **p01** calculates the bivariate predicted probability $Pr(y_{1j} = 0, y_{2j} = 1)$.
p00 calculates the bivariate predicted probability \( \Pr(y_{1j} = 0, y_{2j} = 0) \).

pmarg1 calculates the univariate (marginal) predicted probability of success \( \Pr(y_{1j} = 1) \).

pmarg2 calculates the univariate (marginal) predicted probability of success \( \Pr(y_{2j} = 1) \).

pcond1 calculates the conditional (on success in equation 2) predicted probability of success \( \Pr(y_{1j} = 1, y_{2j} = 1)/\Pr(y_{2j} = 1) \).

pcond2 calculates the conditional (on success in equation 1) predicted probability of success \( \Pr(y_{1j} = 1, y_{2j} = 1)/\Pr(y_{1j} = 1) \).

xb1 calculates the probit linear prediction \( x_j \beta \).

xb2 calculates the probit linear prediction \( z_j \gamma \).

stdp1 calculates the standard error of the linear prediction for equation 1.

stdp2 calculates the standard error of the linear prediction for equation 2.

nooffset is relevant only if you specified \texttt{offset1(varname)} or \texttt{offset2(varname)} for \texttt{biprobit}.

It modifies the calculations made by \texttt{predict} so that they ignore the offset variables; the linear predictions are treated as \( x_j \beta \) rather than as \( x_j \beta + \text{offset}_{1j} \) and \( z_j \gamma \) rather than as \( z_j \gamma + \text{offset}_{2j} \).

scores calculates equation-level score variables.

The first new variable will contain \( \partial \ln L/\partial (x_j \beta) \).

The second new variable will contain \( \partial \ln L/\partial (z_j \gamma) \).

The third new variable will contain \( \partial \ln L/\partial (\text{atanh} \rho) \).
margins

Description for margins

margins estimates margins of response for probabilities and linear predictions.

</table>

Statistics not allowed with margins are functions of stochastic quantities other than $e(b)$.

For the full syntax, see [R] margins.

Also see

[R] biprobit — Bivariate probit regression
[U] 20 Estimation and postestimation commands
bitest — Binomial probability test

Description

bitest performs exact hypothesis tests for binomial random variables. The null hypothesis is that the probability of a success on a trial is \( p \). The total number of trials is the number of nonmissing values of `varname` (in `bitest`) or \( N \) (in `bitesti`). The number of observed successes is the number of 1s in `varname` (in `bitest`) or \( \text{#succ} \) (in `bitesti`). `varname` must contain only 0s, 1s, and missing.

`bitesti` is the immediate form of `bitest`; see [U] 19 Immediate commands for a general introduction to immediate commands.

Quick start

Exact test for probability of success \((a = 1)\) is 0.4

```
bitest a = .4
```

With additional exact probabilities

```
bitest a = .4, detail
```

Exact test that the probability of success is 0.46, given 22 successes in 74 trials

```
bitesti 74 22 .46
```

Menu

**bitest**

Statistics  >  Summaries, tables, and tests  >  Classical tests of hypotheses  >  Binomial probability test

**bitesti**

Statistics  >  Summaries, tables, and tests  >  Classical tests of hypotheses  >  Binomial probability test calculator
Syntax

Binomial probability test

\texttt{bitest \ varname\==\#_p\ [if\] [in\] [weight\] [\ , detail\]}

Immediate form of binomial probability test

\texttt{bitesti \#_N \#_{succ} \#_p\ [\ , detail\]}

by is allowed with bitest; see [D] by.
fweights are allowed with bitest; see [U] 11.1.6 weight.

Option

\texttt{(Advanced\)}

detail shows the probability of the observed number of successes, \(k_{obs}\); the probability of the number of successes on the opposite tail of the distribution that is used to compute the two-sided \(p\)-value, \(k_{opp}\); and the probability of the point next to \(k_{opp}\). This information can be safely ignored. See the technical note below for details.

Remarks and examples

Remarks are presented under the following headings:

\texttt{bitest}

\texttt{bitesti}

\texttt{bitest}

\texttt{Example 1}

We test 15 university students for high levels of one measure of visual quickness which, from other evidence, we believe is present in 30\% of the nonuniversity population. Included in our data is quick, taking on the values 1 (“success”) or 0 (“failure”) depending on the outcome of the test.

\begin{verbatim}
. use https://www.stata-press.com/data/r16/quick
. bitest quick == 0.3
\end{verbatim}

<table>
<thead>
<tr>
<th>Variable</th>
<th>N</th>
<th>Observed k</th>
<th>Expected k</th>
<th>Assumed p</th>
<th>Observed p</th>
</tr>
</thead>
<tbody>
<tr>
<td>quick</td>
<td>15</td>
<td>7</td>
<td>4.5</td>
<td>0.30000</td>
<td>0.46667</td>
</tr>
</tbody>
</table>

\begin{align*}
\Pr(k \geq 7) &= 0.131143 \text{ (one-sided test)} \\
\Pr(k \leq 7) &= 0.949987 \text{ (one-sided test)} \\
\Pr(k \leq 1 \text{ or } k \geq 7) &= 0.166410 \text{ (two-sided test)}
\end{align*}

The first part of the output reveals that, assuming a true probability of success of 0.3, the expected number of successes is 4.5 and that we observed seven. Said differently, the assumed frequency under the null hypothesis \(H_0\) is 0.3, and the observed frequency is 0.47.
The first line under the table is a one-sided test; it is the probability of observing seven or more successes conditional on \( p = 0.3 \). It is a test of \( H_0 : p = 0.3 \) versus the alternative hypothesis \( H_A : p > 0.3 \). Said in English, the alternative hypothesis is that more than 30\% of university students score at high levels on this test of visual quickness. The \( p \)-value for this hypothesis test is 0.13.

The second line under the table is a one-sided test of \( H_0 \) versus the opposite alternative hypothesis \( H_A : p < 0.3 \).

The third line is the two-sided test. It is a test of \( H_0 \) versus the alternative hypothesis \( H_A : p \neq 0.3 \).

\[ \text{Technical note} \]

The \( p \)-value of a hypothesis test is the probability (calculated assuming \( H_0 \) is true) of observing any outcome as extreme or more extreme than the observed outcome, with extreme meaning in the direction of the alternative hypothesis. In example 1, the outcomes \( k = 8, 9, \ldots, 15 \) are clearly “more extreme” than the observed outcome \( k_{\text{obs}} = 7 \) when considering the alternative hypothesis \( H_A : p \neq 0.3 \). However, outcomes with only a few successes are also in the direction of this alternative hypothesis. For two-sided hypotheses, outcomes with \( k \) successes are considered “as extreme or more extreme” than the observed outcome \( k_{\text{obs}} \) if \( \Pr(k) \leq \Pr(k_{\text{obs}}) \). Here \( \Pr(k = 0) \) and \( \Pr(k = 1) \) are both less than \( \Pr(k = 7) \), so they are included in the two-sided \( p \)-value.

The \texttt{detail} option allows you to see the probability (assuming that \( H_0 \) is true) of the observed successes \( (k = 7) \) and the probability of the boundary point \( (k = 1) \) of the opposite tail used for the two-sided \( p \)-value.

\[ \text{. bitest quick == 0.3, detail} \]

\begin{table}[h]
\centering
\begin{tabular}{l|ccc}

quick & 15 & 7 & 4.5 & 0.30000 & 0.46667 \\
Pr(k >= 7) & & = 0.131143 (one-sided test) & & & \\
Pr(k <= 7) & & = 0.949987 (one-sided test) & & & \\
Pr(k <= 1 or k >= 7) & & = 0.166410 (two-sided test) & & & \\
Pr(k == 7) & & = 0.081130 (observed) & & & \\
Pr(k == 2) & & = 0.091560 & & & \\
Pr(k == 1) & & = 0.030520 (opposite extreme) & & & \\
\hline
\end{tabular}
\end{table}

Also shown is the probability of the point next to the boundary point. This probability, namely, \( \Pr(k = 2) = 0.092 \), is certainly close to the probability of the observed outcome \( \Pr(k = 7) = 0.081 \), so some people might argue that \( k = 2 \) should be included in the two-sided \( p \)-value. Statisticians (at least some we know) would reply that the \( p \)-value is a precisely defined concept and that this is an arbitrary “fuzzification” of its definition. When you compute exact \( p \)-values according to the precise definition of a \( p \)-value, your type I error is never more than what you say it is—so no one can criticize you for being anticonservative. Including the point \( k = 2 \) is being overly conservative because it makes the \( p \)-value larger yet. But it is your choice; being overly conservative, at least in statistics, is always safe. Know that \texttt{bitest} and \texttt{bittesti} always keep to the precise definition of a \( p \)-value, so if you wish to include this extra point, you must do so by hand or by using the \texttt{r()} stored results; see \textit{Stored results} below.
Example 2

The binomial test is a function of two statistics and one parameter: \(N\), the number of observations; \(k_{\text{obs}}\), the number of observed successes; and \(p\), the assumed probability of a success on a trial. For instance, in a city of \(N = 2,500,000\), we observe \(k_{\text{obs}} = 36\) cases of a particular disease when the population rate for the disease is \(p = 0.00001\).

\[
\begin{array}{ccccc}
\text{N} & \text{Observed } k & \text{Expected } k & \text{Assumed } p & \text{Observed } p \\
2500000 & 36 & 25 & 0.00001 & 0.00001 \\
\end{array}
\]

\[
\begin{align*}
\Pr(k \geq 36) &= 0.022458 \text{ (one-sided test)} \\
\Pr(k \leq 36) &= 0.985448 \text{ (one-sided test)} \\
\Pr(k \leq 14 \text{ or } k \geq 36) &= 0.034859 \text{ (two-sided test)}
\end{align*}
\]

Stored results

`bitest` and `bitesti` store the following in `r()`:

Scalars

- `r(N)` number \(N\) of trials
- `r(P_p)` assumed probability \(p\) of success
- `r(k)` observed number \(k\) of successes
- `r(p_1)` lower one-sided \(p\)-value
- `r(p_u)` upper one-sided \(p\)-value
- `r(p)` two-sided \(p\)-value
- `r(k_opp)` opposite extreme \(k\)
- `r(P_k)` probability of observed \(k\) (detail only)
- `r(P_oppk)` probability of opposite extreme \(k\) (detail only)
- `r(k_nopp)` \(k\) next to opposite extreme (detail only)
- `r(P_noppk)` probability of \(k\) next to opposite extreme (detail only)
Methods and formulas

Let $N$, $k_{obs}$, and $p$ be, respectively, the number of observations, the observed number of successes, and the assumed probability of success on a trial. The expected number of successes is $Np$, and the observed probability of success on a trial is $k_{obs}/N$.

`bitest` and `bitesti` compute exact $p$-values based on the binomial distribution. The upper one-sided $p$-value is

$$\Pr(k \geq k_{obs}) = \sum_{m=k_{obs}}^{N} \binom{N}{m} p^m (1-p)^{N-m}$$

The lower one-sided $p$-value is

$$\Pr(k \leq k_{obs}) = \sum_{m=0}^{k_{obs}} \binom{N}{m} p^m (1-p)^{N-m}$$

If $k_{obs} \geq Np$, the two-sided $p$-value is

$$\Pr(k \leq k_{opp} \text{ or } k \geq k_{obs})$$

where $k_{opp}$ is the largest number $\leq Np$ such that $\Pr(k = k_{opp}) \leq \Pr(k = k_{obs})$. If $k_{obs} < Np$, the two-sided $p$-value is

$$\Pr(k \leq k_{obs} \text{ or } k \geq k_{opp})$$

where $k_{opp}$ is the smallest number $\geq Np$ such that $\Pr(k = k_{opp}) \leq \Pr(k = k_{obs})$.

### Description

`bootstrap` performs nonparametric bootstrap estimation of specified statistics (or expressions) for a Stata command or a user-written program. Statistics are bootstrapped by resampling the data in memory with replacement. `bootstrap` is designed for use with nonestimation commands, functions of coefficients, or user-written programs. To bootstrap coefficients, we recommend using the `vce(bootstrap)` option when allowed by the estimation command.

### Quick start

**Bootstrap the mean of v1 returned by summarize in r(mean)**

```stata
bootstrap mean=r(mean): summarize v1
```

**Bootstrap the statistic `r(mystat)` returned by program `myprog1`**

```stata
bootstrap stat=r(mystat): myprog1 v1
```

As above, but use 100 replications

```stata
bootstrap stat=r(mystat), reps(100): myprog1 v1
```

As above, and save the results from each replication in `mydata.dta`

```stata
bootstrap stat=r(mystat), reps(100) saving(mydata): myprog1 v1
```

**Bootstrap a difference in coefficients estimated by `regress`**

```stata
bootstrap diff=(_b[x2]-_b[x1]): regress y x1 x2 x3
```

**Bootstrap the coefficients stored in `e(b)` by `myprog2`**

```stata
bootstrap _b: myprog2 y x1 x2 x3
```

As above, but with bootstrap samples taken independently within strata identified by `svar`

```stata
bootstrap _b, strata(svar): myprog2 y x1 x2 x3
```

Resample clusters defined by `cvar` and create `newcvar` identifying resampled clusters

```stata
bootstrap _b, cluster(cvar) idcluster(newcvar): myprog2 y x1 x2 x3
```

### Menu

- **Statistics > Resampling > Bootstrap estimation**
## Syntax

```
bootstrap `exp_list` [, `options eform_option`] : `command`
```

command is any command that follows standard Stata syntax. weights are not allowed in command. group(), jackknifeopts(), and coeflegend do not appear in the dialog box. See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

exp_list contains (name: elist)
  elist
eexp
elist contains newvar = (exp)
  (exp)
eexp is specname
  [eqno]specname
specname is _b
  _b[]
  _se
  _se[]
eqno is #
  name

exp is a standard Stata expression; see [U] 13 Functions and expressions.

Distinguish between [], which are to be typed, and [], which indicate optional arguments.

Options

Main

reps(#) specifies the number of bootstrap replications to be performed. The default is 50. A total of 50–200 replications are generally adequate for estimates of standard error and thus are adequate for normal-approximation confidence intervals; see Mooney and Duval (1993, 11). Estimates of confidence intervals using the percentile or bias-corrected methods typically require 1,000 or more replications.

strata(varlist) specifies the variables that identify strata. If this option is specified, bootstrap samples are taken independently within each stratum.

size(#) specifies the size of the samples to be drawn. The default is _N, meaning to draw samples of the same size as the data. If specified, # must be less than or equal to the number of observations within strata().

If cluster() is specified, the default size is the number of clusters in the original dataset. For unbalanced clusters, resulting sample sizes will differ from replication to replication. For cluster sampling, # must be less than or equal to the number of clusters within strata().

cluster(varlist) specifies the variables that identify resampling clusters. If this option is specified, the sample drawn during each replication is a bootstrap sample of clusters.

idcluster(newvar) creates a new variable containing a unique identifier for each resampled cluster. This option requires that cluster() also be specified.
saving(filename[, suboptions]) creates a Stata data file (.dta file) consisting of (for each statistic in exp_list) a variable containing the replicates.

double specifies that the results for each replication be saved as doubles, meaning 8-byte reals.

By default, they are saved as floats, meaning 4-byte reals. This option may be used without the saving() option to compute the variance estimates by using double precision.

every(#) specifies that results be written to disk every #th replication. every() should be specified only in conjunction with saving() when command takes a long time for each replication. This option will allow recovery of partial results should some other software crash your computer. See [P] postfile.

replace specifies that filename be overwritten if it exists. This option does not appear in the dialog box.

bca specifies that bootstrap estimate the acceleration of each statistic in exp_list. This estimate is used to construct BCα confidence intervals. Type estat bootstrap, bca to display the BCα confidence interval generated by the bootstrap command.

ties specifies that bootstrap adjust for ties in the replicate values when computing the median bias used to construct BC and BCα confidence intervals.

mse specifies that bootstrap compute the variance by using deviations of the replicates from the observed value of the statistics based on the entire dataset. By default, bootstrap computes the variance by using deviations from the average of the replicates.

---

Reporting

level(#); see [R] Estimation options.

notable suppresses the display of the table of results.

noheader suppresses the display of the table header. This option implies nolegend. This option may also be specified when replaying estimation results.

nolegend suppresses the display of the table legend. This option may also be specified when replaying estimation results.

verbose specifies that the full table legend be displayed. By default, coefficients and standard errors are not displayed. This option may also be specified when replaying estimation results.

nodots and dots(#) specify whether to display replication dots. By default, one dot character is displayed for each successful replication. A red ‘x’ is displayed if command returns an error or if any value in exp_list is missing. You can also control whether dots are displayed using set dots; see [R] set.

nodots suppresses display of the replication dots.

dots(#) displays dots every # replications. dots(0) is a synonym for nodots.

noisily specifies that any output from command be displayed. This option implies the nodots option.

trace causes a trace of the execution of command to be displayed. This option implies the noisily option.

title(text) specifies a title to be displayed above the table of bootstrap results. The default title is the title stored in e(title) by an estimation command, or if e(title) is not filled in, Bootstrap results is used. title() may also be specified when replaying estimation results.
display_options: noci, nopvalues, noomitted, vsquish, noemptycells, baselevels, 
alibaselevels, nofvlabel, fvwrap(#), fvwrapon(style), cformat(%,fmt), pformat(%,fmt), 
sformat(%,fmt), and nolstretch; see [R] Estimation options.

eform_option causes the coefficient table to be displayed in exponentiated form; see [R] eform_option.

command determines which of the following are allowed (eform(string) and eform are always 
allowed):

eform_option Description
---
eform(string) use string for the column title

eform exponentiated coefficient, string is exp(b)

hr hazard ratio, string is Haz. Ratio

shr subhazard ratio, string is SHR

irr incidence-rate ratio, string is IRR

or odds ratio, string is Odds Ratio

rrr relative-risk ratio, string is RRR

Advanced

nodrop prevents observations outside e(sample) and the if and in qualifiers from being dropped 
before the data are resampled.

nowarn suppresses the display of a warning message when command does not set e(sample).

force suppresses the restriction that command not specify weights or be a svy command. This is a 
rarely used option. Use it only if you know what you are doing.

reject(exp) identifies an expression that indicates when results should be rejected. When exp is 
true, the resulting values are reset to missing values.

seed(#) sets the random-number seed. Specifying this option is equivalent to typing the following 
command prior to calling bootstrap:

   . set seed #

The following options are available with bootstrap but are not shown in the dialog box:

group(varname) re-creates varname containing a unique identifier for each group across the resampled 
clusters. This option requires that idcluster() also be specified.

   This option is useful for maintaining unique group identifiers when sampling clusters with replacement. 
   Suppose that cluster 1 contains 3 groups. If the idcluster(newclid) option is specified and cluster 1 is sampled multiple times, newclid uniquely identifies each copy of cluster 1. If 
   group(newgroupid) is also specified, newgroupid uniquely identifies each copy of each group.

jackknifeopts(jkopts) identifies options that are to be passed to jackknife when it computes the 
acceleration values for the BC_a confidence intervals; see [R] jackknife. This option requires the 
bca option and is mostly used for passing the eclass, rclass, or n(#) option to jackknife.

coefflegend; see [R] Estimation options.
Remarks and examples

Remarks are presented under the following headings:

- Introduction
- Using bootstrap
- Regression coefficients
- Expressions
- Combining bootstrap datasets

- Achieved significance level
- Bootstrapping a ratio
- Warning messages and e(sample)
- Bootstrapping statistics from data with a complex structure

Introduction

With few assumptions, bootstrapping provides a way of estimating standard errors and other measures of statistical precision (Efron 1979; Efron and Stein 1981; Efron 1982; Efron and Tibshirani 1986; Efron and Tibshirani 1993; also see Davison and Hinkley [1997]; Guan [2003]; Mooney and Duval [1993]; Poi [2004]; and Stine [1990]). It provides a way to obtain such measures when no formula is otherwise available or when available formulas make inappropriate assumptions. Cameron and Trivedi (2010, chap. 13) discuss many bootstrapping topics and demonstrate how to do them in Stata.

To illustrate bootstrapping, suppose that you have a dataset containing $N$ observations and an estimator that, when applied to the data, produces certain statistics. You draw, with replacement, $N$ observations from the $N$-observation dataset. In this random drawing, some of the original observations will appear once, some more than once, and some not at all. Using the resampled dataset, you apply the estimator and collect the statistics. This process is repeated many times; each time, a new random sample is drawn and the statistics are recalculated.

This process builds a dataset of replicated statistics. From these data, you can calculate the standard error by using the standard formula for the sample standard deviation

$$\hat{s}_e = \left\{ \frac{1}{k-1} \sum (\hat{\theta}_i - \bar{\theta})^2 \right\}^{1/2}$$

where $\hat{\theta}_i$ is the statistic calculated using the $i$th bootstrap sample and $k$ is the number of replications. This formula gives an estimate of the standard error of the statistic, according to Hall and Wilson (1991). Although the average, $\bar{\theta}$, of the bootstrapped estimates is used in calculating the standard deviation, it is not used as the estimated value of the statistic itself. Instead, the original observed value of the statistic, $\hat{\theta}$, is used, meaning the value of the statistic computed using the original $N$ observations.

You might think that $\bar{\theta}$ is a better estimate of the parameter than $\hat{\theta}$, but it is not. If the statistic is biased, bootstrapping exaggerates the bias. In fact, the bias can be estimated as $\bar{\theta} - \hat{\theta}$ (Efron 1982, 33). Knowing this, you might be tempted to subtract this estimate of bias from $\hat{\theta}$ to produce an unbiased statistic. The bootstrap bias estimate has an indeterminate amount of random error, so this unbiased estimator may have greater mean squared error than the biased estimator (Mooney and Duval 1993; Hinkley 1978). Thus $\hat{\theta}$ is the best point estimate of the statistic.

The logic behind the bootstrap is that all measures of precision come from a statistic’s sampling distribution. When the statistic is estimated on a sample of size $N$ from some population, the sampling distribution tells you the relative frequencies of the values of the statistic. The sampling distribution, in turn, is determined by the distribution of the population and the formula used to estimate the statistic.
Sometimes the sampling distribution can be derived analytically. For instance, if the underlying population is distributed normally and you calculate means, the sampling distribution for the mean is also normal but has a smaller variance than that of the population. In other cases, deriving the sampling distribution is difficult, as when means are calculated from nonnormal populations. Sometimes, as in the case of means, it is not too difficult to derive the sampling distribution as the sample size goes to infinity \((N \to \infty)\). However, such asymptotic distributions may not perform well when applied to finite samples.

If you knew the population distribution, you could obtain the sampling distribution by simulation: you could draw random samples of size \(N\), calculate the statistic, and make a tally. Bootstrapping does precisely this, but it uses the observed distribution of the sample in place of the true population distribution. Thus the bootstrap procedure hinges on the assumption that the observed distribution is a good estimate of the underlying population distribution. In return, the bootstrap produces an estimate, called the bootstrap distribution, of the sampling distribution. From this, you can estimate the standard error of the statistic, produce confidence intervals, etc.

The accuracy with which the bootstrap distribution estimates the sampling distribution depends on the number of observations in the original sample and the number of replications in the bootstrap. A crudely estimated sampling distribution is adequate if you are only going to extract, say, a standard error. A better estimate is needed if you want to use the 2.5th and 97.5th percentiles of the distribution to produce a 95\% confidence interval. To extract many features simultaneously about the distribution, an even better estimate is needed. Generally, replications on the order of 1,000 produce very good estimates, but only 50–200 replications are needed for estimates of standard errors. See Poi (2004) for a method to choose the number of bootstrap replications.

### Using bootstrap

Typing

```
. bootstrap exp_list, reps(#): command
```

executes `command` multiple times, bootstrapping the statistics in `exp_list` by resampling observations (with replacement) from the data in memory # times. This method is commonly referred to as the nonparametric bootstrap.

`command` defines the statistical command to be executed. Most Stata commands and user-written programs can be used with `bootstrap`, as long as they follow standard Stata syntax; see [U] 11 Language syntax. If the `bca` option is supplied, `command` must also work with `jackknife`; see [R] jackknife. The by prefix may not be part of `command`.

`exp_list` specifies the statistics to be collected from the execution of `command`. If `command` changes the contents in `e(b)`, `exp_list` is optional and defaults to `_b`.

Because bootstrapping is a random process, if you want to be able to reproduce results, set the random-number seed by specifying the `seed(#)` option or by typing

```
. set seed #
```

where # is a seed of your choosing, before running `bootstrap`; see [R] set seed.
Regression coefficients

Example 1

Let’s say that we wish to compute bootstrap estimates for the standard errors of the coefficients from the following regression:

```
. use https://www.stata-press.com/data/r16/auto
(1978 Automobile Data)
. regress mpg weight gear foreign
```

```
<table>
<thead>
<tr>
<th>Source</th>
<th>SS</th>
<th>df</th>
<th>MS</th>
<th>Number of obs = 74</th>
</tr>
</thead>
<tbody>
<tr>
<td>Model</td>
<td>1629.67805</td>
<td>3</td>
<td>543.226016</td>
<td>F(3, 70) = 46.73</td>
</tr>
<tr>
<td>Residual</td>
<td>813.781411</td>
<td>70</td>
<td>11.6254487</td>
<td>Prob &gt; F = 0.0000</td>
</tr>
<tr>
<td>Total</td>
<td>2443.45946</td>
<td>73</td>
<td>33.4720474</td>
<td>R-squared = 0.6670</td>
</tr>
</tbody>
</table>

```

```
| mpg     | Coef. | Std. Err. | t     | P>|t|  | [95% Conf. Interval] |
|---------|-------|-----------|-------|------|---------------------|
| weight  | -.006139 | .0007949 | -7.72 | 0.000 | -.0077245 -.0045536 |
| gear_ratio | 1.457113 | 1.541286 | 0.95 | 0.348 | -1.616884 4.53111 |
| foreign | -2.221682 | 1.234961 | -1.80 | 0.076 | -4.684735 .2413715 |
| _cons   | 36.10135 | 6.285984 | 5.74 | 0.000 | 23.56435 48.63835 |
```

To run the bootstrap, we simply prefix the above regression command with the `bootstrap` command (specifying its options before the colon separator). We must set the random-number seed before calling `bootstrap`.

```
. bootstrap, reps(100) seed(1): regress mpg weight gear foreign
```

```
Bootstrap replications (100)                                50

</table>
```

The displayed confidence interval is based on the assumption that the sampling (and hence bootstrap) distribution is approximately normal (see Methods and formulas below). Because this confidence interval is based on the standard error, it is a reasonable estimate if normality is approximately true, even for a few replications. Other types of confidence intervals are available after bootstrap; see [R] bootstrap postestimation.
We could instead supply names to our expressions when we run \texttt{bootstrap}. For example,

\begin{verbatim}
  . bootstrap diff=(\_b[weight]-\_b[gear]): regress mpg weight gear foreign
\end{verbatim}

would bootstrap a statistic, named \texttt{diff}, equal to the difference between the coefficients on \texttt{weight} and \texttt{gear}.

\section*{Technical note}

\texttt{regress}, like many estimation commands, allows the \texttt{vce(bootstrap)} option. For any estimation command that allows this option, we recommend using \texttt{vce(bootstrap)} over \texttt{bootstrap} because the estimation command automatically handles clustering and other model-specific details for you.

\section*{Expressions}

\subsection*{Example 2}

When we use \texttt{bootstrap}, the list of statistics can contain complex expressions, as long as each expression is enclosed in parentheses. For example, to bootstrap the range of a variable \texttt{x}, we could type

\begin{verbatim}
  . bootstrap range=(r(max)-r(min)), reps(1000): summarize x
\end{verbatim}

Of course, we could also bootstrap the minimum and maximum and later compute the range.

\begin{verbatim}
  . bootstrap max=r(max) min=r(min), reps(1000) saving(mybs): summarize x
  . use mybs, clear
  (bootstrap: summarize)
  . generate range = max - min
  . bstat range, stat(19.5637501)
\end{verbatim}

The difference between the maximum and minimum of \texttt{x} in the sample is 19.5637501.

The \texttt{stat()} option to \texttt{bstat} specifies the observed value of the statistic (\texttt{range}) to be summarized. This option is useful when, as shown above, the statistic of ultimate interest is not specified directly to \texttt{bootstrap} but instead is calculated by other means.

Here the observed values of \texttt{r(max)} and \texttt{r(min)} are stored as characteristics of the dataset created by \texttt{bootstrap} and are thus available for retrieval by \texttt{bstat}; see \cite{R bstat}. The observed range, however, is unknown to \texttt{bstat}, so it must be specified.

\section*{Combining bootstrap datasets}

You can combine two datasets from separate runs of \texttt{bootstrap} by using \texttt{append} (see \cite{D append}) and then get the bootstrap statistics for the combined datasets by running \texttt{bstat}. The runs must have been performed independently (having different starting random-number seeds), and the original dataset, command, and bootstrap statistics must have been all the same.
A note about macros

In example 2, we executed the command

```
bootstrap max=r(max) min=r(min), reps(1000) saving(mybs): summarize x
```

We did not enclose $r(max)$ and $r(min)$ in single quotes, as we would in most other contexts, because it would not produce what was intended:

```
bootstrap ‘r(max)’ ‘r(min)’, reps(1000) saving(mybs): summarize x
```

To understand why, note that ‘$r(max)$’, like any reference to a local macro, will evaluate to a literal string containing the contents of $r(max)$ before `bootstrap` is even executed. Typing the command above would appear to Stata as if we had typed

```
bootstrap 14.5441234 33.4393293, reps(1000) saving(mybs): summarize x
```

Even worse, the current contents of $r(min)$ and $r(max)$ could be empty, producing an even more confusing result. To avoid this outcome, refer to statistics by name (for example, $r(max)$) and not by value (for example, ‘$r(max)$’).

Achieved significance level

Example 3

Suppose that we wish to estimate the achieved significance level (ASL) of a test statistic by using the bootstrap. ASL is another name for $p$-value. An example is

\[
\text{ASL} = \Pr \left( \hat{\theta}^* \geq \hat{\theta} \mid H_0 \right)
\]

for an upper-tailed, alternative hypothesis, where $H_0$ denotes the null hypothesis, $\hat{\theta}$ is the observed value of the test statistic, and $\hat{\theta}^*$ is the random variable corresponding to the test statistic, assuming that $H_0$ is true.

Here we will compare the mean miles per gallon ($mpg$) between foreign and domestic cars by using the two-sample $t$ test with unequal variances. The following results indicate the $p$-value to be 0.0034 for the two-sided test using Satterthwaite’s approximation. Thus assuming that mean $mpg$ is the same for foreign and domestic cars, we would expect to observe a $t$ statistic more extreme (in absolute value) than 3.1797 in about 0.3% of all possible samples of the type that we observed. Thus we have evidence to reject the null hypothesis that the means are equal.
. use https://www.stata-press.com/data/r16/auto
(1978 Automobile Data)
. ttest mpg, by(foreign) unequal
Two-sample t test with unequal variances

</table>

| Ho: diff = 0 | Satterthwaite's degrees of freedom = 30.5463 |
| diff < 0     | Ha: diff != 0 |
| diff > 0     | Ha: diff > 0 |
| Pr(T < t) = 0.0017 | Pr(|T| > |t|) = 0.0034 |
| Pr(T > t) = 0.9983 |

We also place the value of the test statistic in a scalar for later use.
. scalar tobs = r(t)

Efron and Tibshirani (1993, 224) describe an alternative to Satterthwaite’s approximation that estimates the ASL by bootstrapping the statistic from the test of equal means. Their idea is to recenter the two samples to the combined sample mean so that the data now conform to the null hypothesis but that the variances within the samples remain unchanged.

. summarize mpg, meanonly
. scalar omean = r(mean)
. summarize mpg if foreign==0, meanonly
. replace mpg = mpg - r(mean) + scalar(omean) if foreign==0
variable mpg was int now float
(52 real changes made)
. summarize mpg if foreign==1, meanonly
. replace mpg = mpg - r(mean) + scalar(omean) if foreign==1
(22 real changes made)
. sort foreign
. by foreign: summarize mpg

```
-> foreign = Domestic
  Variable |  Obs  | Mean   | Std. Dev. | Min     | Max     |
           |      |        |           |         |         |
  mpg     |  52  | 21.2973| 4.743297  | 13.47037| 35.47038|

-> foreign = Foreign
  Variable |  Obs  | Mean   | Std. Dev. | Min     | Max     |
           |      |        |           |         |         |
  mpg     |  22  | 21.2973| 6.611187  | 10.52457| 37.52457|
```

Each sample (foreign and domestic) is a stratum, so the bootstrapped samples must have the same number of foreign and domestic cars as the original dataset. This requirement is facilitated by the `strata()` option to bootstrap. By typing the following, we bootstrap the test statistic using the modified dataset and save the values in `bsauto2.dta`:

bootstrap — Bootstrap sampling and estimation 151
. keep mpg foreign
. set seed 1
. bootstrap t=r(t), rep(1000) strata(foreign) saving(bsauto2) nodots: ttest mpg, > by(foreign) unequal

Warning: Because `ttest' is not an estimation command or does not set e(sample), bootstrap has no way to determine which observations are used in calculating the statistics and so assumes that all observations are used. This means that no observations will be excluded from the resampling because of missing values or other reasons.

If the assumption is not true, press Break, save the data, and drop the observations that are to be excluded. Be sure that the dataset in memory contains only the relevant data.

Bootstrap results
Number of strata = 2 Number of obs = 74
Replications = 1,000
command: ttest mpg, by(foreign) unequal
t: r(t)

<table>
<thead>
<tr>
<th></th>
<th>Observed</th>
<th>Bootstrap</th>
<th>Normal-based</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Coef.</td>
<td>Std. Err.</td>
<td>z</td>
</tr>
<tr>
<td>t</td>
<td>1.75e-07</td>
<td>1.051867</td>
<td>0.00</td>
</tr>
</tbody>
</table>

We can use the data in `bsauto2.dta' to estimate ASL via the fraction of bootstrap test statistics that are more extreme than 3.1797.

. use bsauto2, clear
(bootstrap: ttest)
. generate indicator = abs(t)>=abs(scalar(tobs))
. summarize indicator, meanonly
. display "ASLboot = " r(mean)
ASLboot = .004

The result is $\text{ASL}_{\text{boot}} = 0.004$. Assuming that the mean mpg is the same between foreign and domestic cars, we would expect to observe a $t$ statistic more extreme (in absolute value) than 3.1797 in about 0.4% of all possible samples of the type we observed. This finding is still strong evidence to reject the hypothesis that the means are equal.

$\text{Example 4}$

Suppose that we wish to produce a bootstrap estimate of the ratio of two means. Because `summarize' stores results for only one variable, we must call `summarize' twice to compute the means. Actually, we could use `collapse' to compute the means in one call, but calling `summarize' twice is much faster. Thus we will have to write a small program that will return the results we want.
We write the program below and save it to a file called ratio.ado (see [U] 17 Ado-files). Our program takes two variable names as input and saves them in the local macros $y$ (first variable) and $x$ (second variable). It then computes one statistic: the mean of $y$ divided by the mean of $x$. This value is returned as a scalar in `r(ratio)`. `ratio` also returns the ratio of the number of observations used to the mean for each variable.

```
program myratio, rclass
    version 16.0
    args y x
    confirm var `y'
    confirm var `x'
    tempname ymean yn
    summarize `y', meanonly
    scalar `ymean' = r(mean)
    return scalar n_`y' = r(N)
    summarize `x', meanonly
    return scalar n_`x' = r(N)
    return scalar ratio = `ymean'/r(mean)
end
```

Remember to test any newly written commands before using them with `bootstrap`.

```
. use https://www.stata-press.com/data/r16/auto, clear
   (1978 Automobile Data)
. summarize price
       Variable |       Obs  Mean   Std. Dev.      Min       Max
              |        74 6165.257 2949.496    3291 15906
. scalar mean1=r(mean)
. summarize weight
       Variable |       Obs   Mean   Std. Dev.      Min       Max
              |        74 3019.459  777.1936   1760  4840
. scalar mean2=r(mean)
. di scalar(mean1)/scalar(mean2)
  2.0418412
. myratio price weight
. return list
   scalars:
      r(ratio) = 2.041841210168278
      r(n_weight) = 74
      r(n_price) = 74
```
The results of running `bootstrap` on our program are

```stata
. use https://www.stata-press.com/data/r16/auto
(1978 Automobile Data)
. set seed 1
. bootstrap ratio=r(ratio), reps(1000) nowarn nodots: myratio price weight
Bootstrap results
Number of obs = 74
Replications = 1,000
command: myratio price weight
ratio: r(ratio)

<table>
<thead>
<tr>
<th>Observed</th>

<th>Normal-based</th>
</tr>
</thead>
<tbody>
<tr>
<td>Coef.</td>
<td>Std. Err.</td>
<td>z</td>
</tr>
<tr>
<td>ratio</td>
<td>2.041841</td>
<td>.0953559</td>
</tr>
</tbody>
</table>
```

As mentioned previously, we should specify the `saving()` option if we wish to save the bootstrap dataset.

---

**Warning messages and e(sample)**

`bootstrap` is not meant to be used with weighted calculations. `bootstrap` determines the presence of weights by parsing the prefixed command with standard syntax. However, commands like `stcox` and `streg` require that weights be specified in `stset`, and some user commands may allow weights to be specified by using an option instead of the standard syntax. Both cases pose a problem for `bootstrap` because it cannot determine the presence of weights under these circumstances. In these cases, we can only assume that you know what you are doing.

`bootstrap` does not know which variables of the dataset in memory matter to the calculation at hand. You can speed their execution by dropping unnecessary variables because, otherwise, they are included in each bootstrap sample.

You should thus drop observations with missing values. Leaving in missing values causes no problem in one sense because all Stata commands deal with missing values gracefully. It does, however, cause a statistical problem. Bootstrap sampling is defined as drawing, with replacement, samples of size \(N\) from a set of \(N\) observations. `bootstrap` determines \(N\) by counting the number of observations in memory, not counting the number of nonmissing values on the relevant variables. The result is that too many observations are resampled; the resulting bootstrap samples, because they are drawn from a population with missing values, are of unequal sizes.

If the number of missing values relative to the sample size is small, this will make little difference. If you have many missing values, however, you should first drop the observations that contain them.

---

**Example 5**

To illustrate, we use the previous example but replace some of the values of `price` with missing values. The number of values of `price` used to compute the mean for each bootstrap is not constant. This is the purpose of the Warning message.
. use https://www.stata-press.com/data/r16/auto
(1978 Automobile Data)
. replace price = . if inlist(_n,1,3,5,7)
(4 real changes made, 4 to missing)
. set seed 1
. bootstrap ratio=r(ratio) np=r(n_price) nw=r(n_weight), reps(100) nodots:
> myratio price weight
Warning: Because myratio is not an estimation command or does not set
\texttt{e(sample)}, bootstrap has no way to determine which observations are
used in calculating the statistics and so assumes that all
observations are used. This means that no observations will be
excluded from the resampling because of missing values or other
reasons.
If the assumption is not true, press Break, save the data, and drop
the observations that are to be excluded. Be sure that the dataset
in memory contains only the relevant data.

\section*{Bootstrapping statistics from data with a complex structure}

Here we describe how to bootstrap statistics from data with a complex structure, for example, longitudinal or panel data, or matched data. bootstrap, however, is not designed to work with complex survey data. It is important to include all necessary information about the structure of the data in the bootstrap syntax to obtain correct bootstrap estimates for standard errors and confidence intervals.

\texttt{bootstrap} offers several options identifying the specifics of the data. These options are \texttt{strata()}, \texttt{cluster()}, \texttt{idcluster()}, and \texttt{group()}. The usage of \texttt{strata()} was described in \texttt{example 3} above. Below we demonstrate several examples that require specifying the other three options.

\subsection*{Example 6}

Suppose that the auto data in \texttt{example 1} above are clustered by \texttt{rep78}. We want to obtain bootstrap estimates for the standard errors of the difference between the coefficients on weight and gear__ratio, taking into account clustering.

We supply the \texttt{cluster(rep78)} option to \texttt{bootstrap} to request resampling from clusters rather than from observations in the dataset.
We drop missing values in `rep78` before issuing the command because `bootstrap` does not allow missing values in `cluster()`. See the section above about using `bootstrap` when variables contain missing values.

We can also obtain these same results by using the following syntax:

```stata
. bootstrap diff=(_b[weight]-_b[gear]), seed(1): regress mpg weight gear foreign,
> vce(cluster rep78)
```

When only clustered information is provided to the command, `bootstrap` can pick up the `vce(cluster clustvar)` option from the main command and use it to resample from clusters.

---

### Example 7

Suppose now that we have matched data and want to use `bootstrap` to obtain estimates of the standard errors of the exponentiated difference between two coefficients (or, equivalently, the ratio of two odds ratios) estimated by `clogit`. Consider the example of matched case–control data on birthweight of infants described in example 2 of [R] clogit.

The infants are paired by being matched on mother’s age. All groups, defined by the `pairid` variable, have 1:1 matching. `clogit` requires that the matching information, `pairid`, be supplied to the `group()` (or, equivalently, `strata()`) option to be used in computing the parameter estimates. Because the data are matched, we need to resample from groups rather than from the whole dataset. However, simply supplying the grouping variable `pairid` in `cluster()` is not enough with `bootstrap`, as it is with clustered data.
. use https://www.stata-press.com/data/r16/lowbirth2, clear
(Applied Logistic Regression, Hosmer & Lemeshow)
. bootstrap ratio=exp(_b[smoke]-_b[ptd]), seed(1) cluster(pairid):  clogit low
> lwt smoke ptd ht ui i.race, group(pairid)
(running clogit on estimation sample)
Bootstrap replications (50)
1 2 3 4 5 .......................... 50
Bootstrap results

| Coef. Std. Err. z P>|z| [95% Conf. Interval] |
|-----------------|-----------------|--------------------|-------------------|
| ratio | 0.6654095 | 2.043274 | 0.33 | 0.745 | -3.339334 | 4.670153 |

For the syntax above, imagine that the first pair was sampled twice during a replication. Then the bootstrap sample has four subjects with pairid equal to one, which clearly violates the original 1:1 matching design. As a result, the estimates of the coefficients obtained from this bootstrap sample will be incorrect.

Therefore, in addition to resampling from groups, we need to ensure that resampled groups are uniquely identified in each of the bootstrap samples. The idcluster(newcluster) option is designed for this. It requests that at each replication bootstrap create the new variable, newcluster, containing unique identifiers for all resampled groups. Thus, to make sure that the correct matching is preserved during each replication, we need to specify the grouping variable in cluster(), supply a variable name to idcluster(), and use this variable as the grouping variable with clogit, as we demonstrate below.

. bootstrap ratio=exp(_b[smoke]-_b[ptd]), seed(1) cluster(pairid)
> idcluster(newpairid): clogit low lwt smoke ptd ht ui i.race, group(newpairid)
(running clogit on estimation sample)
Bootstrap replications (50)
1 2 3 4 5 .......................... 50
Bootstrap results

| Coef. Std. Err. z P>|z| [95% Conf. Interval] |
|-----------------|-----------------|--------------------|-------------------|
| ratio | 0.6654095 | 1.156848 | 0.58 | 0.565 | -1.601972 | 2.932791 |

Note the difference between the estimates of the bootstrap standard error for the two specifications of the bootstrap syntax.
**Technical note**

Similarly, when you have panel (longitudinal) data, all resampled panels must be unique in each of the bootstrap samples to obtain correct bootstrap estimates of statistics. Therefore, both `cluster(panelvar)` and `idcluster(newpanelvar)` must be specified with bootstrap, and `i(newpanelvar)` must be used with the main command. Moreover, you must clear the current `xtset` settings by typing `xtset, clear` before calling bootstrap.

**Example 8**

Continuing with our birthweight data, suppose that we have more information about doctors supervising women’s pregnancies. We believe that the data on the pairs of infants from the same doctor may be correlated and want to adjust standard errors for possible correlation among the pairs. `clogit` offers the `vce(cluster clustvar)` option to do this.

Let’s add a cluster variable to our dataset. One thing to keep in mind is that to use `vce(cluster clustvar)`, groups in `group()` must be nested within clusters.

```
. use https://www.stata-press.com/data/r16/lowbirth2, clear
(Applied Logistic Regression, Hosmer & Lemeshow)
. set seed 12345
. by pairid, sort: egen byte doctor = total(int(2*runiform())+1)*(_n == 1))
. clogit low lwt smoke ptd ht ui i.race, group(pairid) vce(cluster doctor)
Iteration 0: log pseudolikelihood = -26.768693

Iteration 4: log pseudolikelihood = -25.794271
Conditional (fixed-effects) logistic regression
Number of obs = 112
Wald chi2(1) = .
Prob > chi2 = .
Log pseudolikelihood = -25.794271 Pseudo R2 = 0.3355
(Std. Err. adjusted for 2 clusters in doctor)

| low | Coef. | Std. Err. | z    | P>|z|  | [95% Conf. Interval] |
|-----|-------|-----------|------|------|----------------------|
| lwt | -.0183757 | .0020314 | -9.05 | 0.000 | -.0223571 -.0143942 |
| smoke | 1.400656 | .3067525 | 4.57 | 0.000 | .7994322 2.00188 |
| ptd | 1.808009 | .2092246 | 8.64 | 0.000 | 1.397936 2.218082 |
| ht | 2.361152 | 1.410341 | 1.67 | 0.094 | -.4030665 5.12537 |
| ui | 1.401929 | .9406248 | 1.49 | 0.094 | -.4416617 3.24552 |
| race | black | .5713643 | .9992656 | 0.57 | 0.567 | -1.38716 2.529889 |
| other | -.0253148 | .8453206 | -0.03 | 0.976 | -1.682113 1.631483 |
```

To obtain correct bootstrap standard errors of the exponentiated difference between the two coefficients in this example, we need to make sure that both resampled clusters and groups within resampled clusters are unique in each of the bootstrap samples. To achieve this, `bootstrap` needs the information about clusters in `cluster()`, the variable name of the new identifier for clusters in `idcluster()`, and the information about groups in `group()`. We demonstrate the corresponding syntax of `bootstrap` below.
. bootstrap ratio=exp(_b[smoke]-_b[ptd]), seed(1) cluster(doctor) idcluster(uidoctor) group(pairid): clogit low lwt smoke ptd ht ui i.race, group(pairid)
(running clogit on estimation sample)

In the above syntax, although we specify `group(pairid)` with `clogit`, it is not the group identifiers of the original `pairid` variable that are used to compute parameter estimates from bootstrap samples. The way `bootstrap` works is that, at each replication, the clusters defined by `doctor` are resampled and the new variable, `uidoctor`, uniquely identifying resampled clusters is created. After that, another new variable uniquely identifying the `(uidoctor, group)` combination is created and renamed to have the same name as the grouping variable, `pairid`. This newly defined grouping variable is then used by `clogit` to obtain the parameter estimates from this bootstrap sample of clusters. After all replications are performed, the original values of the grouping variable are restored.

Bradley Efron (1938– ) was born in 1938 in Minnesota and studied mathematics and statistics at Caltech and Stanford; he has lived in northern California since 1960. He has worked on empirical Bayes, survival analysis, exponential families, bootstrap and jackknife methods, and confidence intervals, in conjunction with applied work in biostatistics, astronomy, and physics.

Efron is a member of the U.S. National Academy of Sciences and was awarded the U.S. National Medal of Science in 2005. He is by any standards one of the world’s leading statisticians: his work ranges from deep and elegant contributions in theoretical statistics to pathbreaking involvement in a variety of practical applications.
bootstrap stores the following in e():

Scalars

- \texttt{e(N)}: sample size
- \texttt{e(N_reps)}: number of complete replications
- \texttt{e(N_misreps)}: number of incomplete replications
- \texttt{e(N_strata)}: number of strata
- \texttt{e(N_clust)}: number of clusters
- \texttt{e(k_eq)}: number of equations in \texttt{e(b)}
- \texttt{e(k_exp)}: number of standard expressions
- \texttt{e(k_eexp)}: number of extended expressions (i.e., _b)
- \texttt{e(k_extra)}: number of extra equations beyond the original ones from \texttt{e(b)}
- \texttt{e(level)}: confidence level for bootstrap CIs
- \texttt{e(bs_version)}: version for bootstrap results
- \texttt{e(rank)}: rank of \texttt{e(V)}

Macros

- \texttt{e(cmdname)}: command name from \texttt{command}
- \texttt{e(cmd)}: same as \texttt{e(cmdname)} or bootstrap
- \texttt{e(command)}: command as typed
- \texttt{e(cmdline)}: command as typed
- \texttt{e(prefix)}: bootstrap
- \texttt{e(title)}: title in estimation output
- \texttt{e(strata)}: strata variables
- \texttt{e(cluster)}: cluster variables
- \texttt{e(rngstate)}: random-number state used
- \texttt{e(size)}: from the size(#) option
- \texttt{e(exp#)}: expression for the \texttt{#th} statistic
- \texttt{e(ties)}: ties, if specified
- \texttt{e(mse)}: mse, if specified
- \texttt{e(vce)}: bootstrap
- \texttt{e(vcetype)}: title used to label Std. Err.
- \texttt{e(properties)}: \texttt{b V}

Matrices

- \texttt{e(b)}: observed statistics
- \texttt{e(b_bs)}: bootstrap estimates
- \texttt{e(reps)}: number of nonmissing results
- \texttt{e(bias)}: estimated biases
- \texttt{e(se)}: estimated standard errors
- \texttt{e(z0)}: median biases
- \texttt{e(accel)}: estimated accelerations
- \texttt{e(ci_normal)}: normal-approximation CIs
- \texttt{e(ci_percentile)}: percentile CIs
- \texttt{e(ci_bc)}: bias-corrected CIs
- \texttt{e(ci_bca)}: bias-corrected and accelerated CIs
- \texttt{e(V)}: bootstrap variance–covariance matrix
- \texttt{e(V_modelbased)}: model-based variance

When \texttt{exp_list} is \_b, bootstrap will also carry forward most of the results already in \texttt{e()} from \texttt{command}.

Methods and formulas

Let \( \hat{\theta} \) be the observed value of the statistic, that is, the value of the statistic calculated with the original dataset. Let \( i = 1, 2, \ldots, k \) denote the bootstrap samples, and let \( \hat{\theta}_i \) be the value of the statistic from the \( i \)th bootstrap sample.
When the `mse` option is specified, the standard error is estimated as

\[
\hat{s} e_{\text{MSE}} = \left\{ \frac{1}{k} \sum_{i=1}^{k} (\hat{\theta}_i - \bar{\theta})^2 \right\}^{1/2}
\]

Otherwise, the standard error is estimated as

\[
\hat{s} e = \left\{ \frac{1}{k-1} \sum_{i=1}^{k} (\hat{\theta}_i - \bar{\theta})^2 \right\}^{1/2}
\]

where

\[
\bar{\theta} = \frac{1}{k} \sum_{i=1}^{k} \hat{\theta}_i
\]

The variance–covariance matrix is similarly computed. The bias is estimated as

\[
\hat{\text{bias}} = \bar{\theta} - \hat{\theta}
\]

Confidence intervals with nominal coverage rates \(1 - \alpha\) are calculated according to the following formulas. The normal-approximation method yields the confidence intervals

\[
[\hat{\theta} - z_{1-\alpha/2} \hat{s} e, \hat{\theta} + z_{1-\alpha/2} \hat{s} e]
\]

where \(z_{1-\alpha/2}\) is the \((1 - \alpha/2)\)th quantile of the standard normal distribution. If the `mse` option is specified, `bootstrap` will report the normal confidence interval using \(\hat{s} e_{\text{MSE}}\) instead of \(\hat{s} e\). `estat bootstrap` only uses \(\hat{s} e\) in the normal confidence interval.

The percentile method yields the confidence intervals

\[
[\theta_{\alpha/2}^*, \theta_{1-\alpha/2}^*]
\]

where \(\theta_p^*\) is the \(p\)th quantile (the 100\(p\)th percentile) of the bootstrap distribution \((\hat{\theta}_1, \ldots, \hat{\theta}_k)\).

Let

\[
z_0 = \Phi^{-1}\left\{ \frac{\#(\hat{\theta}_i \leq \hat{\theta})}{k} \right\}
\]

where \(#(\hat{\theta}_i \leq \hat{\theta})\) is the number of elements of the bootstrap distribution that are less than or equal to the observed statistic and \(\Phi\) is the standard cumulative normal. \(z_0\) is known as the median bias of \(\hat{\theta}\). When the `ties` option is specified, \(z_0\) is estimated as \(#(\hat{\theta}_i < \hat{\theta}) + #(\hat{\theta}_i = \hat{\theta}) / 2\), which is the number of elements of the bootstrap distribution that are less than the observed statistic plus half the number of elements that are equal to the observed statistic.

Let

\[
a = \frac{\sum_{i=1}^{n} (\bar{\theta}_{(i)} - \hat{\theta}_{(i)})^3}{6 \left\{ \sum_{i=1}^{n} (\bar{\theta}_{(i)} - \hat{\theta}_{(i)})^2 \right\}^{3/2}}
\]

where \(\hat{\theta}_{(i)}\) are the leave-one-out (jackknife) estimates of \(\hat{\theta}\) and \(\bar{\theta}_{(\cdot)}\) is their mean. This expression is known as the jackknife estimate of acceleration for \(\hat{\theta}\). Let

\[
p_1 = \Phi\left\{ z_0 + \frac{z_0 - z_{1-\alpha/2}}{1 - a(z_0 - z_{1-\alpha/2})} \right\}
\]

\[
p_2 = \Phi\left\{ z_0 + \frac{z_0 + z_{1-\alpha/2}}{1 - a(z_0 + z_{1-\alpha/2})} \right\}
\]
where $z_{1-\alpha/2}$ is the $(1-\alpha/2)$th quantile of the normal distribution. The bias-corrected and accelerated ($BC_a$) method yields confidence intervals

$$\left[ \theta^*_p, \theta^*_2 \right]$$

where $\theta^*_p$ is the $p$th quantile of the bootstrap distribution as defined previously. The bias-corrected (but not accelerated) method is a special case of $BC_a$ with $a = 0$.

bc, bca, normal, and percentile may be used together.

Options for estat

bc is the default and displays bias-corrected confidence intervals.

bca displays bias-corrected and accelerated confidence intervals. This option assumes that you also specified the bca option on the bootstrap prefix command.

normal displays normal approximation confidence intervals.

percentile displays percentile confidence intervals.

all displays all available confidence intervals.

noheader suppresses display of the table header. This option implies nolegend.

nolegend suppresses display of the table legend, which identifies the rows of the table with the expressions they represent.

verbose requests that the full table legend be displayed.
Remarks and examples

Example 1

The estat bootstrap postestimation command produces a table containing the observed value of the statistic, an estimate of its bias, the bootstrap standard error, and up to four different confidence intervals.

If we were interested merely in getting bootstrap standard errors for the model coefficients, we could use the bootstrap prefix with our estimation command. If we were interested in performing a thorough bootstrap analysis of the model coefficients, we could use the estat bootstrap postestimation command after fitting the model with the bootstrap prefix.

Using example 1 from [R] bootstrap, we need many more replications for the confidence interval types other than the normal based, so let’s rerun the estimation command. We will reset the random-number seed—in case we wish to reproduce the results—increase the number of replications, and save the bootstrap distribution as a dataset called bsauto.dta.

```
use https://www.stata-press.com/data/r16/auto
(1978 Automobile Data)
set seed 1
bootstrap _b, reps(1000) saving(bsauto) bca: regress mpg weight gear foreign
(output omitted)
estat bootstrap, all
```

```
Linear regression
Number of obs = 74
Replications = 1,000

(N) normal confidence interval
(P) percentile confidence interval
(BC) bias-corrected confidence interval
(BCa) bias-corrected and accelerated confidence interval

The estimated standard errors here differ from our previous estimates using only 100 replications by, respectively, 7%, 6%, 8%, and 4%; see example 1 of [R] bootstrap. So much for our advice that 50–200 replications are good enough to estimate standard errors. Well, the more replications the better—that advice you should believe.
Which of the methods to compute confidence intervals should we use? If the statistic is unbiased, the percentile \( (P) \) and bias-corrected \( (BC) \) methods should give similar results. The bias-corrected confidence interval will be the same as the percentile confidence interval when the observed value of the statistic is equal to the median of the bootstrap distribution. Thus, for unbiased statistics, the two methods should give similar results as the number of replications becomes large. For biased statistics, the bias-corrected method should yield confidence intervals with better coverage probability (closer to the nominal value of 95% or whatever was specified) than the percentile method. For statistics with variances that vary as a function of the parameter of interest, the bias-corrected and accelerated method \( (BC_a) \) will typically have better coverage probability than the others.

When the bootstrap distribution is approximately normal, all of these methods should give similar confidence intervals as the number of replications becomes large. If we examine the normality of these bootstrap distributions using, say, the \texttt{pnorm} command (see \textit{\texttt{R} Diagnostic plots}), we see that they closely follow a normal distribution. Thus here, the normal approximation would also be a valid choice. The chief advantage of the normal-approximation method is that it (supposedly) requires fewer replications than the other methods. Of course, it should be used only when the bootstrap distribution exhibits normality.

We can load \texttt{bsauto.dta} containing the bootstrap distributions for these coefficients:

\begin{verbatim}
. use bsauto
(bootstrap: regress)
. describe *

storage  display  value
variable name  type  format  label  variable label

_b_weight  float  %9.0g  _b[weight]
_b_gear_ratio  float  %9.0g  _b[gear_ratio]
_b_foreign  float  %9.0g  _b[foreign]
_b_cons  float  %9.0g  _b[_cons]
\end{verbatim}

We can now run other commands, such as \texttt{pnorm}, on the bootstrap distributions. As with all standard estimation commands, we can use the \texttt{bootstrap} command to replay its output table. The default variable names assigned to the statistics in \texttt{exp_list} are \_bs\_1, \_bs\_2, \ldots, and each variable is labeled with the associated expression. The naming convention for the extended expressions \_b and \_se is to prepend \_b\_ and \_se\_, respectively, onto the name of each element of the coefficient vector. Here the first coefficient is \_b[weight], so \texttt{bootstrap} named it \_b\_weight.

### Description

`boxcox` finds the maximum likelihood estimates of the parameters of the Box–Cox transform, the coefficients on the independent variables, and the standard deviation of the normally distributed errors. Any `depvar` or `indepvars` to be transformed must be strictly positive. Options can be used to control which variables remain untransformed.

### Quick start

**Box–Cox transform of \( y \) in a model of \( y \) as a function of \( x_1 \)**

```
boxcox y x1
```

**Same as above**

```
boxcox y x1, model(lhsonly)
```

**Likelihood-ratio test for each scale-variant parameter**

```
boxcox y x1, lrtest
```

**Different transform for each side and adding covariates \( x_2 \) and \( x_3 \)**

```
boxcox y x1 x2 x3, model(theta)
```

**Same transform for both sides, and include \( x_3 \) as an untransformed variable transformation**

```
boxcox y x1 x2, model(lambda) notrans(x3)
```

</table>

`depvar` and `indepvars` may contain time-series operators; see [U] 11.4.4 Time-series varlists.

`bootstrap`, `by`, `jackknife`, `rolling`, `statsby`, and `xi` are allowed; see [U] 11.1.10 Prefix commands.

Weights are not allowed with the `bootstrap` prefix; see [R] bootstrap.

`fweight` s and `iweight` s are allowed; see [U] 11.1.6 weight.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

**Options**

`noconstant`; see [R] Estimation options.

`model(lhsonly | rhsonly | lambda | theta)` specifies which of the four models to fit.

- `model(lhsonly)` applies the Box–Cox transform to `depvar` only. `model(lhsonly)` is the default.
- `model(rhsonly)` applies the transform to the `indepvars` only.
- `model(lambda)` applies the transform to both `depvar` and `indepvars`, and they are transformed by the same parameter.
- `model(theta)` applies the transform to both `depvar` and `indepvars`, but this time, each side is transformed by a separate parameter.

`notrans(varlist)` specifies that the variables in `varlist` not be transformed when included in the model. You can specify `notrans(varlist)` with `model(lhsonly)`, but the results will be the same as specifying the variables in `varlist` in `indepvars`.

`level(#)`; see [R] Estimation options.
lrtest specifies that a likelihood-ratio test of significance be performed and reported for each independent variable.

log and nolog specify whether to display the iteration log. The iteration log is displayed by default unless you used set iterlog off to suppress it; see set iterlog in [R] set iter. These options control the iteration log produced by the full model and, if option lrtest is specified, by the fitted restricted models.

nologlr suppresses the iteration log when fitting the restricted models required by the lrtest option.
mmaximize_options: iterate(\#) and from(init_specs); see [R] Maximize.

Remarks and examples

Remarks are presented under the following headings:

Introduction
Theta model
Lambda model
Left-hand-side-only model
Right-hand-side-only model

Introduction

The Box–Cox transform
\[
y^{(\lambda)} = \frac{y^\lambda - 1}{\lambda}
\]

has been widely used in applied data analysis. Box and Cox (1964) developed the transformation and argued that the transformation could make the residuals more closely normal and less heteroskedastic. Cook and Weisberg (1982) discuss the transform in this light. Because the transform embeds several popular functional forms, it has received some attention as a method for testing functional forms, in particular,

\[
y^{(\lambda)} = \begin{cases} 
  y - 1 & \text{if } \lambda = 1 \\
  \ln(y) & \text{if } \lambda = 0 \\
  1 - 1/y & \text{if } \lambda = -1 
\end{cases}
\]

Theta model

boxcox obtains the maximum likelihood estimates of the parameters for four different models. The most general of the models, the theta model, is

$$y_j^{(\theta)} = \beta_0 + \beta_1 x_{1j}^{(\lambda)} + \beta_2 x_{2j}^{(\lambda)} + \cdots + \beta_k x_{kj}^{(\lambda)} + \gamma_1 z_{1j} + \gamma_2 z_{2j} + \cdots + \gamma_l z_{lj} + \epsilon_j$$

where $\epsilon \sim N(0, \sigma^2)$. Here the dependent variable, $y$, is subject to a Box–Cox transform with parameter $\theta$. Each of the indepvars, $x_1, x_2, \ldots, x_k$, is transformed by a Box–Cox transform with parameter $\lambda$. The $z_1, z_2, \ldots, z_l$ specified in the notrans() option are independent variables that are not transformed.

Box and Cox (1964) argued that this transformation would leave behind residuals that more closely follow a normal distribution than those produced by a simple linear regression model. Bear in mind that the normality of $\epsilon$ is assumed and that boxcox obtains maximum likelihood estimates of the $k + l + 4$ parameters under this assumption. boxcox does not choose $\lambda$ and $\theta$ so that the residuals are approximately normally distributed. If you are interested in this type of transformation to normality, see the official Stata commands lnskew0 and bcskew0 in [R] lnskew0. However, those commands work on a more restrictive model in which none of the independent variables is transformed.

Example 1

Below we fit a theta model to a nonrepresentative extract of the Second National Health and Nutrition Examination Survey (NHANES II) dataset discussed in McDowell et al. (1981).

We model individual-level diastolic blood pressure (bpdiast) as a function of the transformed variables body mass index (bmi) and cholesterol level (tcresult) and of the untransformed variables age (age) and sex (sex).
. use https://www.stata-press.com/data/r16/nhanes2

</tbody>
</table>
The output is composed of the iteration logs and three distinct tables. The first table contains a standard header for a maximum likelihood estimator and a standard output table for the Box–Cox transform parameters. The second table contains the estimates of the scale-variant parameters. The third table contains the output from likelihood-ratio tests on three standard functional form specifications.

The right-hand-side and the left-hand-side transformations each add to the regression fit at the 1% significance level and are both positive but less than 1. All the variables have significant impacts on diastolic blood pressure, \( bpdiast \). As expected, the transformed variables—the body mass index, \( bmi \), and cholesterol level, \( tresult \)—contribute to higher blood pressure. The last output table shows that the linear, multiplicative inverse, and log specifications are strongly rejected.

Technical note

Spitzer (1984) showed that the Wald tests of the joint significance of the coefficients of the right-hand-side variables, either transformed or untransformed, are not invariant to changes in the scale of the transformed dependent variable. Davidson and MacKinnon (1993) also discuss this point. This problem demonstrates that Wald statistics can be manipulated in nonlinear models. Lafontaine and White (1986) analyze this problem numerically, and Phillips and Park (1988) analyze it by using Edgeworth expansions. See Drukker (2000) for a more detailed discussion of this issue. Because the parameter estimates and their Wald tests are not scale invariant, no Wald tests or confidence intervals are reported for these parameters. However, when the `lrtest` option is specified, likelihood-ratio tests are performed and reported. Schlesselman (1971) showed that, if a constant is included in the model, the parameter estimates of the Box–Cox transforms are scale invariant. For this reason, we strongly recommend that you not use the `noconstant` option.

The `lrtest` option does not perform a likelihood-ratio test on the constant, so no value for this statistic is reported. Unless the data are properly scaled, the restricted model does not often converge. For this reason, no likelihood-ratio test on the constant is performed by the `lrtest` option. However, if you have a special interest in performing this test, you can do so by fitting the constrained model separately. If problems with convergence are encountered, rescaling the data by their means may help.

Lambda model

A less general model than the one above is called the `lambda` model. It specifies that the same parameter be used in both the left-hand-side and right-hand-side transformations. Specifically,

\[
y_j^{(\lambda)} = \beta_0 + \beta_1 x_1^{(\lambda)} + \beta_2 x_2^{(\lambda)} + \cdots + \beta_k x_k^{(\lambda)} + \gamma_1 z_1 + \gamma_2 z_2 + \cdots + \gamma_l z_l + \epsilon_j
\]

where \( \epsilon \sim N(0, \sigma^2) \). Here the `depvar` variable, \( y \), and each of the `indepvars`, \( x_1, x_2, \ldots, x_k \), is transformed by a Box–Cox transform with the common parameter \( \lambda \). Again the \( z_1, z_2, \ldots, z_l \) are independent variables that are not transformed.

Left-hand-side-only model

Even more restrictive than a common transformation parameter is transforming the dependent variable only. Because the dependent variable is on the left-hand side of the equation, this model is known as the `lhsonly` model. Here you are estimating the parameters of the model.
\[ y_j^{(\theta)} = \beta_0 + \beta_1 x_{1j} + \beta_2 x_{2j} + \cdots + \beta_k x_{kj} + \epsilon_j \]

where \( \epsilon \sim N(0, \sigma^2) \). Here only the depvar, \( y \), is transformed by a Box–Cox transform with the parameter \( \theta \).

### Example 2

In this example, we model the transform of diastolic blood pressure as a linear combination of the untransformed body mass index, cholesterol level, age, and sex.

```
. boxcox bpdiast bmi tcretult age sex, model(lhsonly) lrtest nolog nologlr

The maximum likelihood estimate of the transformation parameter for this model is positive and significant. Once again, all the scale-variant parameters are significant, and we find a positive impact of body mass index (bmi) and cholesterol levels (tcretult) on the transformed diastolic blood pressure (bpdiast). This model rejects the linear, multiplicative inverse, and log specifications.
Right-hand-side-only model

The fourth model leaves the *depvar* alone and transforms a subset of the *indepvars* using the parameter $\lambda$. This is the *rhsonly* model. In this model, the *depvar*, $y$, is given by

$$y_j = \beta_0 + \beta_1 x_{1j}^{(\lambda)} + \beta_2 x_{2j}^{(\lambda)} + \cdots + \beta_k x_{kj}^{(\lambda)} + \gamma_1 z_{1j} + \gamma_2 z_{2j} + \cdots + \gamma_l z_{lj} + \epsilon_j$$

where $\epsilon \sim N(0, \sigma^2)$. Here each of the *indepvars*, $x_1, x_2, \ldots, x_k$, is transformed by a Box–Cox transform with the parameter $\lambda$. Again the $z_1, z_2, \ldots, z_l$ are independent variables that are not transformed.

Example 3

Now we consider a *rhsonly* model in which the regressors *sex* and *age* are not transformed.

The maximum likelihood estimate of the transformation parameter in this model is positive and significant at the 1% level. The transformed *bmi* coefficient behaves as expected, and the remaining scale-variant parameters are significant at the 1% level. This model rejects the multiplicative inverse and log specifications strongly. However, we cannot reject the hypothesis that the model is linear.
boxcox stores the following in e():

Scalars
- e(N) number of observations
- e(ll) log likelihood
- e(chi2) LR statistic of full vs. comparison
- e(df_m) full model degrees of freedom
- e(ll0) log likelihood of the restricted model
- e(df_r) restricted model degrees of freedom
- e(ll_t1) log likelihood of model \( \lambda=\theta=1 \)
- e(chi2_t1) LR of \( \lambda=\theta=1 \) vs. full model
- e(p_t1) \( p \)-value of \( \lambda=\theta=1 \) vs. full model
- e(ll_t1) log likelihood of model \( \lambda=\theta=-1 \)
- e(chi2_t1) LR of \( \lambda=\theta=-1 \) vs. full model
- e(p_t1) \( p \)-value of \( \lambda=\theta=-1 \) vs. full model
- e(ll_t0) log likelihood of model \( \lambda=\theta=0 \)
- e(chi2_t0) LR of \( \lambda=\theta=0 \) vs. full model

Functions
- e(sample) marks estimation sample

Note: e(V) contains all zeros, except for the elements that correspond to the parameters of the Box–Cox transform.
Methods and formulas

In the internal computations,

\[ y^{(\lambda)} = \begin{cases} \frac{y^{\lambda-1}}{\lambda} & \text{if } |\lambda| > 10^{-10} \\ \ln(y) & \text{otherwise} \end{cases} \]

The unconcentrated log likelihood for the theta model is

\[ \ln L = \left( -\frac{N}{2} \right) \left\{ \ln(2\pi) + \ln(\sigma^2) \right\} + (\theta - 1) \sum_{i=1}^{N} \ln(y_i) - \left( \frac{1}{2\sigma^2} \right) \text{SSR} \]

where

\[ \text{SSR} = \sum_{i=1}^{N} (y_i^{(\theta)} - \beta_0 + \beta_1 x_{i1}^{(\lambda)} + \beta_2 x_{i2}^{(\lambda)} + \cdots + \beta_k x_{ik}^{(\lambda)} + \gamma_1 z_{i1} + \gamma_2 z_{i2} + \cdots + \gamma_l z_{il})^2 \]

Writing the SSR in matrix form,

\[ \text{SSR} = (y^{(\theta)} - X^{(\lambda)} b' - Zg')'(y^{(\theta)} - X^{(\lambda)} b' - Zg') \]

where \( y^{(\theta)} \) is an \( N \times 1 \) vector of elementwise transformed data, \( X^{(\lambda)} \) is an \( N \times k \) matrix of elementwise transformed data, \( Z \) is an \( N \times l \) matrix of untransformed data, \( b \) is a \( 1 \times k \) vector of coefficients, and \( g \) is a \( 1 \times l \) vector of coefficients. Letting

\[ W_\lambda = \begin{pmatrix} X^{(\lambda)} & Z \end{pmatrix} \]

be the horizontal concatenation of \( X^{(\lambda)} \) and \( Z \) and

\[ d' = \begin{pmatrix} b' \\ g' \end{pmatrix} \]

be the vertical concatenation of the coefficients yields

\[ \text{SSR} = (y^{(\theta)} - W_\lambda d')'(y^{(\theta)} - W_\lambda d') \]

For given values of \( \lambda \) and \( \theta \), the solutions for \( d' \) and \( \sigma^2 \) are

\[ \hat{d}' = (W_\lambda' W_\lambda)^{-1} W_\lambda' y^{(\theta)} \]

and

\[ \hat{\sigma}^2 = \frac{1}{N} \left( y^{(\theta)} - W_\lambda \hat{d}' \right)' \left( y^{(\theta)} - W_\lambda \hat{d}' \right) \]

Substituting these solutions into the log-likelihood function yields the concentrated log-likelihood function

\[ \ln L_c = \left( -\frac{N}{2} \right) \left\{ \ln(2\pi) + 1 + \ln(\hat{\sigma}^2) \right\} + (\theta - 1) \sum_{i=1}^{N} \ln(y_i) \]
Similar calculations yield the concentrated log-likelihood function for the \texttt{lambda} model,

$$\ln L_c = \left( -\frac{N}{2} \right) \left\{ \ln(2\pi) + 1 + \ln(\hat{\sigma}^2) \right\} + (\lambda - 1) \sum_{i=1}^{N} \ln(y_i)$$

the \texttt{lhsonly} model,

$$\ln L_c = \left( -\frac{N}{2} \right) \left\{ \ln(2\pi) + 1 + \ln(\hat{\sigma}^2) \right\} + (\theta - 1) \sum_{i=1}^{N} \ln(y_i)$$

and the \texttt{rhsonly} model,

$$\ln L_c = \left( -\frac{N}{2} \right) \left\{ \ln(2\pi) + 1 + \ln(\hat{\sigma}^2) \right\}$$

where $\hat{\sigma}^2$ is specific to each model and is defined analogously to that in the \texttt{theta} model.

predict

Description for predict

predict creates a new variable containing predictions such as predicted values and residuals.

Menu for predict

Statistics > Postestimation

Syntax for predict

    predict [type] newvar [if] [in] [, statistic options]

statistic     Description

Main

  yhat           predicted value of y; the default
  residuals      residuals

options       Description

Options

  smear          compute statistic using smearing method; the default
  bt             compute statistic using back-transform method

These statistics are available both in and out of sample; type predict ... if e(sample) ... if wanted only for the estimation sample.

Options for predict

Main

  yhat, the default, calculates the predicted value of the dependent variable.
  residuals calculates the residuals, that is, the observed value minus the predicted value.

Options

  smear          calculates the statistics yhat and residuals using the smearing method proposed by
                  Duan (1983) (see Methods and formulas for a description of this method). smear is the default.
  bt             calculates the statistics yhat and residuals using the back-transform method (see
                  Methods and formulas for a description of this method).

Remarks and examples

Below we present two examples that illustrate how to use the smear and bt options.
Example 1: Predictions with the smearing option

In this example, we calculate the predicted values of diastolic blood pressure, `bpdiast`, that arise from the `theta` model calculated in example 1 of [R] boxcox.

```
. use https://www.stata-press.com/data/r16/nhanes2
. boxcox bpdiast bmi tcresult, notrans(age sex) model(theta) lrtest
(output omitted)
. predict yhat
(statistic yhat and option smearing are assumed)
```

In the expression above, `yhat` is the name we gave to the estimates of the conditional expectation. Given that we did not specify any statistic or option, the corresponding defaults `yhat` and `smearing` were assumed.

As the summary table below illustrates, the mean of the dependent variable is close to the mean of the predicted value `yhat`. This indicates that the `theta` model does a good job approximating the true value of diastolic blood pressure, `bpdiast`.

```
. summarize bpdiast yhat
    Variable |     Obs  Mean    Std. Dev.   Min    Max
-------------|---------|---------|-----------------|-------|-------
    bpdiast   | 10351   81.715  12.92722       35   150
      yhat    | 10351   81.71406  5.983486  66.93709  110.5283
```

Similarly, we could have asked that residuals be calculated. Here we again use the default `smearing` option:

```
. predict resid, residuals
(option smearing assumed to compute residuals)
```

Example 2: Predictions with the btransform option

In this example, we illustrate the tradeoffs involved by using the `btransform` option as opposed to the default `smearing` option. Continuing with example 1, we compute the predicted values using the back-transform method.

```
. predict yhatb, btransform
(statistic yhat assumed)
```

We now compute the predicted values using the `smearing` option and summarize both computations.

```
. predict yhats
(statistic yhat and option smearing are assumed)
. summarize bpdiast yhats yhatb
    Variable |     Obs  Mean    Std. Dev.   Min    Max
-------------|---------|---------|-----------------|-------|-------
    bpdiast   | 10351   81.715  12.92722       35   150
      yhats   | 10351   81.71406  5.983486  66.93709  110.5283
      yhatb   | 10351   81.08018  5.955490  66.37479  109.7671
```

As can be seen from the mean and the standard deviation of the summary table, the predicted values using the back-transform method give biased estimates but are less variable than those coming from the smearing method. However, the efficiency loss is small compared with the bias reduction.
Technical note

boxcox estimates variances only for the $\lambda$ and $\theta$ parameters (see the technical note in [R] boxcox), so the extent to which postestimation commands can be used following boxcox is limited. Formulas used in lincom, nlcom, test, and testnl are dependent on the estimated variances. Therefore, the use of these commands is limited and generally applicable only to inferences on the $\lambda$ and $\theta$ coefficients.

Methods and formulas

The computation of the expected value of the dependent variable conditional on the regressors for the Box–Cox model does not follow the logic of the standard linear regression model because the random disturbance does not vanish from the conditional expectation and must be accounted for. To show this, we will revisit the lhsonly model described by

$$y_j^{(\lambda)} = \beta_0 + \beta_1 x_{1j} + \beta_2 x_{2j} + \cdots + \beta_{(k-1)} x_{(k-1)j} + \epsilon_j$$

where

$$y^{(\lambda)} = \frac{y^{\lambda} - 1}{\lambda}$$

and

$$y^{(\lambda)} = \begin{cases} y - 1 & \text{if } \lambda = 1 \\ \ln(y) & \text{if } \lambda = 0 \\ 1 - 1/y & \text{if } \lambda = -1 \end{cases}$$

For the presentation below, let $y^{(\lambda)}$ be an $N \times 1$ vector of elementwise transformed data, $X$ be an $N \times k$ matrix of regressors, $\beta$ be a $k \times 1$ vector of parameters, and $\iota$ be an $n \times 1$ vector of ones.

If we were interested in $E(y^{(\lambda)}|X)$, then the conventional logic would follow, and we would obtain predictions as $y^{(\lambda)}(\hat{\beta}) = X\hat{\beta}$, where $\hat{\beta}$ is the estimate of $\beta$. However, to estimate the conditional expectation of $y$, we need to isolate it on the left-hand side of the model. In the case of the lhsonly model, this yields

$$y = \left\{ \lambda(X\hat{\beta} + \epsilon) + \iota \right\}^{1/\lambda}$$

The conditional expectation is then defined by

$$E(y|X) = \int \{\lambda(X\beta + \epsilon) + \iota\}^{1/\lambda} dF(\epsilon|X)$$

In the expression above, $dF(\epsilon|X)$ corresponds to the cdf of $\epsilon$ conditional on the regressors. It is also clear that the random disturbance does not vanish.

To address this issue, the default methodology used by predict computes this integral using the smearing method proposed by Duan (1983) to implement a two-step estimator, as was suggested by Abrevaya (2002).

In the first step, we get an estimate for $\epsilon$ defined as

$$\hat{\epsilon} = y^{(\lambda)} - X\hat{\beta}$$
In the second step, for each \( j \) we compute our predicted values as the sum:

\[
\hat{y}_j = \frac{1}{N} \sum_{i=1}^{N} \{\hat{\lambda}(x_j\hat{\beta} + \hat{\epsilon}_i) + 1\}^{1/\hat{\lambda}}
\]

In the expression above, \( x_j \) is the \( j \)th row of the matrix \( X \) (in other words, the values of the covariates for individual \( j \)), and \( \hat{\epsilon}_i \) is the residual for individual \( i \). The result of this summation gives us the conditional expectation of the dependent variable for individual \( j \). Given that this operation is performed for each individual \( j \), the methodology is computationally intensive.

The back-transform method can be understood as a naïve estimate that disregards the random disturbance. The predictions using this approach are given by

\[
\hat{y}_j = \left(\hat{\lambda}x_j\hat{\beta} + 1\right)^{1/\hat{\lambda}}
\]

[U] 20 Estimation and postestimation commands
**brier — Brier score decomposition**

**Description**

*brier* computes the Yates, Sanders, and Murphy decompositions of the Brier mean probability score. The Brier score is a measure of disagreement between the observed outcome and a forecast (prediction).

**Quick start**

Brier score decomposition for binary outcome *y* and predicted probability *pvar*

```
brier y pvar
```

As above, but use 5 groups rather than 10 to compute the decomposition

```
brier y pvar, group(5)
```

**Menu**

Statistics > Epidemiology and related > Other > Brier score decomposition
Syntax

```
brier outcomevar forecastvar [if] [in] [, group(#)]
```

`outcomevar` is a binary variable indicating the outcome of the experiment.
`forecastvar` is the corresponding probability of a positive outcome and must be between 0 and 1.
`by` is allowed; see [D] by.

Option

```
Main
```

`group(#)` specifies the number of groups that will be used to compute the decomposition. `group(10)` is the default.

Remarks and examples

You have a binary (0/1) response and a formula that predicts the corresponding probabilities of having observed a positive outcome (1). If the probabilities were obtained from logistic regression, there are many methods that assess goodness of fit (see, for instance, [R] estat gof). However, the probabilities might be computed from a published formula or from a model fit on another sample, both completely unrelated to the data at hand, or perhaps the forecasts are not from a formula at all. In any case, you now have a test dataset consisting of the forecast probabilities and observed outcomes. Your test dataset might, for instance, record predictions made by a meteorologist on the probability of rain along with a variable recording whether it actually rained.

The Brier score is an aggregate measure of disagreement between the observed outcome and a prediction—the average squared error difference. The Brier score decomposition is a partition of the Brier score into components that suggest reasons for discrepancy. These reasons fall roughly into three groups: 1) lack of overall calibration between the average predicted probability and the actual probability of the event in your data, 2) misfit of the data in groups defined within your sample, and 3) inability to match actual 0 and 1 responses.

Problem 1 refers to simply overstating or understating the probabilities.

Problem 2 refers to what is standardly called a goodness-of-fit test: the data are grouped, and the predictions for the group are compared with the outcomes.

Problem 3 refers to an individual-level measure of fit. Imagine that the grouped outcomes are predicted on average correctly but that within the group, the outcomes are poorly predicted.

Using logit or probit analysis to fit your data will guarantee that there is no lack of fit due to problem 1, and a good model fitter will be able to avoid problem 2. Problem 3 is inherent in any prediction exercise.
We have data on the outcomes of 20 basketball games (win) and the probability of victory predicted by a local pundit (for).

Sanders-modified Brier score 0.1861
Sanders resolution 0.1400
Outcome index variance 0.2275
Murphy resolution 0.0875
Reliability-in-the-small 0.0461
Forecast variance 0.0438
Excess forecast variance 0.0285
Minimum forecast variance 0.0153
Reliability-in-the-large 0.0294
2*Forecast-Outcome-Covar 0.1179

The mean probabilities of forecast and outcome are simply the mean of the predicted probabilities and the actual outcomes (wins/losses). The correlation is the product-moment correlation between them.

The Brier score measures the total difference between the event (winning) and the forecast probability of that event as an average squared difference. As a benchmark, a perfect forecaster would have a Brier score of 0, a perfect misforecaster (predicts probability of win is 1 when loses and 0 when wins) would have a Brier score of 1, and a fence-sitter (forecasts every game as 50/50) would have a Brier score of 0.25. Our pundit is doing reasonably well.

Spiegelhalter’s $z$ statistic is a standard normal test statistic for testing whether an individual Brier score is extreme. The ROC area is the area under the receiver operating curve, and the associated test is a test of whether it is greater than 0.5. The more accurate the forecast probabilities, the larger the ROC area.

The Sanders-modified Brier score measures the difference between a grouped forecast measure and the event, where the data are grouped by sorting the sample on the forecast and dividing it into approximately equally sized groups. The difference between the modified and the unmodified score is typically minimal. For this and the other statistics that require grouping—the Sanders and Murphy resolutions and reliability-in-the-small—to be well-defined, group boundaries are chosen so as not to allocate observations with the same forecast probability to different groups. This task is done by grouping on the forecast using `xtile`, n(#), with # being the number of groups; see `[D] pctile`.

The Sanders resolution measures error that arises from statistical considerations in evaluating the forecast for a group. A group with all positive or all negative outcomes would have a Sanders resolution of 0; it would most certainly be feasible to predict exactly what happened to each member of the group. If the group had 40% positive responses, on the other hand, a forecast that assigned $p = 0.4$ to each member of the group would be a good one, and yet, there would be “errors” in
the squared difference sense. The “error” would be \((1 - 0.4)^2\) or \((0 - 0.4)^2\) for each member. The Sanders resolution is the average across groups of such “expected” errors. The 0.1400 value in our data from an overall Brier score of 0.1828 or 0.1861 suggests that a substantial portion of the “error” in our data is inherent.

Outcome index variance is just the variance of the outcome variable. This is the expected value of the Brier score if all the forecast probabilities were merely the average observed outcome. Remember that a fence-sitter has an expected Brier score of 0.25; a smarter fence sitter (who would guess \(p = 0.65\) for these data) would have a Brier score of 0.2275.

The Murphy resolution measures the variation in the average outcomes across groups. If all groups have the same frequency of positive outcomes, little information in any forecast is possible, and the Murphy resolution is 0. If groups differ markedly, the Murphy resolution is as large as 0.25. The 0.0875 means that there is some variation but not a lot, and 0.0875 is probably higher than in most real cases. If you had groups in your data that varied between 40% and 60% positive outcomes, the Murphy resolution would be 0.01; between 30% and 70%, it would be 0.04.

Reliability-in-the-small measures the error that comes from the average forecast within group not measuring the average outcome within group—a classical goodness-of-fit measure, with 0 meaning a perfect fit and 1 meaning a complete lack of fit. The calculated value of 0.0461 shows some amount of lack of fit. Remember, the number is squared, and we are saying that probabilities could be just more than \(\sqrt{0.0461} = 0.215\) or 21.5% off.

Forecast variance measures the amount of discrimination being attempted—that is, the variation in the forecasted probabilities. A small number indicates a fence-sitter making constant predictions. If the forecasts were from a logistic regression model, forecast variance would tend to increase with the amount of information available. Our pundit shows considerable forecast variance of 0.0438 (standard deviation \(\sqrt{0.0438} = 0.2093\)), which is in line with the reliability-in-the-small, suggesting that the forecaster is attempting as much variation as is available in these data.

Excess forecast variance is the amount of actual forecast variance over a theoretical minimum. The theoretical minimum—called the minimum forecast variance—corresponds to forecasts of \(p_0\) for observations ultimately observed to be negative responses and \(p_1\) for observations ultimately observed to be positive outcomes. Moreover, \(p_0\) and \(p_1\) are set to the average forecasts made for the ultimate negative and positive outcomes. These predictions would be just as good as the predictions the forecaster did make, and any variation in the actual forecast probabilities above this is useless. If this number is large, above 1%–2%, then the forecaster may be attempting more than is possible. The 0.0285 in our data suggests this possibility.

Reliability-in-the-large measures the discrepancy between the mean forecast and the observed fraction of positive outcomes. This discrepancy will be 0 for forecasts made by most statistical models—at least when measured on the same sample used for estimation—because they, by design, reproduce sample means. For our human pundit, the 0.0294 says that there is a \(\sqrt{0.0294}\), or 17-percentage-point, difference. (This difference can also be found by calculating the difference in the averages of the observed outcomes and forecast probabilities: \(0.65 - 0.4785 = 0.17\).) That difference, however, is not significant, as we would see if we typed \texttt{ttest win=for}; see \texttt{R} \texttt{ttest}. If these data were larger and the bias persisted, this difference would be a critical shortcoming of the forecast.

Twice the forecast-outcome covariance is a measure of how accurately the forecast corresponds to the outcome. The concept is similar to that of \(R\)-squared in linear regression.
Stored results

\texttt{brier} stores the following in \texttt{r()}:

Methods and formulas

See Wilks (2011) or Schmidt and Griffith (2005) for a discussion of the Brier score.

Let \( d_j, j = 1, \ldots, N \), be the observed outcomes with \( d_j = 0 \) or \( d_j = 1 \), and let \( f_j \) be the corresponding forecasted probabilities that \( d_j \) is 1, \( 0 \leq f_j \leq 1 \). Assume that the data are ordered so that \( f_{j+1} \geq f_j \) (\texttt{brier} sorts the data to obtain this order). Divide the data into \( K \) nearly equally sized groups, with group 1 containing observations 1 through \( j_2 - 1 \), group 2 containing observations \( j_2 \) through \( j_3 - 1 \), and so on.

Define

\[
\bar{f}_0 = \text{average } f_j \text{ among } d_j = 0 \\
\bar{f}_1 = \text{average } f_j \text{ among } d_j = 1 \\
\bar{f} = \text{average } f_j \\
\bar{d} = \text{average } d_j \\
\tilde{f}_k = \text{average } f_j \text{ in group } k \\
\tilde{d}_k = \text{average } d_j \text{ in group } k \\
\tilde{n}_k = \text{number of observations in group } k
\]

The Brier score is \( \sum_j (d_j - f_j)^2 / N \).

The Sanders-modified Brier score is \( \sum_j (d_j - \tilde{f}_{k(j)})^2 / N \).
Let $p_j$ denote the true but unknown probability that $d_j = 1$. Under the null hypothesis that $p_j = f_j$ for all $j$, Spiegelhalter (1986) determined that the expectation and variance of the Brier score is given by the following:

$$E(\text{Brier}) = \frac{1}{N} \sum_{j=1}^{N} f_j (1 - f_j)$$

$$\text{Var}(\text{Brier}) = \frac{1}{N^2} \sum_{j=1}^{N} f_j (1 - f_j)(1 - 2f_j)^2$$

Denoting the observed value of the Brier score by $O(\text{Brier})$, Spiegelhalter’s $z$ statistic is given by

$$Z = \frac{O(\text{Brier}) - E(\text{Brier})}{\sqrt{\text{Var}(\text{Brier})}}$$

The corresponding $p$-value is given by the upper-tail probability of $Z$ under the standard normal distribution.

The area under the ROC curve is estimated by applying the trapezoidal rule to the empirical ROC curve. This area is Wilcoxon’s test statistic, so the corresponding $p$-value is just that of a one-sided Wilcoxon test of the null hypothesis that the distribution of predictions is constant across the two outcomes.

The Sanders resolution is $\sum_{k} \tilde{n}_k \{\tilde{d}_k (1 - \tilde{d}_k)\}/N$.

The outcome index variance is $\overline{d}(1 - \overline{d})$.

The Murphy resolution is $\sum_{k} \tilde{n}_k (\tilde{d}_k - \overline{d})^2/N$.

Reliability-in-the-small is $\sum_{k} \tilde{n}_k (\tilde{d}_k - \tilde{f}_k)^2/N$.

The forecast variance is $\sum_{j} (f_j - \overline{f})^2/N$.

The minimum forecast variance is $\{\sum_{j \in F} (f_j - \overline{f}_0)^2 + \sum_{j \in S} (f_j - \overline{f}_1)^2\}/N$, where $F$ is the set of observations for which $d_j = 0$ and $S$ is the complement.

The excess forecast variance is the difference between the forecast variance and the minimum forecast variance.

Reliability-in-the-large is $(\overline{f} - \overline{d})^2$.

Twice the outcome covariance is $2(\overline{f}_1 - \overline{f}_0)\overline{d}(1 - \overline{d})$.

Glenn Wilson Brier (1913–1998) was an American meteorological statistician who, after obtaining degrees in physics and statistics, was for many years head of meteorological statistics at the U.S. Weather Bureau in Washington, DC. In the latter part of his career, he was associated with Colorado State University. Brier worked especially on verification and evaluation of predictions and forecasts, statistical decision making, the statistical theory of turbulence, the analysis of weather modification experiments, and the application of permutation techniques.
Acknowledgment

We thank Richard Goldstein for his contributions to this improved version of `brier`.

### Description

`bsample` replaces the data in memory with a bootstrap sample (random sample with replacement) drawn from the current dataset. Clusters can be optionally sampled during each replication in place of observations. Bootstrap samples can also be selected within strata.

### Quick start

Bootstrap sample with the same number of observations as the current dataset

```
bsample
```

As above, but restrict to just 100 observations

```
bsample 100
```

Stratified bootstrap sample of 100 observations at each level of `svar`

```
bsample 100, strata(svar)
```

Bootstrap sample of 10 clusters identified by values of `cvar`

```
bsample 10, cluster(cvar)
```

As above, but create a new unique ID code for sampled clusters and store it in `cvar2`

```
bsample 10, cluster(cvar) idcluster(cvar2)
```

### Menu

Statistics > Resampling > Draw bootstrap sample
Syntax

```
bsample [exp] [if] [in] [ , options ]
```

where `exp` is a standard Stata expression specifying the size of the sample; see [U] 13 Functions and expressions.

`exp` must be less than or equal to `_N` (the number of observations; [U] 13.4 System variables (_variables)) when neither the `cluster()` nor the `strata()` option is specified. `_N` is the default when `exp` is not specified.

Observations that do not meet the optional if and in criteria are dropped from the resulting dataset.

<table>
<thead>
<tr>
<th>options</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>strata(varlist)</code></td>
<td>variables identifying strata</td>
</tr>
<tr>
<td><code>cluster(varlist)</code></td>
<td>variables identifying resampling clusters</td>
</tr>
<tr>
<td><code>idcluster(newvar)</code></td>
<td>create new cluster ID variable</td>
</tr>
<tr>
<td><code>weight(varname)</code></td>
<td>replace <code>varname</code> with frequency weights</td>
</tr>
</tbody>
</table>

Options

`strata(varlist)` specifies the variables identifying strata. If `strata()` is specified, bootstrap samples are selected within each stratum, and `exp` must be less than or equal to `_N` within the defined strata.

`cluster(varlist)` specifies the variables identifying resampling clusters. If `cluster()` is specified, the sample drawn during each replication is a bootstrap sample of clusters, and `exp` must be less than or equal to `N_c` (the number of clusters identified by the `cluster()` option). If `strata()` is also specified, `exp` must be less than or equal to the number of within-strata clusters.

`idcluster(newvar)` creates a new variable containing a unique identifier for each resampled cluster.

`weight(varname)` specifies a variable in which the sampling frequencies will be placed. `varname` must be an existing variable, which will be replaced. After `bsample`, `varname` can be used as an fweight in any Stata command that accepts fweights, which can speed up resampling for commands like `regress` and `summarize`. This option cannot be combined with `idcluster()`.

By default, `bsample` replaces the data in memory with the sampled observations; however, specifying the `weight()` option causes only the specified `varname` to be changed.
Remarks and examples

Below is a series of examples illustrating how `bsample` is used with various sampling schemes.

- **Example 1: Bootstrap sampling**
  
  We have data on the characteristics of hospital patients and wish to draw a bootstrap sample of 200 patients. We type
  ```
  . use https://www.stata-press.com/data/r16/bsample1
  . bsample 200
  . count
  200
  ```

- **Example 2: Stratified samples with equal sizes**
  
  Among the variables in our dataset is `female`, an indicator for the female patients. To get a bootstrap sample of 200 female patients and 200 male patients, we type
  ```
  . use https://www.stata-press.com/data/r16/bsample1, clear
  . bsample 200, strata(female)
  . tabulate female
  
<table>
<thead>
<tr>
<th>female</th>
<th>Freq.</th>
<th>Percent</th>
<th>Cum.</th>
</tr>
</thead>
<tbody>
<tr>
<td>male</td>
<td>200</td>
<td>50.00</td>
<td>50.00</td>
</tr>
<tr>
<td>female</td>
<td>200</td>
<td>50.00</td>
<td>100.00</td>
</tr>
<tr>
<td>Total</td>
<td>400</td>
<td>100.00</td>
<td></td>
</tr>
</tbody>
</table>
  ```

- **Example 3: Stratified samples with unequal sizes**
  
  To sample 300 females and 200 males, we must generate a variable that is 300 for females and 200 for males and then use this variable in `exp` when we call `bsample`.
  ```
  . use https://www.stata-press.com/data/r16/bsample1, clear
  . generate nsamp = cond(female,300,200)
  . bsample nsamp, strata(female)
  . tabulate female
  
<table>
<thead>
<tr>
<th>female</th>
<th>Freq.</th>
<th>Percent</th>
<th>Cum.</th>
</tr>
</thead>
<tbody>
<tr>
<td>male</td>
<td>200</td>
<td>40.00</td>
<td>40.00</td>
</tr>
<tr>
<td>female</td>
<td>300</td>
<td>60.00</td>
<td>100.00</td>
</tr>
<tr>
<td>Total</td>
<td>500</td>
<td>100.00</td>
<td></td>
</tr>
</tbody>
</table>
Example 4: Stratified samples with proportional sizes

Our original dataset has 2,392 males and 3,418 females.

```
use https://www.stata-press.com/data/r16/bsample1, clear
tabulate female
```

<table>
<thead>
<tr>
<th>female</th>
<th>Freq.</th>
<th>Percent</th>
<th>Cum.</th>
</tr>
</thead>
<tbody>
<tr>
<td>male</td>
<td>2,392</td>
<td>41.17</td>
<td>41.17</td>
</tr>
<tr>
<td>female</td>
<td>3,418</td>
<td>58.83</td>
<td>100.00</td>
</tr>
<tr>
<td>Total</td>
<td>5,810</td>
<td>100.00</td>
<td></td>
</tr>
</tbody>
</table>

To sample 10% from females and males, we type

```
bsample round(0.1*_N), strata(female)
```

bsample requires that the specified size of the sample be an integer, so we use the `round()` function to obtain the nearest integer to 0.1 × 2392 and 0.1 × 3418. Our sample now has 239 males and 342 females:

```
tabulate female
```

<table>
<thead>
<tr>
<th>female</th>
<th>Freq.</th>
<th>Percent</th>
<th>Cum.</th>
</tr>
</thead>
<tbody>
<tr>
<td>male</td>
<td>239</td>
<td>41.14</td>
<td>41.14</td>
</tr>
<tr>
<td>female</td>
<td>342</td>
<td>58.86</td>
<td>100.00</td>
</tr>
<tr>
<td>Total</td>
<td>581</td>
<td>100.00</td>
<td></td>
</tr>
</tbody>
</table>

Example 5: Samples satisfying a condition

For a bootstrap sample of 200 female patients, we type

```
use https://www.stata-press.com/data/r16/bsample1, clear
bsample 200 if female
tabulate female
```

<table>
<thead>
<tr>
<th>female</th>
<th>Freq.</th>
<th>Percent</th>
<th>Cum.</th>
</tr>
</thead>
<tbody>
<tr>
<td>female</td>
<td>200</td>
<td>100.00</td>
<td>100.00</td>
</tr>
<tr>
<td>Total</td>
<td>200</td>
<td>100.00</td>
<td></td>
</tr>
</tbody>
</table>
Example 6: Generating frequency weights

To identify the sampled observations using frequency weights instead of dropping unsampled observations, we use the `weight()` option (we will need to supply it an existing variable name) and type

```stata
use https://www.stata-press.com/data/r16/bsample1, clear
set seed 1234
generate fw = .
(bs5,810 missing values generated)
bsample 200 if female, weight(fw)
tabulate fw female
```

<table>
<thead>
<tr>
<th>fw</th>
<th>female</th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>male</td>
<td>female</td>
<td>Total</td>
</tr>
<tr>
<td></td>
<td>2,392</td>
<td>3,222</td>
<td>5,614</td>
</tr>
<tr>
<td>1</td>
<td>0</td>
<td>192</td>
<td>192</td>
</tr>
<tr>
<td>2</td>
<td>0</td>
<td>4</td>
<td>4</td>
</tr>
<tr>
<td></td>
<td>2,392</td>
<td>3,418</td>
<td>5,810</td>
</tr>
</tbody>
</table>

Note that $(192 \times 1) + (4 \times 2) = 200$.

Example 7: Oversampling observations

`bsample` requires the expression in `exp` to evaluate to a number that is less than or equal to the number of observations. To sample twice as many male and female patients as there are already in memory, we must expand the data before using `bsample`. For example,

```stata
use https://www.stata-press.com/data/r16/bsample1, clear
set seed 1234
expand 2
(bs5,810 observations created)
bsample, strata(female)
tabulate female
```

<table>
<thead>
<tr>
<th>female</th>
<th>Freq.</th>
<th>Percent</th>
<th>Cum.</th>
</tr>
</thead>
<tbody>
<tr>
<td>male</td>
<td>4,784</td>
<td>41.17</td>
<td>41.17</td>
</tr>
<tr>
<td>female</td>
<td>6,836</td>
<td>58.83</td>
<td>100.00</td>
</tr>
<tr>
<td>Total</td>
<td>11,620</td>
<td>100.00</td>
<td></td>
</tr>
</tbody>
</table>

Example 8: Stratified oversampling with unequal sizes

To sample twice as many female patients as male patients, we must expand the records for the female patients because there are less than twice as many of them as there are male patients, but first put the number of observed male patients in a local macro. After expanding the female records, we generate a variable that contains the number of observations to sample within the two groups.
. use https://www.stata-press.com/data/r16/bsample1, clear
. set seed 1234
. count if !female
   2,392
. local nmale = r(N)
. expand 2 if female
(3,418 observations created)
. generate nsamp = cond(female,2*'nmale','nmale')
. bsample nsamp, strata(female)
. tabulate female

<table>
<thead>
<tr>
<th></th>
<th>Freq.</th>
<th>Percent</th>
<th>Cum.</th>
</tr>
</thead>
<tbody>
<tr>
<td>male</td>
<td>2,392</td>
<td>33.33</td>
<td>33.33</td>
</tr>
<tr>
<td>female</td>
<td>4,784</td>
<td>66.67</td>
<td>100.00</td>
</tr>
<tr>
<td>Total</td>
<td>7,176</td>
<td>100.00</td>
<td></td>
</tr>
</tbody>
</table>

Example 9: Oversampling of clusters

For clustered data, sampling more clusters than are present in the original dataset requires more than just expanding the data. To illustrate, suppose we wanted a bootstrap sample of eight clusters from a dataset consisting of five clusters of observations.

. use https://www.stata-press.com/data/r16/bsample2, clear
. tabstat x, stat(n mean) by(group)

Summary for variables: x
   by categories of: group

<table>
<thead>
<tr>
<th>group</th>
<th>N</th>
<th>mean</th>
</tr>
</thead>
<tbody>
<tr>
<td>A</td>
<td>15</td>
<td>-.3073028</td>
</tr>
<tr>
<td>B</td>
<td>10</td>
<td>-.00984</td>
</tr>
<tr>
<td>C</td>
<td>11</td>
<td>.0810985</td>
</tr>
<tr>
<td>D</td>
<td>11</td>

<td>29</td>
<td>-.095203</td>
</tr>
<tr>
<td>Total</td>
<td>76</td>
<td>-.1153269</td>
</tr>
</tbody>
</table>

bsample will complain if we simply expand the dataset.

. use https://www.stata-press.com/data/r16/bsample2
. expand 3
(152 observations created)
. bsample 8, cluster(group)
resample size must not be greater than number of clusters
r(498);

Expanding the data will only partly solve the problem. We also need a new variable that uniquely identifies the copied clusters. We use the expandcl command to accomplish both these tasks; see [D] expandcl.
use https://www.stata-press.com/data/r16/bsample2, clear
.set seed 1234
.expandcl 2, generate(expgroup) cluster(group)

</table>

The results from tabulate on the generated frequency weight variable versus the original cluster ID (group) show us that the bootstrap sample contains one copy of cluster A, one copy of cluster B, two copies of cluster C, two copies of cluster D, and two copies of cluster E (1 + 1 + 2 + 2 + 2 = 8).

Example 10: Stratified oversampling of clusters

Suppose that we have a dataset containing two strata with five clusters in each stratum, but the cluster identifiers are not unique between the strata. To get a stratified bootstrap sample with eight clusters in each stratum, we first use expandcl to expand the data and get a new cluster ID variable. We use cluster(strid group) in the call to expandcl; this action will uniquely identify the 2 * 5 = 10 clusters across the strata.
use https://www.stata-press.com/data/r16/bsample2, clear

The results from by strid: tabulate on the generated frequency weight variable versus the original cluster ID (group) show us how many times each cluster was sampled for each stratum. For stratum 1, the bootstrap sample contains two copies of cluster A, one copy of cluster B, two copies of cluster C, one copy of cluster D, and two copies of cluster E (2 + 1 + 2 + 1 + 2 = 8). For stratum 2, the bootstrap sample contains one copy of cluster A, zero copies of cluster B, three copies of cluster C, one copy of cluster D, and three copies of cluster E (1 + 0 + 3 + 1 + 3 = 8).

**Description**

*bstat* is a programmer’s command that computes and displays estimation results from bootstrap statistics. For each variable in *varlist*, *bstat* computes a covariance matrix, estimates bias, and constructs normal confidence intervals (CIs), percentile CIs, bias-corrected (BC) CIs, and bias-corrected and accelerated (BC$_a$) CIs using a bootstrap dataset in memory or on disk. The computed CIs can be displayed using *estat bootstrap*; see [R] bootstrap postestimation.

*bstat* without *varlist* replays results from the last bootstrap estimation when results are stored in *e()*.

**Menu**

Statistics > Resampling > Report bootstrap results
Syntax

Bootstrap statistics from variables

\texttt{bstat [varlist] [if] [in] [, options]}

Bootstrap statistics from file

\texttt{bstat [namelist] [using filename] [if] [in] [, options]}

\begin{tabular}{|l|l|}
\hline
\textbf{options} & \textbf{Description} \\
\hline
\textbf{Main} & \\
\texttt{*stat(vector)} & observed values for each statistic \\
\texttt{*accel(vector)} & acceleration values for each statistic \\
\texttt{*ties} & adjust BC/BCa confidence intervals for ties \\
\texttt{*mse} & use MSE formula for variance estimation \\
\hline
\textbf{Reporting} & \\
\texttt{level(#)} & set confidence level; default is level(95) \\
\texttt{n(#)} & # of observations from which bootstrap samples were taken \\
\texttt{notable} & suppress table of results \\
\texttt{noheader} & suppress table header \\
\texttt{nolegend} & suppress table legend \\
\texttt{verbose} & display the full table legend \\
\texttt{title(text)} & use \texttt{text} as title for bootstrap results \\
\texttt{display_options} & control column formats and line width \\
\hline
\end{tabular}

*Starred options and qualifiers using, if, and in require a bootstrap dataset.

See \cite{U} 20 Estimation and postestimation commands for more capabilities of estimation commands.

Options

**Main**

\texttt{stat(vector)} specifies the observed value of each statistic (that is, the value of the statistic using the original dataset).

\texttt{accel(vector)} specifies the acceleration of each statistic, which is used to construct BCa CIs.

\texttt{ties} specifies that \texttt{bstat} adjust for ties in the replicate values when computing the median bias used to construct BC and BCa CIs.

\texttt{mse} specifies that \texttt{bstat} compute the variance by using deviations of the replicates from the observed value of the statistics. By default, \texttt{bstat} computes the variance by using deviations from the average of the replicates.

**Reporting**

\texttt{level(#)}; see \cite{R} Estimation options.

\texttt{n(#)} specifies the number of observations from which bootstrap samples were taken. This value is used in no calculations but improves the table header when this information is not saved in the bootstrap dataset.
notable suppresses the display of the output table.
nohandler suppresses the display of the table header. This option implies nolegend.
nolegend suppresses the display of the table legend.
verbose specifies that the full table legend be displayed. By default, coefficients and standard errors are not displayed.
title(text) specifies a title to be displayed above the table of bootstrap results; the default title is Bootstrap results.
display_options: cformat(\%fmt), pformat(\%fmt), sformat(\%fmt), and nolstretch; see [R] Estimation options.

Remarks and examples

Remarks are presented under the following headings:

Bootstrap datasets
Creating a bootstrap dataset

Bootstrap datasets

Although bstat allows you to specify the observed value and acceleration of each bootstrap statistic via the stat() and accel() options, programmers may be interested in what bstat uses when these options are not supplied.

When working from a bootstrap dataset, bstat first checks the data characteristics (see [P] char) that it understands:

_dta[bs_version] identifies the version of the bootstrap dataset. This characteristic may be empty (not defined), 2, or 3; otherwise, bstat will quit and display an error message. This version tells bstat which other characteristics to look for in the bootstrap dataset.

bstat uses the following characteristics from version 3 bootstrap datasets:

_dta[N]
_dta[N_strata]
_dta[N_cluster]
_dta[command]
varname[observed]
varname[acceleration]
varname[expression]

bstat uses the following characteristics from version 2 bootstrap datasets:

_dta[N]
_dta[N_strata]
_dta[N_cluster]
varname[observed]
varname[acceleration]

An empty bootstrap dataset version implies that the dataset was created by the bootstrap command in a version of Stata earlier than Stata 8. Here bstat expects varname[bstrap] to contain the observed value of the statistic identified by varname (varname[observed] in version 2). All other characteristics are ignored.

_dta[N] is the number of observations in the observed dataset. This characteristic may be overruled by specifying the n() option.
_dta[N_strata] is the number of strata in the observed dataset.
_dta[N_cluster] is the number of clusters in the observed dataset.
_dta[command] is the command used to compute the observed values of the statistics.

`varname[observed]` is the observed value of the statistic identified by `varname`. To specify a different value, use the `stat()` option.

`varname[acceleration]` is the estimate of acceleration for the statistic identified by `varname`. To specify a different value, use the `accel()` option.

`varname[expression]` is the expression or label that describes the statistic identified by `varname`.

---

**Creating a bootstrap dataset**

Suppose that we are interested in obtaining bootstrap statistics by resampling the residuals from a regression (which is not possible with the `bootstrap` command). After loading some data, we run a regression, save some results relevant to the `bstat` command, and save the residuals in a new variable, `res`.

```stata
. use https://www.stata-press.com/data/r16/auto
   (1978 Automobile Data)
. regress mpg weight length
```

```
<table>
<thead>
<tr>
<th>Source</th>
<th>SS</th>
<th>df</th>
<th>MS</th>
<th>Number of obs = 74</th>
</tr>
</thead>
<tbody>
<tr>
<td>Model</td>
<td>1616.08062</td>
<td>2</td>
<td>808.040312</td>
<td>F(2, 71) = 69.34</td>
</tr>
<tr>
<td>Residual</td>
<td>827.378835</td>
<td>71</td>
<td>11.653223</td>
<td>Prob &gt; F = 0.0000</td>
</tr>
<tr>
<td>Total</td>
<td>2443.45946</td>
<td>73</td>
<td>33.4720474</td>
<td>Adj R-squared = 0.6519</td>
</tr>
</tbody>
</table>
```

```
| mpg     | Coef.   | Std. Err. | t     | P>|t|   | [95% Conf. Interval] |
|---------|---------|-----------|-------|-------|----------------------|
| weight  | -.0038515 | .001586  | -2.43 | 0.018 | -.0070138 to -.0006891 |
| length  | -.0795935 | .0553577 | -1.44 | 0.155 | -.1899736 to .0307867 |
| _cons   | 47.88487 | 6.08787   | 7.87  | 0.000 | 35.746 to 60.02374   |
```

```stata
. matrix b = e(b)
. local n = e(N)
. predict res, residuals
```
We can resample the residual values in `res` by generating a random observation ID (`rid`), generate a new response variable (`y`), and run the original regression with the new response variables.

```stata
.set seed 54321
.generate rid = int(_N*runiform())+1
.matrix score double y = b
.replace y = y + res[rid]
(74 real changes made)
.regress y weight length
```

<table>
<thead>
<tr>

<td>601.341031</td>
<td>71</td>
<td>8.46959199</td>
<td>Prob &gt; F = 0.0000</td>
</tr>
<tr>
<td>Total</td>
<td>2297.04417</td>
<td>73</td>
<td>31.4663585</td>
<td>Adj R-squared = 0.7308</td>
</tr>
</tbody>
</table>

| y     | Coef.    | Std. Err. | t     | P>|t|  | [95% Conf. Interval] |
|-------|----------|-----------|-------|------|---------------------|
| weight | -.0029676 | .0013521  | -2.19 | 0.031 | -.0056636 to -.0002716 |
| length | -.1158425 | .047194   | -2.45 | 0.017 | -.2099446 to -.0217404 |
| _cons | 51.72451  | 5.190075  | 9.97  | 0.000 | 41.3758 to 62.07323  |

Instead of programming this resampling inside a loop, it is much more convenient to write a short program and use the `simulate` command; see [R] `simulate`. In the following, `mysim_r` requires the user to specify a coefficient vector and a residual variable. `mysim_r` then retrieves the list of predictor variables (removing `_cons` from the list), generates a new temporary response variable with the resampled residuals, and regresses the new response variable on the predictors.

```stata
program mysim_r
.version 16.0
.syntax name(name=bvector), res(varname)
.tempvar y rid
.local xvars : colnames `bvector'
.local cons _cons
.local xvars : list xvars - `cons'
.matrix score double `y' = `bvector'
generate long `rid' = int(_N*runiform()) + 1
.replace `y' = `y' + `res'[`rid']
.regress `y' `xvars'
.end
```
We can now give `mysim_r` a test run, but we first set the random-number seed (to reproduce results).

```
. set seed 54321
. mysim_r b, res(res)
(74 real changes made)
```

```
Source| SS      | df | MS   | Number of obs = 74
------|--------|----|------|-----------------|-----------------|-----------------|
Model | 1695.70314| 2  | 847.851568 | F(2, 71) = 100.11 |
Residual | 601.341031| 71 | 8.46959199 | Prob > F = 0.0000 |
        |         |    |       | R-squared = 0.7382 |
        |         |    |       | Adj R-squared = 0.7308 |
Total  | 2297.04417| 73 | 31.4663585 | Root MSE = 2.9103 |
```

Now that we have a program that will compute the results we want, we can use `simulate` to generate a bootstrap dataset and `bstat` to display the results.

```
. set seed 54321
. simulate, reps(200) nodots: mysim_r b, res(res)
command: mysim_r b, res(res)
. bstat, stat(b) n('n')
Bootstrap results Number of obs = 74
Replications = 200
```

```
Observed| Coef. | Std. Err. | z     | P>|z|  | [95% Conf. Interval] |
---------|-------|-----------|-------|-----|---------------------|
_b_weight| -.0038515 | .0014673 | -2.62 | 0.009 | -.0067274 | -.0009756 |
_b_length| -.0795935 | .0509772 | -1.56 | 0.118 | -.1795069 | .0203199 |
_b_cons  | 47.88487 | 5.650947 | 8.47  | 0.000 | 36.80922 | 58.96053 |
```

Finally, we see that `simulate` created some of the data characteristics recognized by `bstat`. All we need to do is correctly specify the version of the bootstrap dataset, and `bstat` will automatically use the relevant data characteristics.
## Bootstrap Results

Bootstrap results

| Variable | Observed Coef. | Bootstrap Coef. | Std. Err. | z     | P>|z| | 95% Conf. Interval |
|----------|----------------|-----------------|-----------|-------|-----|-------------------|
| weight   | -.0038515       | -.0014673       | .000603   | -2.62 | 0.009 | -.0067274 to -.0009756 |
| length   | -.0795935       | -.0509772       | .025461   | -1.56 | 0.118 | -.1795069 to .0203199 |
| _cons    | 47.88487        | 5.650947        | .452857   | 8.47  | 0.000 | 36.80922 to 58.96053 |

See Poi (2004) for another example of residual resampling.
Stored results

bstat stores the following in e():

Scalars
- e(N) sample size
- e(N_reps) number of complete replications
- e(N_misreps) number of incomplete replications
- e(N_strata) number of strata
- e(N_clust) number of clusters
- e(k_aux) number of auxiliary parameters
- e(k_eq) number of equations in e(b)
- e(k_exp) number of standard expressions
- e(k_eexp) number of extended expressions (i.e., _b)
- e(k_extra) number of extra equations beyond the original ones from e(b)
- e(level) confidence level for bootstrap CIs
- e(bs_version) version for bootstrap results
- e(rank) rank of e(V)

Macros
- e(cmd) bstat
- e(command) from _dta[command]
- e(cmdline) command as typed
- e(title) title in estimation output
- e(exp#) expression for the #th statistic
- e(prefix) bootstrap
- e(ties) ties, if specified
- e(mse) mse, if specified
- e(vce) bootstrap
- e(vcetype) title used to label Std. Err.
- e(properties) b V

Matrices
- e(b) observed statistics
- e(b_bs) bootstrap estimates
- e(reps) number of nonmissing results
- e(bias) estimated biases
- e(se) estimated standard errors
- e(z0) median biases
- e(accel) estimated accelerations
- e(ci_normal) normal-approximation CIs
- e(ci_percentile) percentile CIs
- e(ci_bc) bias-corrected CIs
- e(ci_bca) bias-corrected and accelerated CIs
- e(V) bootstrap variance–covariance matrix

centile estimates specified centiles and calculates confidence intervals. If no `varlist` is specified, `centile` calculates centiles for all the variables in the dataset. If no centiles are specified, medians are reported.

By default, `centile` uses a binomial method for obtaining confidence intervals that makes no assumptions about the underlying distribution of the variable.

Quick start

50th percentile with 95% confidence intervals for `v1` and `v2`
```plaintext
centile v1 v2
```
For all variables in the dataset
```plaintext
centile
```
25th, 50th, and 75th percentiles of `v1`
```plaintext
centile v1, centile(25 50 75)
```
10th, 20th, 30th, ..., 90th percentiles of `v1`
```plaintext
centile v1, centile(10(10)90)
```
Force confidence limits to fall on sample values
```plaintext
centile v1 v2, cci
```
Confidence intervals based on standard errors for a normal-distribution quantile
```plaintext
centile v1 v2, normal
```
Centile and confidence intervals based on mean and standard deviation
```plaintext
centile v1 v2, meansd
```
Replace data in memory with centiles for groups defined by categorical variable `cvar`
```plaintext
statsby, by(cvar) clear: centile v1, centile(25 50 75)
```
Syntax

```
centile [varlist] [if] [in] [, options]
```

by and `statsby` are allowed; see [U] 11.1.10 Prefix commands.

Options

- `centile(numlist)` specifies the centiles to be reported. The default is to display the 50th centile. Specifying `centile(5)` requests that the fifth centile be reported. Specifying `centile(5 50 95)` requests that the 5th, 50th, and 95th centiles be reported. Specifying `centile(10(10)90)` requests that the 10th, 20th, ..., 90th centiles be reported; see [U] 11.1.8 numlist.

- `cci` (conservative confidence interval) forces the confidence limits to fall exactly on sample values. Confidence intervals displayed with the `cci` option are slightly wider than those with the default (`nocci`) option.

- `normal` causes the confidence interval to be calculated by using a formula for the standard error of a normal-distribution quantile given by Kendall and Stuart (1969, 237). The `normal` option is useful when you want empirical centiles—that is, centiles based on sample order statistics rather than on the mean and standard deviation—and are willing to assume normality.

- `meansd` causes the centile and confidence interval to be calculated based on the sample mean and standard deviation, and it assumes normality.

- `level(#)` specifies the confidence level, as a percentage, for confidence intervals. The default is `level(95)` or as set by `set level`; see [R] level.

Remarks and examples

The qth centile of a continuous random variable, X, is defined as the value of C_q, which fulfills the condition Pr(X ≤ C_q) = q/100. The value of q must be in the range 0 < q < 100, though q is not necessarily an integer. By default, `centile` estimates C_q for the variables in `varlist` and for the values of q given in `centile(numlist)`. It makes no assumptions about the distribution of X, and, if necessary, uses linear interpolation between neighboring sample values. Extreme centiles (for example, the 99th centile in samples smaller than 100) are fixed at the minimum or maximum sample value. An “exact” confidence interval for C_q is also given, using the binomial-based method described below in Methods and formulas and in Conover (1999, 143–148). Again linear interpolation is used to improve the accuracy of the estimated confidence limits, but extremes are fixed at the minimum or maximum sample value.
You can prevent `centile` from interpolating when calculating binomial-based confidence intervals by specifying `cci`. The resulting intervals are generally wider than with the default; that is, the coverage (confidence level) tends to be greater than the nominal value (given as usual by `level(#)`), by default 95%.

If the data are believed to be normally distributed (a common case), there are two alternative methods for estimating centiles. If `normal` is specified, \( C_q \) is calculated, as just described, but its confidence interval is based on a formula for the standard error (se) of a normal-distribution quantile given by Kendall and Stuart (1969, 237). If `meansd` is alternatively specified, \( C_q \) is estimated as \( \bar{x} + z_q \times s \), where \( \bar{x} \) and \( s \) are the sample mean and standard deviation, and \( z_q \) is the \( q \)th centile of the standard normal distribution (for example, \( z_{95} = 1.645 \)). The confidence interval is derived from the se of the estimate of \( C_q \).

### Example 1

Using `auto.dta`, we estimate the 5th, 50th, and 95th centiles of the `price` variable:

```
. use https://www.stata-press.com/data/r16/auto
   (1978 Automobile Data)
. format price %8.2fc
. centile price, centile(5 50 95)
```

```
+-----------------+-----------------+
<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Percentile</th>
<th>Centile</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>price</td>
<td>74</td>
<td>5</td>
<td>3,727.75</td>
<td>3,291.23 3,914.16</td>
</tr>
<tr>
<td></td>
<td>50</td>
<td>50,065.50</td>
<td>4,593.57</td>
<td>5,717.90</td>
</tr>
<tr>
<td></td>
<td>95</td>
<td>13,498.00</td>
<td>11,061.53</td>
<td>15,865.30</td>
</tr>
</tbody>
</table>
```

`summarize` produces somewhat different results from `centile`; see *Methods and formulas*.

```
. summarize price, detail
```

```

</table>

With the normal option, the centile estimates are, by definition, the same as before. The confidence intervals for the 5th and 50th centiles are similar to the previous ones, but the interval for the 95th centile is different. The results using the meansd option also differ from both previous sets of estimates.

We can use `sktest` (see [R] `sktest`) to check the correctness of the normality assumption:

```
. sktest price
```

```
Skewness/Kurtosis tests for Normality

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Pr(Skewness)</th>
<th>Pr(Kurtosis)</th>
<th>adj chi2(2)</th>
<th>Prob&gt;chi2</th>
</tr>
</thead>
<tbody>
<tr>
<td>price</td>
<td>74</td>
<td>0.0000</td>
<td>0.0127</td>
<td>21.77</td>
<td>0.0000</td>
</tr>
</tbody>
</table>
```

`sktest` reveals that price is definitely not normally distributed, so the normal assumption is not reasonable, and the normal and meansd options are not appropriate for these data. We should rely on the results from the default choice, which does not assume normality. If the data are normally distributed, however, the precision of the estimated centiles and their confidence intervals will be ordered (best) meansd > normal > [default] (worst). The normal option is useful when we really do want empirical centiles (that is, centiles based on sample order statistics rather than on the mean and standard deviation) but are willing to assume normality.

```
Stored results
```

`centile` stores the following in `r()`:

Scalars

- `r(N)` number of observations
- `r(n_cent)` number of centiles requested
- `r(c_#)` value of # centile
- `r(lb_#)` #-requested centile lower confidence bound
- `r(ub_#)` #-requested centile upper confidence bound

Macros

- `r(cen(tiles))` centiles requested
Methods and formulas

Methods and formulas are presented under the following headings:

Default case
Normal case
meansd case

Default case

The calculation is based on the method of Mood and Graybill (1963, 408). Let \( x_1 \leq x_2 \leq \cdots \leq x_n \) be a sample of size \( n \) arranged in ascending order. Denote the estimated \( q \)th centile of the \( x \)'s as \( c_q \). We require that \( 0 < q < 100 \). Let \( R = (n + 1)q/100 \) have integer part \( r \) and fractional part \( f \); that is, \( r = \text{int}(R) \) and \( f = R - r \). (If \( R \) is itself an integer, then \( r = R \) and \( f = 0 \).) Note that \( 0 \leq r \leq n \). For convenience, define \( x_0 = x_1 \) and \( x_{n+1} = x_n \). \( C_q \) is estimated by

\[
c_q = x_r + f \times (x_{r+1} - x_r)
\]

that is, \( c_q \) is a weighted average of \( x_r \) and \( x_{r+1} \). Loosely speaking, a (conservative) \( p\% \) confidence interval for \( C_q \) involves finding the observations ranked \( t \) and \( u \), which correspond, respectively, to the \( \alpha = (100 - p)/200 \) and \( 1 - \alpha \) quantiles of a binomial distribution with parameters \( n \) and \( q/100 \), that is, \( B(n, q/100) \). More precisely, define the \( i \)th value \( (i = 0, \ldots, n) \) of the cumulative binomial distribution function as \( F_i = \text{Pr}(S \leq i) \), where \( S \) has distribution \( B(n, q/100) \). For convenience, let \( F_{-1} = 0 \) and \( F_{n+1} = 1 \). \( t \) is found such that \( F_t \leq \alpha \) and \( F_{t+1} > \alpha \), and \( u \) is found such that \( 1 - F_u \leq \alpha \) and \( 1 - F_{u-1} > \alpha \).

With the cci option in force, the (conservative) confidence interval is \( (x_{t+1}, x_{u+1}) \), and its actual coverage probability is \( F_u - F_t \).

The default case uses linear interpolation on the \( F_i \) as follows. Let

\[
g = (\alpha - F_t)/(F_{t+1} - F_t)
\]

\[
h = (\alpha - (1 - F_u))/\{(1 - F_{u-1}) - (1 - F_u)\}
\]

\[
= (\alpha - 1 + F_u)/(F_u - F_{u-1})
\]

The interpolated lower and upper confidence limits \( (c_{qL}, c_{qU}) \) for \( C_q \) are

\[
c_{qL} = x_{t+1} + g \times (x_{t+2} - x_{t+1})
\]

\[
c_{qU} = x_{u+1} - h \times (x_{u+1} - x_u)
\]

Suppose that we want a 95% confidence interval for the median of a sample of size 13. \( n = 13 \), \( q = 50 \), \( p = 95 \), \( \alpha = 0.025 \), \( R = 14 \times 50/100 = 7 \), and \( f = 0 \). Therefore, the median is the 7th observation. Some example data, \( x_i \), and the values of \( F_i \) are as follows:

<table>
<thead>
<tr>
<th>( i )</th>
<th>( F_i )</th>
<th>( 1 - F_i )</th>
<th>( x_i )</th>
<th>( i )</th>
<th>( F_i )</th>

<td>28</td>
<td>13</td>
<td>1.0000</td>
<td>0.0000</td>
<td>211</td>
</tr>
</tbody>
</table>
The median is $x_7 = 33$. Also, $F_2 \leq 0.025$ and $F_3 > 0.025$, so $t = 2$; $1 - F_{10} \leq 0.025$ and $1 - F_9 > 0.025$, so $u = 10$. The conservative confidence interval is therefore

$$(c_{50L}, c_{50U}) = (x_{t+1}, x_{u+1}) = (x_3, x_{11}) = (10, 77)$$

with actual coverage $F_{10} - F_2 = 0.9888 - 0.0112 = 0.9776$ (97.8% confidence). For the interpolation calculation, we have

$$g = (0.025 - 0.0112)/(0.0461 - 0.0112) = 0.395$$

$$h = (0.025 - 1 + 0.9888)/(0.9888 - 0.9539) = 0.395$$

So,

$$c_{50L} = x_3 + 0.395 \times (x_4 - x_3) = 10 + 0.395 \times 5 = 11.98$$

$$c_{50U} = x_{11} - 0.395 \times (x_{11} - x_{10}) = 77 - 0.395 \times 18 = 69.89$$

**Normal case**

The value of $c_q$ is as above. Its se is given by the formula

$$s_q = \sqrt{q(100 - q)} \bigg/ \left\{ 100\sqrt{n}Z(c_q; \bar{x}, s) \right\}$$

where $\bar{x}$ and $s$ are the mean and standard deviation of the $x_i$, and

$$Z(Y; \mu, \sigma) = \left(1/\sqrt{2\pi\sigma^2}\right) e^{-(Y-\mu)^2/2\sigma^2}$$

is the density function of a normally distributed variable $Y$ with mean $\mu$ and standard deviation $\sigma$. The confidence interval for $C_q$ is $(c_q - z_{100(1-\alpha)}s_q, c_q + z_{100(1-\alpha)}s_q)$.

**meansd case**

The value of $c_q$ is $\bar{x} + z_q \times s$. Its se is given by the formula

$$s_q^* = s \sqrt{1/n + z_q^2/(2n - 2)}$$

The confidence interval for $C_q$ is $(c_q - z_{100(1-\alpha)} \times s_q^*, c_q + z_{100(1-\alpha)} \times s_q^*)$.

churdle fits a linear or exponential hurdle model for a bounded dependent variable. The hurdle model combines a selection model that determines the boundary points of the dependent variable with an outcome model that determines its nonbounded values. Separate independent covariates are permitted for each model.

### Quick start

Linear hurdle model of \( y_1 \) on \( x_1 \) and \( x_2 \), specifying that \( y_1 \) is truncated at 0 with \( x_1 \) and \( x_3 \) predicting selection

\[
\text{churdle linear } y_1 \ x_1 \ x_2, \text{ select}(x_1 \ x_3) \ ll(0)
\]

Add an upper truncation limit of 40

\[
\text{churdle linear } y_1 \ x_1 \ x_2, \text{ select}(x_1 \ x_3) \ ll(0) \ ul(40)
\]

As above, with the upper truncation limit specified in \( \text{trunc} \)

\[
\text{churdle linear } y_1 \ x_1 \ x_2, \text{ select}(x_1 \ x_3) \ ll(0) \ ul(\text{trunc})
\]

As above, and use \( x_3 \) to model the variance of the selection model

\[
\text{churdle linear } y_1 \ x_1 \ x_2, \text{ select}(x_1 \ x_3, \text{het}(x_3)) \ ll(0) \ ul(\text{trunc})
\]

As above, and use \( x_4 \) to model the variance of the outcome model

\[
\text{churdle linear } y_1 \ x_1 \ x_2, \text{ select}(x_1 \ x_3, \text{het}(x_3)) \ ll(0) \ ///
\]

\[
ul(\text{trunc}) \ \text{het}(x_4)
\]

Exponential hurdle model of \( y_2 \) on \( x_1 \) and \( x_2 \), specifying that \( y_2 \) is truncated at 4 with \( x_1 \) and \( x_3 \) predicting selection

\[
\text{churdle exponential } y_2 \ x_1 \ x_2, \text{ select}(x_1 \ x_3) \ ll(4)
\]

SE/Robust

vce(vcetype) vcetype may be oim, robust, cluster clustvar, bootstrap, or jackknife

Reporting

level(#) set confidence level; default is level(95)
noconsreport do not display constraints
display_options control columns and column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling

Maximization

maximize_options control the maximization process; seldom used
coefflegend display legend instead of statistics
select() is required. The full specification is `select(varlist_s, noconstant het(varlist_o))`.

noconstant specifies that the constant be excluded from the selection model.

het(varlist_o) specifies the variables in the error-variance function of the selection model.

‡ You must specify at least one of `ul(# | varname)` or `ll(# | varname)` for the linear model and must specify `ll(# | varname)` for the exponential model.

`indepvars`, `varlist_s`, and `varlist_o` may contain factor variables; see [U] 11.4.3 Factor variables.

bootstrap, by, fp, jackknife, rolling, statsby, and svy are allowed; see [U] 11.1.10 Prefix commands.

Weights are not allowed with the bootstrap prefix; see [R] bootstrap.

vce() and weights are not allowed with the svy prefix; see [SVY] svy.

`fweights`, `iweights`, and `pweights` are allowed; see [U] 11.1.6 weight.

coefflegend does not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

**Options**

---

**Model**

`select(varlist_s, noconstant het(varlist_o))` specifies the variables and options for the selection model. `select()` is required.

`ll(# | varname)` and `ul(# | varname)` indicate the lower and upper limits, respectively, for the dependent variable. You must specify one or both for the linear model and must specify a lower limit for the exponential model. Observations with `depvar ≤ ll()` have a lower bound; observations with `depvar ≥ ul()` have an upper bound; and the remaining observations are in the continuous region.

noconstant, `constraints(constraints)`; see [R] Estimation options.

het(varlist) specifies the variables in the error-variance function of the outcome model.

---

**SE/Robust**

`vce(vcetype)` specifies the type of standard error reported, which includes types that are derived from asymptotic theory (`oim`), that are robust to some kinds of misspecification (`robust`), that allow for intragroup correlation (`cluster`, `clustvar`), and that use bootstrap or jackknife methods (`bootstrap`, `jackknife`); see [R] `vce_option`.

---

**Reporting**

`level(#), nocnsreport`; see [R] Estimation options.

`display_options`: `noci`, `nopvalues`, `noomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fwrap(#), fwrapon(style), cformat(%fmt), pformat(%fmt), sformat(%fmt)`, and `nolstretch`; see [R] Estimation options.

---

**Maximization**

`maximize_options`: `difficult`, `technique(algorithm_spec)`, `iterate(#)`, `[no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(init_specs)`; see [R] Maximize. These options are seldom used.
The following option is available with \texttt{churdle} but is not shown in the dialog box: \texttt{coeflegend}; see \cite{R} \texttt{Estimation options}.

\section*{Remarks and examples}

\texttt{churdle} fits a linear or an exponential hurdle model. It combines a selection model that determines the boundary points of the dependent variable with an outcome model that determines its nonbounded values. Hurdle models treat these boundary values as observed instead of censored. That is to say, observations where the dependent variable is equal to one of the boundary values are not the result of our inability to observe the distribution above or below a certain point; see \citet{Wooldridge} chapter 17 for a thorough discussion of this point.

These models were proposed by \citet{Cragg} to explain the demand for durable goods. In the Cragg model, individuals purchase zero or a positive amount of the durable good, with different factors determining each of these choices. This may be generalized to other individual decisions, such as money donated to charity, cigarette consumption, and time spent volunteering.

Hurdle models are characterized by the relationship $y_i = s_i h_i^*$, where $y_i$ is the observed value of the dependent variable.

The selection variable, $s_i$, is 1 if the dependent variable is not bounded and 0 otherwise. In the Cragg model, the lower limit that binds the dependent variable is 0 so the selection model is

$$s_i = \begin{cases} 1 & \text{if } z_i \gamma + \epsilon_i > 0 \\ 0 & \text{otherwise} \end{cases}$$

where $z_i$ is a vector of explanatory variables, $\gamma$ is a vector of coefficients, and $\epsilon_i$ is a standard normal error term. \texttt{churdle} allows a different lower limit to be specified in \texttt{ll()} and, for the linear model, an upper limit in \texttt{ul()}. Conditional heteroskedasticity of the random error $\epsilon_i$ is allowed if suboption \texttt{het()} is specified in \texttt{select()}.

The continuous latent variable $h_i^*$ is observed only if $s_i = 1$. The outcome model can be either the linear model or the exponential model, as proposed in \citet{Cragg}:

- **Linear**:
  $$h_i^* = x_i \beta + \nu_i$$

- **Exponential**:
  $$h_i^* = \exp (x_i \beta + \nu_i)$$

where $x_i$ is a vector of explanatory variables, $\beta$ is a vector of coefficients, and $\nu_i$ is an error term.

For the linear model, $\nu_i$ has a truncated normal distribution with lower truncation point $-x_i \beta$. For the exponential model, $\nu_i$ has a normal distribution. \texttt{churdle} extends the Cragg hurdle models to allow for conditional heteroskedasticity of the random error $\nu_i$ if the user specifies the \texttt{het()} option.

The parameters and regressors in the models for $h_i^*$ and for $s_i$ may differ.
Example 1: Linear hurdle model

Consider a dataset that contains the number of hours an individual exercises per day (hours), their age (age), whether they are single (single), hours they work per day (whours), whether they smoke (smoke), their weight in kilograms (weight), their distance from the nearest gym (distance), and their average commute from work (commute).

Figure 1 shows that 43.9% of the individuals in the sample do not exercise and that the hours exercised varies among individuals that decide to exercise.

We model the decision to exercise or not as a function of commute, whours, and age. These variables are written in select(). Once a decision to exercise is made, the time an individual exercises is modeled as a linear function of age, smoke, distance, and single.

| _cons  | 2.649945   | 0.0499795 | 53.02 | 0.000 | 2.551987 2.747903   |
| lnsigma | | | | | |
| _cons  | 0.0083199 | 0.0099648 | 0.83  | 0.404 | -0.0112107 0.0278506 |
| /sigma | 1.008355   | 0.010048  |       |       | 0.9888519 1.028242  |

The coefficients in the outcome model for the latent variable appear under hours. Because we only specified a lower limit to bind the dependent variable, the output shows parameter estimates for a single selection model under selection_ll. Information about the estimated standard deviation of the error term in the outcome model appears under lnsigma and /sigma.

The coefficient estimates are not directly interpretable. To obtain the effect of a covariate on the model, we need to use the margins command; see [R] churdle postestimation. Consider the effect of age:
. margins, dydx(age)

Average marginal effects
Number of obs = 19,831
Model VCE : OIM
Expression : Conditional mean estimates of dependent variable, predict()
dy/dx w.r.t. : age

| Delta-method | dy/dx  | Std. Err. | z    | P>|z|    |      [95% Conf. Interval] |
|--------------|--------|-----------|------|--------|--------------------------|
| age          | -.0216855 | .000289 | -75.03 | 0.000 | -.022252 - .021119       |

Each additional year of age is associated with about −0.02 fewer hours, or 1.2 minutes, of exercise.

> Example 2: Linear hurdle with models for the outcome and selection variances

In this example, we illustrate the possibility of fitting a heteroskedastic probit for the selection and latent model. In both cases, this is done by specifying `age` and `single` as the variables that affect the conditional variance. As in example 1, we have separate parameters for the outcome model and lower-limit selection model.

|       | _cons  | 2.669613 | .1139478 | 23.43  | 0.000 | 2.44628 - 2.892947      |
| lnsigma | age    | .0003537 | .0004026 | 0.88  | 0.380 | -.0004354 .0011427      |
|       | single | -.0080667 | .019253 | -0.42  | 0.675 | -.0458019 .0296685      |
| lnsigma_ll | age | -.0002035 | .0008424 | -0.24  | 0.809 | -.0018546 .0014475      |
|       | single | .0268271 | .0270133 | 0.99  | 0.321 | -.0261179 .0797721      |
The coefficients on **age** and **single** have no effect on the conditional variance of the outcome model or on the conditional variance of the selection model. Thus, there is no evidence that the variance depends on age and marital status.

### Example 3: Exponential hurdle model

Returning to **example 1**, if we believe that the conditional mean of the latent variable has an exponential form instead of a linear form, we use **churdle exponential**.

```
. churdle exponential hours age i.smoke distance i.single, > select(commute whours age) ll(0) nolog
Cragg hurdle regression
Number of obs = 19,831
LR chi2(4)    =  8663.21
Prob > chi2   =    0.000
Log likelihood = -15666.195  Pseudo R2 = 0.2166

Coef. Std. Err. z   P>|z|    [95% Conf. Interval]
hours         0.0008368  0.0005341  1.57 0.117  -0.00021   0.0018836
age          -0.6431348  0.0258509 -24.88 0.000  -0.6938016  -0.592468
smoke         0.0772879  0.0079132  -9.77 0.000  -0.0927976   -0.061778
smoking       -0.5975111  0.0161081  -37.09 0.000  -0.6394046  -0.5556176
single        -0.0770619  0.0254833  -3.02 0.002  -0.1270082  -0.0271157
_cons         -0.0770619  0.0254833  -3.02 0.002  -0.1270082  -0.0271157

selection_ll
commute      -0.2953345  0.0624665  -4.73 0.000  -0.4177666  -0.1729024
whours         0.0022974  0.0069306   0.33 0.740  -0.0112864   0.0158811
age          -0.0485347  0.0006501 -74.65 0.000  -0.0498090  -0.0472604
_cons          2.649945   0.0499795  53.02 0.000   2.551987    2.747903

lnsigma
_cons        -0.186917   0.0067067  -27.87 0.000   -0.200062  -0.1737721
/sigma       0.8295126   0.0055633    81.68 0.000    0.821868    0.8404884
```

What was said previously regarding the interpretation of the effects of the different regressors also holds true for **churdle exponential**. We again use **margins** to estimate the effect of **age** on time spent exercising.

```
. margins, dydx(age)
Average marginal effects
Model VCE : OIM
Expression : Conditional mean estimates of dependent variable, predict()
dy/dx w.r.t. : age

| Delta-method | dy/dx | Std. Err. | z    | P>|z| | [95% Conf. Interval] |
|--------------|-------|-----------|------|------|----------------------|
| age          | -0.0245582 | 0.0004805 | -51.11 | 0.000 | -0.0255   -0.0236164 |
```
With the exponential outcome model of the latent variable, our estimate is that each additional year of age decreases exercise time by about 0.025 hours, or 1.5 minutes.

### Stored results

churdle stores the following in e():

**Scalars**
- e(N) number of observations
- e(k_eq_model) number of equations in overall model test
- e(df_m) model degrees of freedom
- e(r2_p) pseudo-$R$-squared
- e(chi2) $\chi^2$
- e(ll) log likelihood
- e(ll_0) log likelihood, constant-only model
- e(N_clust) number of clusters
- e(p) $p$-value for model test
- e(rank) rank of e(v)
- e(converged) 1 if converged, 0 otherwise

**Macros**
- e(cmd) churdle
- e(cmdline) command as typed
- e(depvar) name of dependent variable
- e(estimator) linear or exponential
- e(model) Linear or Exponential
- e(wtype) weight type
- e(wexp) weight expression
- e(title) title in estimation output
- e(clustvar) name of cluster variable
- e(chi2type) Wald or LR; type of model $\chi^2$ test
- e(vce) vcetype specified in vce()
- e(vcetype) title used to label Std. Err.
- e(opt) type of optimization
- e(which) max or min; whether optimizer is to perform maximization or minimization
- e(technique) maximization technique
- e(properties) b V
- e(predict) program used to implement predict
- e(marginsnotok) predictions disallowed by margins
- e(asbalanced) factor variables fvset as asbalanced
- e(asobserved) factor variables fvset as asobserved

**Matrices**
- e(b) coefficient vector
- e(Cns) constraints matrix
- e(ilog) iteration log
- e(V) variance–covariance matrix of the estimators
- e(V_modelbased) model-based variance

**Functions**
- e(sample) marks estimation sample

### Methods and formulas

Let $\ell\ell$ refer to the lower limit and $u\ell$ to the upper limit. Also let the probabilities of being at these limits be given by

\[
\Pr(y_i = \ell\ell | z_i) = \Phi(\ell\ell - z_i' \gamma_{\ell\ell})
\]
\[
\Pr(y_i = u\ell | z_i) = \Phi(z_i' \gamma_{u\ell} - u\ell)
\]
where $z_i$ are the covariates of the selection model for individual $i$, which may be distinct from the covariates $x_i$ for the latent model; $\Phi$ corresponds to the standard normal cumulative distribution function; $\gamma_{\ell\ell}$ is the parameter vector for the lower-limit selection model; and $\gamma_{u\ell}$ is the parameter vector for the upper-limit selection model.

Under the assumptions that $\nu_i$ has a truncated normal distribution with lower truncation point $\ell - x_i'\beta$ and upper truncation point $u - x_i'\beta$ and has a homoskedastic variance, the log-likelihood function is given by

$$\ln L = \sum_{i=1}^{n} \left( y_i \leq \ell \right) \log \Phi \left( \ell - z_i'\gamma_{\ell\ell} \right) + \left( y_i \geq u \right) \log \{ 1 - \Phi \left( u - z_i'\gamma_{u\ell} \right) \}$$

$$+ \left( u > y_i > \ell \right) \left[ 1 - \Phi \left( u - z_i'\gamma_{u\ell} \right) - \Phi \left( \ell - z_i'\gamma_{\ell\ell} \right) \right]$$

$$- \left( u > y_i > \ell \right) \left[ \log \left\{ \Phi \left( \frac{u - x_i'\beta}{\sigma} \right) - \Phi \left( \frac{\ell - x_i'\beta}{\sigma} \right) \right\} \right]$$

$$+ \left( u > y_i > \ell \right) \left[ \log \left\{ \phi \left( \frac{y_i - x_i'\beta}{\sigma} \right) \right\} \right]$$

Without the homoskedasticity assumption, the heteroskedasticity can be modeled using the form $\sigma^2(w_i) = \exp(2w_i'\theta)$, where $w_i$ are the variables that affect the conditional variance of $\nu_i$. The log-likelihood function is obtained by replacing $\sigma$ with $\exp(w_i'\theta)$.

The log-likelihood function for the exponential model is given by

$$\ln L = \sum_{i=1}^{n} \left( y_i \leq \ell \right) \log \Phi \left( \ell - z_i'\gamma \right) + \left( y_i > \ell \right) \left[ \log \left\{ 1 - \Phi \left( \ell - z_i'\gamma \right) \right\} \right]$$

$$+ \left( y_i > \ell \right) \left[ \log \left\{ \phi \left[ \log(y_i - \ell) - x_i'\beta \right] / \sigma \right\} \right] - \log(\sigma) - \log(y_i - \ell)$$

Analogous to the linear case, we can model heteroskedasticity by $\sigma^2(w_i) = \exp(2w_i'\theta)$.

Estimation of both of the aforementioned likelihood functions is done by maximum likelihood.

* `forecast`, `hausman`, and `lrtest` are not appropriate with `svy` estimation results.
predict

Description for predict

predict creates a new variable containing predictions such as conditional expectation of \textit{depvar}, residuals, linear predictions, standard errors, and probabilities.

Menu for predict

Statistics > Postestimation

Syntax for predict

\begin{verbatim}
  predict [\textit{type}] \textit{newvar} [\textit{if}] [\textit{in}] [, \textit{statistic} \textit{equation(eqno)}]

  predict [\textit{type}] \{\textit{stub*|newvarlist}\} [\textit{if}] [\textit{in}], \textit{scores}
\end{verbatim}

\begin{tabular}{ll}
\textit{statistic} & Description \\
\hline
\textit{ystar} & conditional expectation of \textit{depvar}; the default \\
\textit{residuals} & residuals \\
\textit{ystar}(a,b) & \(E(y_j^*), y_j^* = \max\{a, \min(y_j,b)\}\) \\
\textit{xb} & linear prediction \\
\textit{stdp} & standard error of the linear prediction \\
\textit{pr}(a,b) & \(\Pr(a < y_j < b)\) \\
\textit{e}(a,b) & \(E(y_j|a < y_j < b)\)
\end{tabular}

These statistics are available both in and out of sample; type \texttt{predict ... if \textit{e(sample)} ...} if wanted only for the estimation sample.

where \(a\) and \(b\) may be numbers or variables; \(a\) missing \((a \geq .)\) means \(-\infty\), and \(b\) missing \((b \geq .)\) means \(+\infty\); see \[12.2.1 Missing values\]. For \texttt{churdle exponential}, \(b\) is \(.\) (missing).

Options for predict

\begin{verbatim}
  ystar, the default, calculates the conditional expectation of the dependent variable.
  residuals calculates the residuals.
  ystar\((a,b)\) calculates \(E(y_j^*)\). \(a\) and \(b\) are specified as they are for \textit{pr}(). If \(a\) and \(b\) are equal to the lower and upper bounds specified in \texttt{churdle}, then \(E(y_j^*)\) is equivalent to the predicted value of the dependent variable \textit{ystar}.
  xb calculates the linear prediction.
  stdp calculates the standard error of the linear prediction.
\end{verbatim}
\text{pr}(a,b) \text{ calculates } \Pr(a < y_j < b), \text{ the probability that } y_j|\mathbf{x}_i \text{ would be observed in the interval } (a,b).

\(a\) and \(b\) may be specified as numbers or variable names; \(lb\) and \(ub\) are variable names; \text{pr}(20,30) \text{ calculates } \Pr(20 < y_j < 30); \text{pr}(lb, ub) \text{ calculates } \Pr(lb < y_j < ub); \text{ and } \text{pr}(20, ub) \text{ calculates } \Pr(20 < y_j < ub).

\(a\) missing (\(a \geq .\)) means \(11\); \text{pr}(.30) \text{ calculates } \Pr(ll < y_j < 30);
\text{pr}(lb,30) \text{ calculates } \Pr(ll < y_j < 30) \text{ in observations for which } lb \geq . \text{ and calculates } \Pr(lb < y_j < 30) \text{ elsewhere.}

\(b\) missing (\(b \geq .\)) means \(\infty\); \text{pr}(20,.) \text{ calculates } \Pr(\infty > y_j > 20);
\text{pr}(20,ub) \text{ calculates } \Pr(\infty > y_j > 20) \text{ in observations for which } ub \geq . \text{ and calculates } \Pr(ub > y_j > 20) \text{ elsewhere. For churdle } \text{linear, ul is } \infty.

\text{e}(a,b) \text{ calculates } E(y_j \mid a < y_j < b), \text{ the expected value of } y_j|\mathbf{x}_j \text{ conditional on } y_j|\mathbf{x}_j \text{ being in the interval } (a,b), \text{ meaning that } y_j|\mathbf{x}_j \text{ is bounded. } a \text{ and } b \text{ are specified as they are for } \text{pr}.\)

\text{equation(eqno)} \text{ specifies the equation for which predictions are to be made for the } \text{xb and stdp options. } \text{equation()} \text{ should contain either one equation name or one of } #1, #2, \ldots \text{ with } #1 \text{ meaning the first equation, } #2 \text{ meaning the second equation, etc.}

If you do not specify \text{equation()}, the results are the same as if you specified \text{equation(# 1)}.

\text{scores} \text{ calculates the equation-level score variables. If you specify one new variable, the scores for the latent-variable equation are computed. If you specify a variable list, the scores for each equation are calculated. The following scores may be obtained:}

- the first new variable will contain \(\frac{\partial \ln L}{\partial (x_j \beta)}\),
- the second new variable will contain \(\frac{\partial \ln L}{\partial (z_j \gamma_{ll})}\),
- the third new variable will contain \(\frac{\partial \ln L}{\partial (z_j \gamma_{ul})}\),
- the fourth new variable will contain \(\frac{\partial \ln L}{\partial (\sigma)}\),
- the fifth new variable will contain \(\frac{\partial \ln L}{\partial (\sigma_{ll})}\), and
- the sixth new variable will contain \(\frac{\partial \ln L}{\partial (\sigma_{ul})}\).
margins

Description for margins

margins estimates margins of response for conditional expectations, linear predictions, and probabilities.

Menu for margins

Statistics > Postestimation

Syntax for margins

margins [marginlist] [ , options ]
margins [marginlist], predict(statistic ...) [predict(statistic ...) ...] [options]

statistic          Description

Main
ystar              conditional expectation of depvar; the default
ystar(a,b)         \( E(y_j^*), y_j^* = \max\{a, \min(y_j, b)\} \); for churdle exponential \( b \) is .
xb                  linear prediction
pr(a,b)            \( \Pr(a < y_j < b) \); for churdle exponential \( b \) is .
e(a,b)             \( E(y_j | a < y_j < b) \); for churdle exponential \( b \) is .
residuals         not allowed with margins
stdp               not allowed with margins

Statistics not allowed with margins are functions of stochastic quantities other than \( e(b) \).
For the full syntax, see [R] margins.

Remarks and examples

Example 1: Predictions for depvar

Below we use the parameters estimated in example 1 of [R] churdle to calculate the average hours exercised given the covariates.

. use https://www.stata-press.com/data/r16/fitness
. churdle linear hours age i.smoke distance i.single, > select(commute whours age) ll(0)
   (output omitted)
. predict hourshat
   (statistic ystar assumed)
We might also be interested in estimating the average number of hours exercised given that an individual exercises. Below we estimate this quantity and compare it to the predicted and true values of the dependent variable for all the observations.

```
.predict exercises, e(0,.)
.summarize hours hourshat exercises
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>hours</td>
<td>19,831</td>
<td>.8800172</td>
<td>1.051221</td>
<td>0</td>
<td>5.308835</td>
</tr>
<tr>
<td>hourshat</td>
<td>19,831</td>
<td>.8786302</td>
<td>.4915214</td>
<td>.0754708</td>
<td>1.904694</td>
</tr>
<tr>
<td>exercises</td>
<td>19,831</td>
<td>1.580729</td>
<td>.3998335</td>
<td>.5630298</td>
<td>2.079012</td>
</tr>
</tbody>
</table>

As expected, we observe that the sample-average predictions are higher for those who exercise.

### Example 2: Marginal effects

Suppose we want to study whether single individuals exercise more on average than married individuals. Below, we use `margins` to estimate the average effect of being single on hours spent exercising in the population.

```
.margins, dydx(1.single)
```

Average marginal effects

```
Model VCE : OIM
Expression : Conditional mean estimates of dependent variable, predict()
dy/dx w.r.t. : 1.single
```

| single  | dy/dx     | Std. Err. | z     | P>|z|   | [95% Conf. Interval] |
|---------|-----------|-----------|-------|-------|----------------------|
| single  | .3858462  | .0091398  | 42.22 | 0.000 | .3679324            | .4037599            |

Note: dy/dx for factor levels is the discrete change from the base level.

The average effect of moving each individual from not single to single is an increase in exercise of 0.39 hours, or about 23 minutes.

The statistics \( pr(a,b), e(a,b), \) and \( ystar(a,b) \) produce counterfactual predictions.

These statistics predict what would be observed if the limits \( \ell \ell \) and \( ul \) were the specified \( a \) and \( b \) and the estimated parameters did not change, even though the parameters of the model were estimated using the limits \( \ell \ell \) and \( ul \).

For example, suppose we model contributions to a retirement plan in a world where the government requires a minimum contribution of 2% so \( \ell \ell = 2 \). After estimating the model parameters, we could predict the average contribution, given the covariates, when the government raises the minimum contribution to 3% with the statistic \( ystar(3,.). \)

### Methods and formulas

Let \( \ell \ell \) refer to the lower limit and \( ul \) to the upper limit. Also let the probabilities of being at these limits be given by

\[
\Pr(y_i = \ell \ell | z_i) = \Phi(\ell \ell - z_i' \gamma_{\ell \ell}) \\
\Pr(y_i = ul | z_i) = \Phi(z_i' \gamma_{ul} - ul)
\]
where \( \mathbf{z}_i \) are the covariates of the selection model for individual \( i \), which may be distinct from the covariates \( \mathbf{x}_i \) for the outcome model; \( \Phi \) is the standard normal cumulative distribution function; \( \gamma_{\ell\ell} \) is the parameter vector for the lower-limit selection model; and \( \gamma_{u\ell} \) is the parameter vector for the upper-limit selection model.

We will limit the exposition below to the case with a lower and upper limit.

In churdle linear, \( \text{ystar} \) is equivalent to \( E(y_i|x_i) \) and is given by

\[
E(y_i|x_i, \mathbf{z}_i) = \Phi(z_i'y_{ul} - u\ell) u\ell + \Phi(\ell\ell - z_i'y_{u\ell}) \ell\ell
\]

\[
+ \{ \Phi(u\ell - z_i'\gamma) - \Phi(\ell\ell - z_i'\gamma) \} \left\{ x_i'\beta + \frac{\phi(a-x_i'\beta)}{\phi(b-x_i'\beta)} - \frac{\phi(b-x_i'\beta)}{\phi(a-x_i'\beta)} \right\}
\]

\[\text{pr}(a,b) \text{ is given by} \]

\[
\Pr(a < y_i < b|\mathbf{z}_i) = \Phi(b - z_i'\beta) - \Phi(a - z_i'\beta)
\]

\[\text{e}(a,b) \text{ is given by} \]

\[
E(a < y_i < b|x_i) = x_i'\beta + \frac{\phi(a-x_i'\beta)}{\phi(b-x_i'\beta)} - \frac{\phi(b-x_i'\beta)}{\phi(a-x_i'\beta)}
\]

\[\text{and ystar}(a,b) \text{ is given by} \]

\[
E(y^*) = \Phi(z_i'y_{ul} - b) b + \Phi(a - z_i'y_{u\ell}) a
+ \Pr(a < y_i < b|x_i) E(a < y_i < b|x_i)
\]

For churdle exponential, \( \text{ystar} \) is equivalent to

\[
E(y_i|x_i) = \Phi(\ell\ell - z_i'y_{u\ell}) \ell\ell
\]

\[
+ \{1 - \Phi(\ell\ell - z_i'\gamma)\} \exp(x_i'\beta + \sigma^2/2) \left[ 1 - \Phi\left\{ \frac{\ln(\ell\ell) - x_i'\beta}{\sigma} - \frac{\ln(\ell\ell) - x_i'\beta}{\sigma} \right\} \right]
\]

\[\text{p}(a,.) \text{ is given by} \]

\[
\Pr(a < y_i|x_i) = 1 - \Phi(a - z_i'y_{u\ell})
\]

\[\text{e}(a,.) \text{ is given by} \]

\[
E(a < y_i|x_i) = \exp(x_i'\beta + \sigma^2/2) \left[ 1 - \Phi\left\{ \frac{\ln(a) - x_i'\beta}{\sigma} - \frac{\ln(a) - x_i'\beta}{\sigma} \right\} \right]
\]

\[\text{and ystar}(a,.) \text{ is given by} \]

\[
E(y^*) = a\Phi(a - z_i'y_{u\ell}) + \Pr(a < y_i|x_i) E(a < y_i|x_i)
\]

[U] 20 Estimation and postestimation commands

**Title**

| ci — Confidence intervals for means, proportions, and variances |

**Description**

`ci` computes confidence intervals for population means, proportions, variances, and standard deviations.

`cii` is the immediate form of `ci`; see [U] 19 Immediate commands for a general discussion of immediate commands.

**Quick start**

Confidence intervals for means of normally distributed variables `v1`, `v2`, and `v3`

`ci means v1-v3`

Confidence interval for mean of Poisson-distributed variable `v4`

`ci means v4, poisson`

Confidence interval for rate of `v4` with total exposure recorded in `v5`

`ci means v4, poisson exposure(v5)`

Confidence interval for proportion of binary variable `v6`

`ci proportions v6`

Confidence intervals for variances of `v1`, `v2`, and `v3`

`ci variances v1-v3`

As above, but Bonett confidence intervals are produced

`ci variances v1-v3, bonett`

90% Bonett confidence intervals for standard deviations of `v1`, `v2`, and `v3`

`ci variances v1-v3, sd bonett level(90)`

Confidence interval for a mean based on a sample with 85 observations, a sample mean of 10, and a standard deviation of 3

`cii means 85 10 3`

90% confidence interval for rate from a sample with 4,379 deaths over 11,394 person-years

`cii means 11394 4379, poisson level(90)`

Agresti–Coull confidence interval for proportion based on a sample with 2,377 observations and 136 successes

`cii proportions 2377 136, agresti`
Bonett confidence interval for variance based on a sample with 20 observations, sample variance of 9, and estimated kurtosis of 1.8

    cii variances 20 9 1.8, bonett

As above, but with confidence interval for standard deviation

    cii variances 20 3 1.8, sd bonett

Confidence intervals for means, normal distribution

\texttt{ci means} \ [\texttt{varlist}] \ [\texttt{if}] \ [\texttt{in}] \ [\texttt{weight}] \ [, \texttt{options}] \\
\texttt{cii means} \ #_\texttt{obs} \ #_\texttt{mean} \ #_\texttt{sd} \ [, \texttt{level(#)}] \\

Confidence intervals for means, Poisson distribution

\texttt{ci means} \ [\texttt{varlist}] \ [\texttt{if}] \ [\texttt{in}] \ [\texttt{weight}], \texttt{poisson} \ [\texttt{exposure(varname)} \ \texttt{options}] \\
\texttt{cii means} \ #_\texttt{exposure} \ #_\texttt{events} \ , \texttt{poisson} \ [\texttt{level(#)}] \\

Confidence intervals for proportions

\texttt{ci proportions} \ [\texttt{varlist}] \ [\texttt{if}] \ [\texttt{in}] \ [\texttt{weight}] \ [, \texttt{prop_options} \ \texttt{options}] \\
\texttt{cii proportions} \ #_\texttt{obs} \ #_\texttt{succ} \ [, \texttt{prop_options} \ \texttt{level(#)}] \\

Confidence intervals for variances

\texttt{ci variances} \ [\texttt{varlist}] \ [\texttt{if}] \ [\texttt{in}] \ [\texttt{weight}] \ [, \texttt{bonett} \ \texttt{options}] \\
\texttt{cii variances} \ #_\texttt{obs} \ #_\texttt{variance} \ [, \texttt{level(#)}] \\
\texttt{cii variances} \ #_\texttt{obs} \ #_\texttt{variance} \ #_\texttt{kurtosis}, \texttt{bonett} \ [\texttt{level(#)}] \\

Confidence intervals for standard deviations

\texttt{ci variances} \ [\texttt{varlist}] \ [\texttt{if}] \ [\texttt{in}] \ [\texttt{weight}], \texttt{sd} \ [\texttt{bonett} \ \texttt{options}] \\
\texttt{cii variances} \ #_\texttt{obs} \ #_\texttt{sd} \ [, \texttt{level(#)}] \\
\texttt{cii variances} \ #_\texttt{obs} \ #_\texttt{sd} \ #_\texttt{kurtosis}, \texttt{sd bonett} \ [\texttt{level(#)}] \\

\texttt{#_obs} must be a positive integer. \texttt{#_exposure}, \texttt{#_sd}, and \texttt{#_variance} must be a positive number. \texttt{#_succ} and \texttt{#_events} must be a nonnegative integer or between 0 and 1. If the number is between 0 and 1, Stata interprets it as the fraction of successes or events and converts it to an integer number representing the number of successes or events. The computation then proceeds as if two integers had been specified. If option \texttt{bonett} is specified, you must additionally specify \texttt{#_kurtosis} with \texttt{cii variances}. 
### Options

Options are presented under the following headings:

- Options for `ci` and `cii` means
- Options for `ci` and `cii` proportions
- Options for `ci` and `cii` variances

### Options for `ci` and `cii` means

- **poisson** specifies that the variables (or numbers for `cii`) are Poisson-distributed counts; exact Poisson confidence intervals will be calculated. By default, confidence intervals for means are calculated based on a normal distribution.

- **exposure(\textit{varname})** is used only with `poisson`. You do not need to specify `poisson` if you specify `exposure()`; `poisson` is assumed. \textit{varname} contains the total exposure (typically a time or an area) during which the number of events recorded in \textit{varlist} was observed.

- **level(\#)** specifies the confidence level, as a percentage, for confidence intervals. The default is `level(95)` or as set by `set level`; see [R] \texttt{level}.

- **separator(\#)** specifies how often separation lines should be inserted into the output. The default is `separator(5)`, meaning that a line is drawn after every five variables. `separator(10)` would draw the line after every 10 variables. `separator(0)` suppresses the separation line.

- **total** is used with the `by` prefix. It requests that in addition to output for each `by`-group, output be added for all groups combined.
Options for ci and cii proportions

```
Main

exact, wald, wilson, agresti, and jeffreys specify how binomial confidence intervals are to be calculated.

  exact is the default and specifies exact (also known in the literature as Clopper–Pearson [1934])
  binomial confidence intervals.

  wald specifies calculation of Wald confidence intervals.

  wilson specifies calculation of Wilson confidence intervals.

  agresti specifies calculation of Agresti–Coull confidence intervals.

  jeffreys specifies calculation of Jeffreys confidence intervals.

See Brown, Cai, and DasGupta (2001) for a discussion and comparison of the different binomial
confidence intervals.

level(#) specifies the confidence level, as a percentage, for confidence intervals. The default is
level(95) or as set by set level; see [R] level.

separator(#) specifies how often separation lines should be inserted into the output. The default is
separator(5), meaning that a line is drawn after every five variables. separator(10) would
draw the line after every 10 variables. separator(0) suppresses the separation line.

total is used with the by prefix. It requests that in addition to output for each by-group, output be
added for all groups combined.
```

Options for ci and cii variances

```
Main

sd specifies that confidence intervals for standard deviations be calculated. The default is to compute
confidence intervals for variances.

bonett specifies that Bonett confidence intervals be calculated. The default is to compute normal-based
confidence intervals, which assume normality for the data.

level(#) specifies the confidence level, as a percentage, for confidence intervals. The default is
level(95) or as set by set level; see [R] level.

separator(#) specifies how often separation lines should be inserted into the output. The default is
separator(5), meaning that a line is drawn after every five variables. separator(10) would
draw the line after every 10 variables. separator(0) suppresses the separation line.

total is used with the by prefix. It requests that in addition to output for each by-group, output be
added for all groups combined.
```

Remarks and examples

Remarks are presented under the following headings:

- Confidence intervals for means
- Normal-based confidence intervals
- Poisson confidence intervals
- Confidence intervals for proportions
- Confidence intervals for variances
- Immediate form
Confidence intervals for means

`ci means` computes a confidence interval for the population mean for each of the variables in `varlist`.

Normal-based confidence intervals

Example 1: Normal-based confidence intervals

Without the `poisson` option, `ci means` produces normal-based confidence intervals that are correct if the variable is normally distributed and asymptotically correct for all other distributions satisfying the conditions of the central limit theorem.

```
. use https://www.stata-press.com/data/r16/auto
(1978 Automobile Data)
. ci means mpg price
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>mpg</td>
<td>74</td>
<td>21.2973</td>
<td>.6725511</td>
<td>19.9569 22.63769</td>
</tr>
<tr>
<td>price</td>
<td>74</td>
<td>6165.257</td>
<td>342.8719</td>
<td>5481.914 6848.6</td>
</tr>
</tbody>
</table>

The standard error of the mean of `mpg` is 0.67, and the 95% confidence interval is [19.96, 22.64]. We can obtain wider confidence intervals, 99%, by typing

```
. ci means mpg price, level(99)
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>[99% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>mpg</td>
<td>74</td>
<td>21.2973</td>
<td>.6725511</td>
<td>19.51849 23.07611</td>
</tr>
<tr>
<td>price</td>
<td>74</td>
<td>6165.257</td>
<td>342.8719</td>
<td>5258.405 7072.108</td>
</tr>
</tbody>
</table>

Example 2: The by prefix

The `by` prefix breaks out the confidence intervals according to by-group; `total` adds an overall summary. For instance,

```
. by foreign: ci means mpg, total
```

<table>
<thead>
<tr>
<th><code>foreign = Domestic</code></th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>mpg</td>
<td>52</td>
<td>19.82692</td>
<td>.657777</td>
<td>18.50638 21.14747</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th><code>foreign = Foreign</code></th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>mpg</td>
<td>22</td>
<td>24.77273</td>
<td>1.40951</td>
<td>21.84149 27.70396</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th><code>Total</code></th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>mpg</td>
<td>74</td>
<td>21.2973</td>
<td>.6725511</td>
<td>19.9569 22.63769</td>
</tr>
</tbody>
</table>
Example 3: Controlling the format

You can control the formatting of the numbers in the output by specifying a display format for the variable; see [U] 12.5 Formats: Controlling how data are displayed. For instance,

```
. format mpg %9.2f
. ci means mpg
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>mpg</td>
<td>74</td>
<td>21.30</td>
<td>0.67</td>
<td>19.96 22.64</td>
</tr>
</tbody>
</table>

Poisson confidence intervals

If you specify the poisson option, `ci means` assumes count data and computes exact Poisson confidence intervals.

Example 4: Poisson confidence intervals

We have data on the number of bacterial colonies on a Petri dish. The dish has been divided into 36 small squares, and the number of colonies in each square has been counted. Each observation in our dataset represents a square on the dish. The variable `count` records the number of colonies in each square counted, which varies from 0 to 5.

```
. use https://www.stata-press.com/data/r16/petri, clear
. ci means count, poisson
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Exposure</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>count</td>
<td>36</td>
<td>2.33333</td>
<td>.2545875</td>
<td>1.861158 2.888825</td>
</tr>
</tbody>
</table>

ci reports that the average number of colonies per square is 2.33. If the expected number of colonies per square were as low as 1.86, the probability of observing 2.33 or more colonies per square would be 2.5%. If the expected number were as large as 2.89, the probability of observing 2.33 or fewer colonies per square would be 2.5%.

Example 5: Option exposure()

The number of “observations”—how finely the Petri dish is divided—makes no difference. The Poisson distribution is a function only of the count. In example 4, we observed a total of $2.33 \times 36 = 84$ colonies and a confidence interval of $[1.86 \times 36, 2.89 \times 36] = [67, 104]$. We would obtain the same [67, 104] confidence interval if our dish were divided into, say, 49 squares rather than 36.

For the counts, it is not even important that all the squares be of the same size. For rates, however, such differences do matter but in an easy-to-calculate way. Rates are obtained from counts by dividing by exposure, which is typically a number multiplied by either time or an area. For our Petri dishes, we divide by an area to obtain a rate, but if our example were cast in terms of being infected by a disease, we might divide by person-years to obtain the rate. Rates are convenient because they are easier to compare: we might have 2.3 colonies per square inch or 0.0005 infections per person-year.

So let’s assume that we wish to obtain the number of colonies per square inch and, moreover, that not all the “squares” on our dish are of equal size. We have a variable called `area` that records the area of each square:
The rates are now in more familiar terms. In our sample, there are 28 colonies per square inch, and the 95% confidence interval is [22.3, 34.7]. When we did not specify exposure(), ci means with option poisson assumed that each observation contributed 1 to exposure.

Technical note

If there were no colonies on our dish, ci means with option poisson would calculate a one-sided confidence interval:

```stata
use https://www.stata-press.com/data/r16/petrinone
. ci means count, poisson
```

Confidence intervals for proportions

The ci proportions command assumes binary (0/1) data and computes binomial confidence intervals.

Example 6: Exact binomial (Clopper–Pearson) confidence interval

We have data on employees, including a variable marking whether the employee was promoted last year.

```stata
use https://www.stata-press.com/data/r16/promo
. ci proportions promoted
```

The exact binomial, also known as the Clopper–Pearson (1934) interval, is computed by default.

Nominally, the interpretation of a 95% confidence interval is that under repeated samples or experiments, 95% of the resultant intervals would contain the unknown parameter in question. However, for binomial data, the actual coverage probability, regardless of method, usually differs from that interpretation. This result occurs because of the discreteness of the binomial distribution, which produces only a finite set of outcomes, meaning that coverage probabilities are subject to discrete jumps and that the exact nominal level cannot always be achieved. Therefore, the term “exact confidence interval” refers to its being derived from the binomial distribution, the distribution exactly generating the data, rather than resulting in exactly the nominal coverage.
For the Clopper–Pearson interval, the actual coverage probability is guaranteed to be greater than or equal to the nominal confidence level, here 95%. Because of the way it is calculated—see Methods and formulas—it may also be interpreted as follows: If the true probability of being promoted were 0.012, the chances of observing a result as extreme or more extreme than the result observed (20 × 0.1 = 2 or more promotions) would be 2.5%. If the true probability of being promoted were 0.317, the chances of observing a result as extreme or more extreme than the result observed (two or fewer promotions) would be 2.5%.

Example 7: Other confidence intervals

The Clopper–Pearson interval is desirable because it guarantees nominal coverage; however, by dropping this restriction, you may obtain accurate intervals that are not as conservative. In this vein, you might opt for the Wilson (1927) interval,

```
. ci proportions promoted, w
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Proportion</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>promoted</td>
<td>20</td>
<td>.1</td>
<td>.067082</td>
<td>.0278665 .3010336</td>
</tr>
</tbody>
</table>
```

the Agresti–Coull (1998) interval,

```
. ci proportions promoted, agresti
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Proportion</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>promoted</td>
<td>20</td>
<td>.1</td>
<td>.067082</td>
<td>.0156562 .3132439</td>
</tr>
</tbody>
</table>
```

or the Bayesian-derived Jeffreys interval (Brown, Cai, and DasGupta 2001),

```
. ci proportions promoted, jeffreys
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Proportion</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>promoted</td>
<td>20</td>
<td>.1</td>
<td>.067082</td>
<td>.0213725 .2838533</td>
</tr>
</tbody>
</table>
```

Picking the best interval is a matter of balancing accuracy (coverage) against precision (average interval length) and depends on sample size and success probability. Brown, Cai, and DasGupta (2001) recommend the Wilson or Jeffreys interval for small sample sizes (≤40) yet favor the Agresti–Coull interval for its simplicity, decent performance for sample sizes less than or equal to 40, and performance comparable to Wilson or Jeffreys for sample sizes greater than 40. They also deem the Clopper–Pearson interval to be “wastefully conservative and […] not a good choice for practical use”, unless of course one requires, at a minimum, the nominal coverage level.

Finally, the binomial Wald confidence interval is obtained by specifying the *wald* option. The Wald interval is the one taught in most introductory statistics courses and, for the above, is simply, for level 1 − α, \( \text{Proportion} \pm z_{\alpha/2} \text{(Std. Err.)} \), where \( z_{\alpha/2} \) is the \( 1 - \alpha/2 \) quantile of the standard normal. Because its overall poor performance makes it impractical, the Wald interval is available mainly for pedagogical purposes. The binomial Wald interval is also similar to the interval produced by treating binary data as normal data and using *ci means*, with two exceptions. First, the calculation of the standard error in *ci proportions* uses denominator \( n \) rather than \( n - 1 \), used for normal data in *ci means*. Second, confidence intervals for normal data are based on the \( t \) distribution rather than the standard normal. Of course, both discrepancies vanish as sample size increases.
Technical note

Let’s repeat example 6, but this time with data in which there are no promotions over the observed period:

```
. use https://www.stata-press.com/data/r16/promonone
. ci proportions promoted
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Proportion</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>promoted</td>
<td>20</td>
<td>0</td>
<td>0</td>
<td>0 0.1684335*</td>
</tr>
</tbody>
</table>

(* one-sided, 97.5% confidence interval

The confidence interval is [0, 0.168], and this is the confidence interval that most books publish. It is not, however, a true 95% confidence interval because the lower tail has vanished. As Stata notes, it is a one-sided, 97.5% confidence interval. If you wanted to put 5% in the right tail, you could type `ci proportions promoted, level(90)`.

Technical note

`ci proportions` ignores any variables that do not take on the values 0 and 1 exclusively. For instance, with our automobile dataset,

```
. use https://www.stata-press.com/data/r16/auto
(1978 Automobile Data)
. ci proportions mpg foreign
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Proportion</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>foreign</td>
<td>74</td>
<td>0.2972973</td>
<td>0.0531331</td>
<td>0.196584 0.4148353</td>
</tr>
</tbody>
</table>

Note: The results are produced only for binary (0/1) variables.

We also requested the confidence interval for `mpg`, but Stata ignored us. It does that so you can type `ci proportions` and obtain correct confidence intervals for all the variables that are 0/1 in your data.

Confidence intervals for variances

The `ci variances` command computes confidence intervals for the variances or, if the `sd` option is specified, for the standard deviations. The default is a normal-based confidence interval that assumes the data are normal and uses a $\chi^2$ distribution to construct the confidence intervals. If normality is suspect, you may consider using the `bonett` option to compute Bonett (2006) confidence intervals, which are more robust to nonnormality.

Example 8: Normal-based confidence intervals

So far, we have restricted our attention to confidence intervals for means and proportions. Typically, when people think of statistical inference, they usually have in mind inferences concerning population means. However, the population parameter of interest will vary from one situation to another. In many scenarios, the population variance is as important as the population mean. For example, in a quality
control study, a machine that fills 16-ounce canned peas is investigated at regular time intervals. A random sample of \( n = 8 \) containers is selected every hour. Ideally, the amount of peas in a can should vary only slightly about the 16-ounce value. If the variance was large, then a large proportion of cans would be either underfilled, thus cheating the customer, or overfilled, thus resulting in economic loss to the manufacturing company. Suppose that the weights of 16-ounce cans filled by the machine are normally distributed. The acceptable variability in the weights is expected to be 0.09 with the respective standard deviation of 0.3 ounces. To monitor the machine’s performance, we can compute confidence intervals for the variance of the weights of cans:

```
. use https://www.stata-press.com/data/r16/peas_normdist
(Weights of Canned Peas, Normal Distribution)
. ci variances weight
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Variance</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>weight</td>
<td>8</td>
<td>.3888409</td>
<td>.1699823 1.610708</td>
</tr>
</tbody>
</table>

The command reports the sample estimate of the variance of 0.39 with the 95% confidence interval of [0.17, 1.61].

Instead of the variance, we may be interested in confidence intervals for the standard deviation. We can specify the `sd` option to compute such confidence intervals.

```
. ci variances weight, sd
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Std. Dev.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>weight</td>
<td>8</td>
<td>.6235711</td>
<td>.4122891 1.269137</td>
</tr>
</tbody>
</table>

The 95% confidence interval for the standard deviation of the weights is [0.41, 1.27]. Because the desired value for the standard deviation, 0.3 ounces, falls outside the interval, the machine may require some tuning.

Confidence intervals in example 8 are based on the assumption that the random sample is selected from a population having a normal distribution. Nonnormality of the population distribution, in the form of skewness or heavy tails, can have a drastic impact on the asymptotic coverage probability of the normal-based confidence intervals. This is the case even for distributions that are similar to normal. Scheffé (1959, 336) showed that the normal-based interval has an asymptotic coverage probability of about 0.76, 0.63, 0.60, and 0.51 for the logistic, \( t \) with seven degrees of freedom, Laplace, and \( t \) with five degrees of freedom distributions, respectively. Miller (1997, 264) describes this situation as “catastrophic” because these distributions are symmetric and not easily distinguishable from a normal distribution unless the sample size is large. Hence, it is judicious to evaluate the normality of the data prior to constructing the normal-based confidence intervals for variances or standard deviations.

Bonett (2006) proposed a confidence interval that performs well in small samples under moderate departures from normality. His interval performs only slightly worse than the exact normal-based confidence interval when sampling from a normal distribution. A larger sample size provides Bonett confidence intervals with greater protection against nonnormality.

Example 9: Bonett confidence interval for normal data

We will repeat example 8 and construct a Bonett confidence interval for the standard deviation by specifying the `bonett` option. The results are similar, and both examples lead to the same inferential conclusion.
The Bonett confidence interval is wider than the normal-based confidence interval in example 8. For normal data, Bonett (2006) suggested that if Bonett confidence interval is used for a sample of size $n + 3$, then its average width will be about the same as the average width of the normal-based confidence interval from a sample size of $n$. Sampling three more observations may be a small price to pay because Bonett confidence intervals perform substantially better than the normal-based confidence intervals for nonnormal data.

### Example 10: Bonett confidence interval for nonnormal data

The following data have been generated from a $t$ distribution with five degrees of freedom to illustrate the effect of wrongfully using the normal-based confidence interval when the data-generating process is not normal.

```
.data tdist
.use https://www.stata-press.com/data/r16/peas_tdist
(ci variances weight, sd)
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Std. Dev.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>weight</td>
<td>8</td>
<td>2.226558</td>
<td>1.472143 4.531652</td>
</tr>
</tbody>
</table>

The standard deviation of a $t$ distribution with five degrees of freedom is $\sqrt{\frac{5}{3}} \approx 1.29$ and falls outside the confidence interval limits. If we suspect that data may not be normal, the Bonett confidence interval is typically a better choice:

```
(ci variances weight, sd bonett)
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Std. Dev.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>weight</td>
<td>8</td>
<td>2.226558</td>
<td>1.137505 5.772519</td>
</tr>
</tbody>
</table>

The value 1.29 is within the limits of the Bonett confidence interval $[1.14, 5.77]$.

### Immediate form

So far, we computed confidence intervals for various parameters using data in memory. We can also compute confidence intervals using only data summaries, without any data in memory. Each of the considered `ci` commands has an immediate `cii` version that computes the respective confidence intervals using data summaries.

### Example 11: Confidence interval for a normal mean

We are reading a soon-to-be-published paper by a colleague. In it is a table showing the number of observations, mean, and standard deviation of the 1980 median family income for the Northeast and West. We correctly think that the paper would be much improved if it included the confidence intervals. The paper claims that for 166 cities in the Northeast, the average of median family income is $19,509 with a standard deviation of $4,379:
For the Northeast:
   \[ .\ cii\ means\ 166\ 19509\ 4379 \]
   \[ \begin{array}{cccc}
   \text{Variable} & \text{Obs} & \text{Mean} & \text{Std. Err.} & [95\% \text{ Conf. Interval}] \\
   \hline
   & 166 & 19509 & 339.8763 & 18837.93 - 20180.07
   \end{array} \]

For the West:
   \[ .\ cii\ means\ 256\ 22557\ 5003 \]
   \[ \begin{array}{cccc}
   \text{Variable} & \text{Obs} & \text{Mean} & \text{Std. Err.} & [95\% \text{ Conf. Interval}] \\
   \hline
   & 256 & 22557 & 312.6875 & 21941.22 - 23172.78
   \end{array} \]

Example 12: Confidence interval for a Poisson mean

The number of reported traffic accidents in Santa Monica over a 24-hour period is 27. We need know nothing else to compute a confidence interval for the mean number of accidents for a day:
   \[ .\ cii\ means\ 1\ 27,\ poisson \]
   \[ \begin{array}{cccc}
   \text{Variable} & \text{Exposure} & \text{Mean} & \text{Std. Err.} & [95\% \text{ Conf. Interval}] \\
   \hline
   & 1 & 27 & 5.196152 & 17.79317 - 39.28358
   \end{array} \]

Example 13: Confidence interval for a proportion

We flip a coin 10 times, and it comes up heads only once. We are shocked and decide to obtain a 99% confidence interval for this coin:
   \[ .\ cii\ proportions\ 10\ 1,\ level(99) \]
   \[ \begin{array}{cccc}
   \text{Variable} & \text{Obs} & \text{Proportion} & \text{Std. Err.} & [99\% \text{ Conf. Interval}] \\
   \hline
   & 10 & .1 & .0948683 & .0005011 - .5442871
   \end{array} \]

Example 14: Confidence interval for a variance

A company fills 32-ounce tomato juice jars with a quantity of juice having a normal distribution with a claimed variance not exceeding 0.2. A random sample of 15 jars is collected to evaluate this claim. The sample variance is 0.5:
   \[ .\ cii\ variances\ 15\ 0.5 \]
   \[ \begin{array}{ccccc}
   \text{Variable} & \text{Obs} & \text{Variance} & [95\% \text{ Conf. Interval}] \\
   \hline
   & 15 & .5 & .2680047 & 1.243621
   \end{array} \]

Because the advertised value of 0.2 does not fall inside the confidence interval, the company is allowing too much variation in the amount of tomato juice per jar.
Example 15: Confidence interval for a standard deviation

Suppose the director of statistical development at a statistical software company is a big soccer fan and requires all developers to play on the company team in the city’s local soccer league. Ten developers are randomly selected to participate in the game. To ensure an advantage over other teams, the director requires each of the 10 developers to cover 6 miles on average each game. Being merciful, she will tolerate a standard deviation of 0.3 miles across different players, arguing that this will keep the team’s performance consistent. The distance covered by each player is measured using a pedometer. At the end of the game, the sample standard deviation of the distances covered by the 10 players was 0.56 miles:

```
cii variances 10 0.56, sd
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Std. Dev.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>10</td>
<td>.56</td>
<td>.3851877</td>
<td>1.022342</td>
</tr>
</tbody>
</table>

Because the confidence interval does not include the designated value for the standard deviation, 0.3 miles, it is clear the team is not meeting standards, and an unpleasant meeting is planned.

Example 16: Confidence interval for a standard deviation of nonnormal data

Continuing with example 15, a clever statistician points out that distances covered by company players in a soccer match do not follow the normal distribution because some players, mostly econometricians, walk on the field, while others, mostly statisticians, do all the running. Therefore, the normal-based confidence interval (which assumes normality) is not valid. Instead, we should use the Bonett confidence interval, which additionally requires an estimate of kurtosis; see *Methods and formulas*. If kurtosis is estimated to be 5, we would obtain the following:

```
cii variances 10 0.56 5, sd bonett
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Std. Dev.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>10</td>
<td>.56</td>
<td>.2689449</td>
<td>1.45029</td>
</tr>
</tbody>
</table>

The Bonett confidence interval now contains the specified value for the standard deviation, 0.3 miles. The director of statistics concludes that overall team performance is acceptable. An uncomfortable meeting is still planned but for a smaller group.

Stored results

*ci means* and *cii means* store the following in r():

Scalars
- `r(N)` number of observations or, if *poisson* is specified, exposure
- `r(mean)` mean
- `r(se)` estimate of standard error
- `r(lb)` lower bound of confidence interval
- `r(ub)` upper bound of confidence interval
- `r(level)` confidence level of confidence interval

Macros
- `r(citype)` normal or *poisson*; type of confidence interval
- `r(exposure)` name of exposure variable with *poisson*
ci proportions and cii proportions store the following in r():

Scalars
- \texttt{r(N)} number of observations
- \texttt{r(proportion)} proportion
- \texttt{r(se)} estimate of standard error
- \texttt{r(lb)} lower bound of confidence interval
- \texttt{r(ub)} upper bound of confidence interval
- \texttt{r(level)} confidence level of confidence interval

Macros
- \texttt{r(citype)} exact, wald, wilson, agresti, or jeffreys; type of confidence interval

ci variances and cii variances store the following in r():

Scalars
- \texttt{r(N)} number of observations
- \texttt{r(Var)} variance
- \texttt{r(sd)} standard deviation, if sd is specified
- \texttt{r(kurtosis)} kurtosis, only if bonett is specified
- \texttt{r(lb)} lower bound of confidence interval
- \texttt{r(ub)} upper bound of confidence interval
- \texttt{r(level)} confidence level of confidence interval

Macros
- \texttt{r(citype)} normal or bonett, type of confidence interval

Methods and formulas

Methods and formulas are presented under the following headings:

- Normal mean
- Poisson mean
- Binomial proportion
- Variance and standard deviation

Normal mean

Define \( n, \bar{x}, \) and \( s^2 \) as, respectively, the number of observations, (weighted) average, and (unbiased) estimated variance of the variable in question; see \texttt{[R] summarize}.

The standard error of the mean, \( s_{\mu} \), is defined as \( \sqrt{s^2/n} \).

Let \( \alpha \) be \( 1 - l/100 \), where \( l \) is the confidence level specified by the user in the \texttt{level()} option. Define \( t_{\alpha/2} \) as the two-sided \( t \) statistic corresponding to a significance level of \( \alpha \) with \( n - 1 \) degrees of freedom; \( t_{\alpha/2} \) is obtained from Stata as \texttt{invttail(n-1,0.5*\alpha)}). The lower and upper confidence bounds are, respectively, \( \bar{x} - s_{\mu}t_{\alpha/2} \) and \( \bar{x} + s_{\mu}t_{\alpha/2} \).

Poisson mean

Given the total cases, \( k \), the estimate of the expected count \( \lambda \) is \( k \), and its standard error is \( \sqrt{k} \). \texttt{ci means} with option poisson calculates the exact confidence interval \([\lambda_1, \lambda_2]\) such that

\[
\Pr(K \geq k|\lambda = \lambda_1) = \alpha/2
\]

and

\[
\Pr(K \leq k|\lambda = \lambda_2) = \alpha/2
\]

where \( K \) is Poisson with mean \( \lambda \). Solution is obtained by Newton’s method. If \( k = 0 \), the calculation of \( \lambda_1 \) is skipped. All values are then reported as rates, which are the above numbers divided by the total exposure.
Binomial proportion

Given \( k \) successes of \( n \) trials, the estimated probability of a success is \( \hat{p} = k/n \) with standard error \( \sqrt{\hat{p}(1 - \hat{p})/n} \). \( \text{ci} \) calculates the exact (Clopper–Pearson) confidence interval \([p_1, p_2]\) such that

\[
\Pr(K \geq k | p = p_1) = \alpha/2
\]

and

\[
\Pr(K \leq k | p = p_2) = \alpha/2
\]

where \( K \) is distributed as binomial\((n, p)\). The endpoints may be obtained directly by using Stata’s `invbinomial()` function. If \( k = 0 \) or \( k = n \), the calculation of the appropriate tail is skipped.

The Wald interval is \( \hat{p} \pm z_{\alpha/2} \sqrt{n^{-1}(1 - \hat{p})/n} \), where \( z_{\alpha/2} \) is the \( 1 - \alpha/2 \) quantile of the standard normal. The interval is obtained by inverting the acceptance region of the large-sample Wald test of \( H_0: p = p_0 \) versus the two-sided alternative. That is, the confidence interval is the set of all \( p_0 \) such that

\[
\left| \frac{\hat{p} - p_0}{\sqrt{n^{-1}\hat{p}(1 - \hat{p})}} \right| \leq z_{\alpha/2}
\]

The Wilson interval is a variation on the Wald interval, using the null standard error \( \sqrt{n^{-1}p_0(1 - p_0)} \) in place of the estimated standard error \( \sqrt{n^{-1}\hat{p}(1 - \hat{p})} \) in the above expression. Inverting this acceptance region is more complicated yet results in the closed form

\[
\frac{k + \frac{z_{\alpha/2}^2}{2}}{n + \frac{z_{\alpha/2}^2}{2}} \pm \frac{z_{\alpha/2} n^{1/2}}{n + \frac{z_{\alpha/2}^2}{2}} \left\{ \frac{\hat{p}(1 - \hat{p}) + \frac{z_{\alpha/2}^2}{4n}}{4} \right\}^{1/2}
\]

The Agresti–Coull interval is basically a Wald interval that borrows its center from the Wilson interval. Defining \( \tilde{k} = k + \frac{z_{\alpha/2}^2}{2}, \tilde{n} = n + \frac{z_{\alpha/2}^2}{2} \), and (hence) \( \tilde{p} = \tilde{k}/\tilde{n} \), the Agresti–Coull interval is

\[
\tilde{p} \pm z_{\alpha/2} \sqrt{\tilde{p}(1 - \tilde{p})/\tilde{n}}
\]

When \( \alpha = 0.05 \), \( z_{\alpha/2} \) is near enough to 2 that \( \tilde{p} \) can be thought of as a typical estimate of proportion where two successes and two failures have been added to the sample (Agresti and Coull 1998). This typical estimate of proportion makes the Agresti–Coull interval an easy-to-present alternative for introductory statistics students.

The Jeffreys interval is a Bayesian credible interval and is based on the Jeffreys prior, which is the Beta\((1/2, 1/2)\) distribution. Assigning this prior to \( p \) results in a posterior distribution for \( p \) that is Beta with parameters \( k + 1/2 \) and \( n - k + 1/2 \). The Jeffreys interval is then taken to be the \( 1 - \alpha \) central posterior probability interval, namely, the \( \alpha/2 \) and \( 1 - \alpha/2 \) quantiles of the Beta\((k + 1/2, n - k + 1/2)\) distribution. These quantiles may be obtained directly by using Stata’s `invibeta()` function. See [BAYES] bayesstats summary for more details about credible intervals.

**Variance and standard deviation**

Let \( X_1, \ldots, X_n \) be a random sample and assume that \( X_i \sim N(\mu, \sigma^2) \). Because \( (n - 1)s^2/\sigma^2 \sim \chi_{n-1,1}^2 \), we have \( \Pr\{\chi_{n-1,1,\alpha/2}^2 \leq (n - 1)s^2/\sigma^2 \leq \chi_{n-1,1,1-\alpha/2}^2\} = 1 - \alpha \), where \( \chi_{n-1,1,\alpha/2}^2 \) and \( \chi_{n-1,1,1-\alpha/2}^2 \) are the \( \alpha/2 \) and \( 1 - \alpha/2 \) quantiles of the \( \chi_{n-1}^2 \) distribution. Thus the normal-based confidence interval for the population variance \( \sigma^2 \) with \( 100(1 - \alpha)\% \) confidence level is given by

\[
I_{\text{normal}} = \left[ \frac{(n - 1)s^2}{\chi_{n-1,1,1-\alpha/2}^2}, \frac{(n - 1)s^2}{\chi_{n-1,1,\alpha/2}^2} \right]
\]
\( \chi_{n-1,1-\alpha/2}^2 \) and \( \chi_{n-1,\alpha/2}^2 \) are obtained from Stata as \texttt{invchi2tail}(n-1,0.5*\alpha) and \texttt{invchi2}(n-1,0.5*\alpha), respectively.

The normal-based confidence interval is very sensitive to minor departures from the normality assumption and its performance does not improve with increasing sample size. For scenarios in which the population distribution is not normal, the actual coverage probability of the normal-based confidence interval can be drastically lower than the nominal confidence level \( \alpha \).

Bonett (2006) proposed an alternative to the normal-based confidence interval that is nearly exact under normality and has coverage probability close to \( 1 - \alpha \) under moderate nonnormality. It also has \( 1 - \alpha \) asymptotic coverage probability for nonnormal distributions with finite fourth moments. Instead of assuming that \( X_i \sim N(\mu, \sigma^2) \), Bonett’s approach requires continuous i.i.d. random variables with finite fourth moment. The variance of \( s^2 \) may be expressed as \( \sigma^4 \left\{ \gamma_4 - (n - 3)/(n - 1) \right\} / n \) (see Casella and Berger [2002, ex. 5.8, 257]), where \( \gamma_4 = \mu^4/\sigma^4 \) is the kurtosis and \( \mu^4 = E(X_i - \mu)^4 \) is the population fourth central moment. The variance-stabilizing transformation \( \ln(s^2) \) and the delta method can be used to construct an asymptotic \( 100(1 - \alpha)\% \) confidence interval for \( \sigma^2 \),

\[
\left[ \exp \left\{ \ln(s^2) - z_{\alpha/2}se \right\}, \exp \left\{ \ln(s^2) + z_{\alpha/2}se \right\} \right]
\]

where \( se = \{ \hat{\gamma}_4 - (n - 3)/(n - 1) \} / n \approx \text{Var}\{\ln(s^2)\} \) and \( \hat{\gamma}_4 \) is an estimate of the kurtosis. Bonett introduced three adjustments to improve the small-sample properties of the above confidence interval. First, he swapped the inner and outer denominator in the expression for \( se \) and changed it to \( \{ \hat{\gamma}_4 - (n - 3)/n \} / (n - 1) \). This was suggested by Shoemaker (2003) who used it to improve the small-sample performance of his variance test. Second, with regard to the estimation of kurtosis, Bonett proposed \( \hat{\gamma}_4 = n \sum (X_i - m)^4 / \left\{ \sum (X_i - \bar{X})^2 \right\}^2 \), where \( m \) is a trimmed mean with a trim-proportion equal to \( 1/\left\{ 2(n - 4)^{1/2} \right\} \). This kurtosis estimator reduces the negative bias in symmetric and skewed heavy-tailed distributions. Last, he empirically derived a small-sample correction factor \( c = n/(n - z_{\alpha/2}) \) that helps equalize the tail probabilities. These modifications yield

\[
I_{\text{Bonett}} = \left[ \exp \left\{ \ln(cs^2) - z_{\alpha/2}se \right\}, \exp \left\{ \ln(cs^2) + z_{\alpha/2}se \right\} \right]
\]

where \( z_{\alpha/2} \) is the \( 1 - \alpha/2 \) quantile of the standard normal and \( se = c \{ \hat{\gamma}_4 - (n - 3)/n \} /(n - 1) \).

Taking the square root of the endpoints of both intervals gives confidence intervals for the standard deviation \( \sigma \).

---

Edwin Bidwell (E. B.) Wilson (1879–1964) majored in mathematics at Harvard and studied and taught at Yale and MIT before returning to Harvard in 1922. He worked in mathematics, physics, and statistics. His method for binomial intervals can be considered a precursor, for a particular problem, of Neyman’s concept of confidence intervals.

Jerzy Neyman (1894–1981) was born in Bendery, Russia, now Moldavia. He studied and then taught at Kharkov University, moving from physics to mathematics. In 1921, Neyman moved to Poland, where he worked in statistics at Bydgoszcz and then Warsaw. Neyman received a Rockefeller Fellowship to work with Karl Pearson at University College London. There he collaborated with Egon Pearson, Karl’s son, on the theory of hypothesis testing. Life in Poland became progressively more difficult, and Neyman returned to UCL to work there from 1934 to 1938. At this time, he published on the theory of confidence intervals. He then was offered a post in California at Berkeley, where he settled. Neyman established an outstanding statistics department and remained highly active in research, including applications in astronomy, meteorology, and medicine. He was one of the great statisticians of the 20th century.
Acknowledgment

We thank Nicholas J. Cox of the Department of Geography at Durham University, UK, and coeditor of the *Stata Journal* and author of *Speaking Stata Graphics* for his assistance with the jeffreys and wilson options.

**Description**

clogit fits a conditional logistic regression model for matched case–control data, also known as a fixed-effects logit model for panel data. clogit can compute robust and cluster–robust standard errors and adjust results for complex survey designs.

See [CM] cmclogit if you want to fit McFadden’s choice model (McFadden 1974).

**Quick start**

Conditional logistic regression model of $y$ on $x$ with matched case–control pairs data identified by `idvar`

```
clogit y x, group(idvar)
```

Fixed-effects logistic regression model with panels identified by `idvar`

```
clogit y x, group(idvar)
```

Add categorical variable `a` and report results as odds ratios

```
clogit y x i.a, or
```

As above, but using sampling probability weight `wvar`

```
clogit y x i.a [pweight = wvar], or
```

**Menu**

Statistics > Binary outcomes > Conditional logistic regression
Syntax

\[ \texttt{clogit \ depvar [ \ indepvars ] [ \ if ] [ \ in ] [ \ weight ] , \ group(\ varname ) [ \ options ]} \]

\( \text{depvar} \) is treated as binary regardless of values; \( \text{depvar} \) equal to nonzero and nonmissing (typically equal to 1) indicates a positive outcome, whereas \( \text{depvar} \) equal to 0 indicates a negative outcome.

*group(\ varname ) is required.

\( \text{indepvars} \) may contain factor variables; see \[U\] 11.4.3 Factor variables.

\( \text{bayes, bootstrap, by, fp, jackknife, mfp, mi estimate, nestreg, rolling, statsby, stepwise, and svy} \) are allowed; see \[U\] 11.1.10 Prefix commands. For more details, see \[BAYES\] bayes: clogit.

\( \text{vce(bootstrap) and vce(jackknife) are not allowed with the mi estimate prefix; see [MI] mi estimate.} \)

Weights are not allowed with the bootstrap prefix; see \[R\] bootstrap.

\( \text{vce(), nonest, and weights are not allowed with the svy prefix; see [SVY] svy.} \)

\( \text{fweights, iweights, and pweights are allowed (see [U] 11.1.6 weight), but they are interpreted to apply to groups as a whole, not to individual observations. See Use of weights below.} \)

collinear and coeflegend do not appear in the dialog box.

See \[U\] 20 Estimation and postestimation commands for more capabilities of estimation commands.

**Options**

\[ \text{group(\ varname ) is required; it specifies an identifier variable (numeric or string) for the matched groups. strata(\ varname ) is a synonym for group().} \]

\( \text{offset(\ varname ), constraints(\ constraints ); see [R] Estimation options.} \)
vce(vcetype) specifies the type of standard error reported, which includes types that are derived from
asymptotic theory (oim, opg), that are robust to some kinds of misspecification (robust), that
allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods
(bootstrap, jackknife); see [R] vce_option.

nonest, available only with vce(cluster clustvar), prevents checking that matched groups are
nested within clusters. It is the user’s responsibility to verify that the standard errors are theoretically
correct.

level(#); see [R] Estimation options.

or reports the estimated coefficients transformed to odds ratios, that is, e^b rather than b. Standard errors
and confidence intervals are similarly transformed. This option affects how results are displayed,
not how they are estimated. or may be specified at estimation or when replaying previously
estimated results.

cnsreport; see [R] Estimation options.

display_options: noci, nopvalues, noomitted, vsquish, noemptycells, baselevels,
allbaselevels, nolabel, fvwrap(#), fvwrapon(style), cformat(%fmt), pformat(%fmt),
sformat(%fmt), and nolstretch; see [R] Estimation options.

Maximization

maximize_options: difficult, technique(algorithm_spec), iterate(#), [no]log, trace,
gradient, showstep, hessian, showtolerance, tolerance(#), lrtolerance(#),
nrtolerance(#), nonrtolerance, and from(init_specs); see [R] Maximize. These options are
seldom used.

Setting the optimization type to technique(bhhh) resets the default vcetype to vce(opg).

The following options are available with clogit but are not shown in the dialog box:
collinear, coeflegend; see [R] Estimation options.

Remarks and examples

Remarks are presented under the following headings:

- Introduction
- Matched case-control data
- Use of weights
- Fixed-effects logit

Introduction

clogit fits maximum likelihood models with a dichotomous dependent variable coded as 0/1
(more precisely, clogit interprets 0 and not 0 to indicate the dichotomy). Conditional logistic analysis
differs from regular logistic regression in that the data are grouped and the likelihood is calculated
relative to each group; that is, a conditional likelihood is used. See Methods and formulas at the end
of this entry.
Biostatisticians and epidemiologists call these models conditional logistic regression for matched case–control groups (see, for example, Hosmer, Lemeshow, and Sturdivant [2013, chap. 7]) and fit them when analyzing matched case–control studies with 1:1 matching, 1:k₂ᵢ matching, or k₁ᵢ:k₂ᵢ matching, where i denotes the iᵗʰ matched group for i = 1, 2, ..., n, where n is the total number of groups. clogit fits a model appropriate for all of these matching schemes or for any mix of the schemes because the matching k₁ᵢ:k₂ᵢ can vary from group to group. clogit always uses the true conditional likelihood, not an approximation. Biostatisticians and epidemiologists sometimes refer to the matched groups as “strata”, but we will stick to the more generic term “group”.

Economists and other social scientists typically call the model fit by clogit a fixed-effects logit model for panel data (see, for example, Chamberlain [1980]). The data used to fit a fixed-effects logit model look exactly like the data biostatisticians and epidemiologists call k₁ᵢ:k₂ᵢ matched case–control data. In terms of how the data are arranged, k₁ᵢ:k₂ᵢ matching means that in the iᵗʰ group, the dependent variable is 1 a total of k₁ᵢ times and 0 a total of k₂ᵢ times. There are a total of Tᵢ = k₁ᵢ + k₂ᵢ observations for the iᵗʰ group. This data arrangement is what economists and other social scientists call “panel data”, “longitudinal data”, or “cross-sectional time-series data”.

So no matter what terminology you use, the computation and the use of the clogit command is the same. The following example shows how your data should be arranged to use clogit.

Example 1

Suppose that we have grouped data with the variable id containing a unique identifier for each group. Our outcome variable, y, contains 0s and 1s. If we were biostatisticians, y = 1 would indicate a case, y = 0 would be a control, and id would be an identifier variable that indicates the groups of matched case–control subjects.

If we were economists, y = 1 might indicate that a person was unemployed at any time during a year and y = 0, that a person was employed all year, and id would be an identifier variable for persons.

If we list the first few observations of this dataset, it looks like

```
. use https://www.stata-press.com/data/r16/clogitid
. list y x1 x2 id in 1/11

 y  x1  x2  id
---  ---  ---  ----
 1.  0   0   4  1014
 2.  0   1   4  1014
 3.  0   1   6  1014
 4.  1   1   8  1014
 5.  0   0   1  1017
 6.  0   0   7  1017
 7.  1   1  10  1017
 8.  0   0   1  1019
 9.  0   1   7  1019
10.  1   1   7  1019
11.  1   1   9  1019
```

Pretending that we are biostatisticians, we describe our data as follows. The first group (id = 1014) consists of four matched persons: 1 case (y = 1) and three controls (y = 0), that is, 1:3 matching. The second group has 1:2 matching, and the third 2:2.
Pretending that we are economists, we describe our data as follows. The first group consists of 4 observations (one per year) for person 1014. This person had a period of unemployment during 1 year of 4. The second person had a period of unemployment during 1 year of 3, and the third had a period of 2 years of 4.

Our independent variables are $x_1$ and $x_2$. To fit the conditional (fixed-effects) logistic model, we type

```
clogit y x1 x2, group(id)
```

Note: multiple positive outcomes within groups encountered.

```
Iteration 0:  log likelihood = -123.42828
Iteration 1:  log likelihood = -123.41386
Iteration 2:  log likelihood = -123.41386

Conditional (fixed-effects) logistic regression

Number of obs = 369

|x1 | 0.653363 | 0.2875215 | 2.27   | 0.023 | 0.0898312 - 1.216895    |
|x2 | 0.0659169 | 0.0449555 | 1.47   | 0.143 | -0.0221943 - 0.1540281  |
```

**Technical note**

The message “note: multiple positive outcomes within groups encountered” at the top of the `clogit` output for the previous example merely informs us that we have $k_1_i : k_2_i$ matching with $k_1_i > 1$ for at least one group. If your data should be $1 : k_2_i$ matched, this message tells you that there is an error in the data somewhere.

We can see the distribution of $k_1_i$ and $T_i = k_1_i + k_2_i$ for the data of the example 1 by using the following steps:

```
. by id, sort: generate k1 = sum(y)
. by id: replace k1 = . if _n < _N
(303 real changes made, 303 to missing)
. by id: generate T = sum(y<.)
. by id: replace T = . if _n < _N
(303 real changes made, 303 to missing)
. tabulate k1
```

We see that $k_{1i}$ ranges from 1 to 4 and $T_i$ ranges from 2 to 10 for these data.

Technical note

For $k_{1i}:k_{2i}$ matching (and hence in the general case of fixed-effects logit), clogit uses a recursive algorithm to compute the likelihood, which means that there are no limits on the size of $T_i$. However, computation time is proportional to $\sum T_i \min(k_{1i}, k_{2i})$, so clogit will take roughly 10 times longer to fit a model with 10:10 matching than one with 1:10 matching. But clogit is fast, so computation time becomes an issue only when $\min(k_{1i}, k_{2i})$ is around 100 or more. See *Methods and formulas* for details.

Matched case–control data

Here we give a more detailed example of matched case–control data.

Example 2

Hosmer, Lemeshow, and Sturdivant (2013, 24) present data on matched pairs of infants, each pair having one with low birthweight and another with regular birthweight. The data are matched on age of the mother. Several possible maternal exposures are considered: race (three categories), smoking status, presence of hypertension, presence of uterine irritability, previous preterm delivery, and weight at the last menstrual period.

| other               | .975003    | .6817263  | -0.04 | 0.971 | .2476522   3.838573  |

Smoking, previous preterm delivery, hypertension, uterine irritability, and possibly the mother’s weight all contribute to low birthweight. Race of black and race of other are statistically insignificant when compared with the race of white omitted group, although the race of black effect is large. We can test the joint statistical significance of race being black (2.race) and race being other (3.race) by using test:

```
. test 2.race 3.race
( 1) [low]2.race = 0
( 2) [low]3.race = 0
ch2( 2) = 0.88
Prob > ch2 = 0.6436
```
For a more complete description of test, see [R] test. test presents results in coefficients rather than odds ratios. Jointly testing that the coefficients on 2.race and 3.race are 0 is equivalent to jointly testing that the odds ratios are 1.

Here one case was matched to one control, that is, 1:1 matching. From clogit’s point of view, that was not important—\(k_1\) cases could have been matched to \(k_2\) controls (\(k_1:k_2\) matching), and we would have fit the model in the same way. Furthermore, the matching can change from group to group, which we have denoted as \(k_{1i}:k_{2i}\) matching, where \(i\) denotes the group. clogit does not care. To fit the conditional logistic regression model, we specified the group(varname) option, group(pairid). The case and control are stored in separate observations. clogit knew that they were linked (in the same group) because the related observations share the same value of pairid.

Technical note

clogit provides a way to extend McNemar’s test to multiple controls per case (1:\(k_{2i}\) matching) and to multiple controls matched with multiple cases (\(k_{1i}:k_{2i}\) matching).

In Stata, McNemar’s test is calculated by the mcc command; see [R] Epitab. The mcc command, however, requires that the matched case and control appear in one observation, so the data will need to be manipulated from 1 to 2 observations per stratum before using clogit. Alternatively, if you begin with clogit’s 2-observations-per-group organization, you will have to change it to 1 observation per group if you wish to use mcc. In either case, reshape provides an easy way to change the organization of the data. We will demonstrate its use below, but we direct you to [D] reshape for a more thorough discussion.

In example 2, we used clogit to analyze the relationship between low birthweight and various characteristics of the mother. Assume that we now want to assess the relationship between low birthweight and smoking, ignoring the mother’s other characteristics. Using clogit, we obtain the following results:

```
clogit low smoke, group(pairid) or
```

|          | Odds Ratio | Std. Err. | z    | P>|z|   | [95% Conf. Interval] |
|----------|------------|-----------|------|-------|----------------------|
| low      | 2.75       | 1.135369  | 2.45 | 0.014 | 1.224347  6.176763   |
Let's compare our estimated odds ratio and 95% confidence interval with that produced by `mcc`. We begin by reshaping the data:

```
. keep low smoke pairid
. reshape wide smoke, i(pairid) j(low 0 1)
```

Data: long -> wide

```
Number of obs. 112 -> 56
Number of variables 3 -> 3
j variable (2 values) low -> (dropped)
xij variables:
    smoke -> smoke0 smoke1
```

We now have the variables `smoke0` (formed from `smoke` and `low = 0`), recording 1 if the control mother smoked and 0 otherwise; and `smoke1` (formed from `smoke` and `low = 1`), recording 1 if the case mother smoked and 0 otherwise. We can now use `mcc`:

```
. mcc smoke1 smoke0
```

</tr>
</tbody>
</table>

Both methods estimated the same odds ratio, and the 95% confidence intervals are similar. `clogit` produced a confidence interval of $[1.22, 6.18]$, whereas `mcc` produced a confidence interval of $[1.18, 7.14]$. 

---

### Use of weights

With `clogit`, weights apply to groups as a whole, not to individual observations. For example, if there is a group in your dataset with a frequency weight of 3, there are a total of three groups in your sample with the same values of the dependent and independent variables as this one group. Weights must have the same value for all observations belonging to the same group; otherwise, an error message will be displayed.
Example 3

We use the example from the above discussion of the `mcc` command. Here we have a total of 56 matched case–control groups, each with one case matched to one control. We had 8 matched pairs in which both the case and the control are exposed, 22 pairs in which the case is exposed and the control is unexposed, 8 pairs in which the case is unexposed and the control is exposed, and 18 pairs in which they are both unexposed.

With weights, it is easy to enter these data into Stata and run `clogit`.

```
. clear
. input id case exposed weight
   id case exposed weight
  1. 1 1 1 8
  2. 1 0 1 8
  3. 2 1 1 22
  4. 2 0 0 22
  5. 3 1 0 8
  6. 3 0 1 8
  7. 4 1 0 18
  8. 4 0 0 18
. end
. clogit case exposed [w=weight], group(id) or
   (frequency weights assumed)
```

```
Iteration 0: log likelihood = -35.425931

```

Fixed-effects logit

The fixed-effects logit model can be written as

$$\Pr(y_{it} = 1 \mid x_{it}) = F(\alpha_i + x_{it}\beta)$$

where $F$ is the cumulative logistic distribution

$$F(z) = \frac{\exp(z)}{1 + \exp(z)}$$

$i = 1, 2, \ldots, n$ denotes the independent units (called “groups” by `clogit`), and $t = 1, 2, \ldots, T_i$ denotes the observations for the $i$th unit (group).
Fitting this model by using a full maximum-likelihood approach leads to difficulties, however. When $T_i$ is fixed, the maximum likelihood estimates for $\alpha_i$ and $\beta$ are inconsistent (Andersen 1970; Chamberlain 1980). This difficulty can be circumvented by looking at the probability of $y_i = (y_{i1}, \ldots, y_{iT_i})$ conditional on $\sum_{t=1}^{T_i} y_{it}$. This conditional probability does not involve the $\alpha_i$, so they are never estimated when the resulting conditional likelihood is used. See Hamerle and Ronning (1995) for a succinct and lucid development. See Methods and formulas for the estimation equation.

> Example 4

We are studying unionization of women in the United States by using the union dataset; see \[\text{XT}\] \text{xt}. We fit the fixed-effects logit model:

```
. use https://www.stata-press.com/data/r16/union, clear
(NLS Women 14-24 in 1968)
. clogit union age grade not_smsa south black, group(idcode)
```

We received three messages at the top of the output. The first one, “multiple positive outcomes within groups encountered”, we expected. Our data do indeed have multiple positive outcomes ($\text{union} = 1$) in many groups. (Here a group consists of all the observations for a particular individual.)

The second message tells us that 2,744 groups were “dropped” by clogit. When either $\text{union} = 0$ or $\text{union} = 1$ for all observations for an individual, this individual’s contribution to the log-likelihood is zero. Although these are perfectly valid observations in every sense, they have no effect on the estimation, so they are not included in the total “Number of obs”. Hence, the reported “Number of obs” gives the effective sample size of the estimation. Here it is 12,035 observations—only 46% of the total 26,200.
We can easily check that there are indeed 2,744 groups with union either all 0 or all 1. We will generate a variable that contains the fraction of observations for each individual who has union = 1.

```
. by idcode, sort: generate fraction = sum(union)/sum(union < .)
. by idcode: replace fraction = . if _n < _N
   (21,766 real changes made, 21,766 to missing)
. tabulate fraction

fraction     Freq.     Percent     Cum.    
              |   |          |          |
0             2,481       55.95    55.95    
.0833333     30          0.68     56.63    
.0909091     33          0.74     57.37    
.1           53          1.20     58.57    
   (output omitted)
.9           10          0.23     93.59    
.9090909     11          0.25     93.84    
.9166667     10          0.23     94.07    
1            263         5.93    100.00    

Total       4,434       100.00
```

Because $2481 + 263 = 2744$, we confirm what *clogit* did.

The third warning message from *clogit* said “black omitted because of no within-group variance”. Obviously, race stays constant for an individual across time. Any such variables are collinear with the $\alpha_i$ (that is, the fixed effects), and just as the $\alpha_i$ drop out of the conditional likelihood, so do all variables that are unchanging within groups. Thus they cannot be estimated with the conditional fixed-effects model.

There are several other estimators implemented in Stata that we could use with these data:

- `cloglog` ...
- `vce(cluster idcode)`
- `logit` ...
- `vce(cluster idcode)`
- `probit` ...
- `vce(cluster idcode)`
- `scobit` ...
- `vce(cluster idcode)`
- `xtcloglog` ...
- `xtgee` ...
- `family(binomial) link(logit) corr(exchangeable)`
- `xtlogit` ...
- `xtprobit` ...

clogit stores the following in \texttt{e()}: 

**Scalars**

- \texttt{e(N)}: number of observations 
- \texttt{e(N_drop)}: number of observations dropped because of all positive or all negative outcomes 
- \texttt{e(N_group_drop)}: number of groups dropped because of all positive or all negative outcomes 
- \texttt{e(k)}: number of parameters 
- \texttt{e(k_eq)}: number of equations in \texttt{e(b)} 
- \texttt{e(k_eq_model)}: number of equations in overall model test 
- \texttt{e(k_dv)}: number of dependent variables 
- \texttt{e(df_m)}: model degrees of freedom 
- \texttt{e(r2_p)}: pseudo-$R^2$-squared 
- \texttt{e(ll)}: log likelihood 
- \texttt{e(ll_0)}: log likelihood, constant-only model 
- \texttt{e(chi2)}: \chi^2 
- \texttt{e(p)}: $p$-value for model test 
- \texttt{e(rank)}: rank of \texttt{e(V)} 
- \texttt{e(ic)}: number of iterations 
- \texttt{e(rc)}: return code 
- \texttt{e(converged)}: 1 if converged, 0 otherwise 

**Macros**

- \texttt{e(cmd)}: \texttt{clogit} 
- \texttt{e(cmdline)}: command as typed 
- \texttt{e(depvar)}: name of dependent variable 
- \texttt{e(group)}: name of \texttt{group()} variable 
- \texttt{e(multiple)}: multiple if multiple positive outcomes within group 
- \texttt{e(wtype)}: weight type 
- \texttt{e(wexp)}: weight expression 
- \texttt{e(title)}: title in estimation output 
- \texttt{e(clustvar)}: name of cluster variable 
- \texttt{e(offset)}: linear offset variable 
- \texttt{e(chi2type)}: Wald or LR; type of model \chi^2 test 
- \texttt{e(vce)}: \texttt{vcetype} specified in \texttt{vce()} 
- \texttt{e(vcetype)}: title used to label Std. Err. 
- \texttt{e(opt)}: type of optimization 
- \texttt{e(which)}: max or min; whether optimizer is to perform maximization or minimization 
- \texttt{e(ml_method)}: type of ml method 
- \texttt{e(user)}: name of likelihood-evaluator program 
- \texttt{e(technique)}: maximization technique 
- \texttt{e(properties)}: \texttt{b V} 
- \texttt{e(predict)}: program used to implement \texttt{predict} 
- \texttt{e(marginsok)}: predictions allowed by \texttt{margins} 
- \texttt{e(marginsnotok)}: predictions disallowed by \texttt{margins} 
- \texttt{e(marginstdefault)}: default \texttt{predict()} specification for \texttt{margins} 
- \texttt{e(asbalanced)}: factor variables \texttt{fvset} as \texttt{asbalanced} 
- \texttt{e(asobserved)}: factor variables \texttt{fvset} as \texttt{asobserved} 

**Matrices**

- \texttt{e(b)}: coefficient vector 
- \texttt{e(Cns)}: constraints matrix 
- \texttt{e(lllog)}: iteration log (up to 20 iterations) 
- \texttt{e(gradient)}: gradient vector 
- \texttt{e(V)}: variance–covariance matrix of the estimators 
- \texttt{e(V_modelbased)}: model-based variance 

**Functions**

- \texttt{e(sample)}: marks estimation sample
Methods and formulas

Let \( i = 1, 2, \ldots, n \) denote the groups and let \( t = 1, 2, \ldots, T_i \) denote the observations for the \( i \)th group. Let \( y_{it} \) be the dependent variable taking on values 0 or 1. Let \( y_i = (y_{i1}, \ldots, y_{iT_i}) \) be the outcomes for the \( i \)th group as a whole. Let \( x_{it} \) be a row vector of covariates. Let \( k_{1i} = \sum_{t=1}^{T_i} y_{it} \) be the observed number of ones for the dependent variable in the \( i \)th group. Biostatisticians would say that there are \( k_{1i} \) cases matched to \( k_{2i} = T_i - k_{1i} \) controls in the \( i \)th group.

We consider the probability of a possible value of \( y_i \) conditional on \( \sum_{t=1}^{T_i} y_{it} = k_{1i} \) (Hamerle and Ronning 1995, eq. 8.33; Hosmer, Lemeshow, and Sturdivant 2013, eq. 7.4),

\[
\Pr(y_i \mid \sum_{t=1}^{T_i} y_{it} = k_{1i}) = \frac{\exp\left(\sum_{t=1}^{T_i} y_{it} x_{it} \beta\right)}{\sum_{d_{it} \in S_i} \exp\left(\sum_{t=1}^{T_i} d_{it} x_{it} \beta\right)}
\]

where \( d_{it} \) is equal to 0 or 1 with \( \sum_{t=1}^{T_i} d_{it} = k_{1i} \), and \( S_i \) is the set of all possible combinations of \( k_{1i} \) ones and \( k_{2i} \) zeros. Clearly, there are \( \binom{T_i}{k_{1i}} \) such combinations, but we need not count all of these combinations to compute the denominator of the above equation. It can be computed recursively.

Denote the denominator by

\[
f_i(T_i, k_{1i}) = \sum_{d_{it} \in S_i} \exp\left(\sum_{t=1}^{T_i} d_{it} x_{it} \beta\right)
\]

Consider, computationally, how \( f_i \) changes as we go from a total of 1 observation in the group to 2 observations to 3, etc. Doing this, we derive the recursive formula

\[
f_i(T, k) = f_i(T - 1, k) + f_i(T - 1, k - 1) \exp(x_{iT} \beta)
\]

where we define \( f_i(T, k) = 0 \) if \( T < k \) and \( f_i(T, 0) = 1 \).

The conditional log-likelihood is

\[
\ln L = \sum_{i=1}^{n} \left\{ \sum_{t=1}^{T_i} y_{it} x_{it} \beta - \log f_i(T_i, k_{1i}) \right\}
\]

The derivatives of the conditional log-likelihood can also be computed recursively by taking derivatives of the recursive formula for \( f_i \).

Computation time is roughly proportional to

\[
p^2 \sum_{i=1}^{n} T_i \min(k_{1i}, k_{2i})
\]

where \( p \) is the number of independent variables in the model. If \( \min(k_{1i}, k_{2i}) \) is small, computation time is not an issue. But if it is large—say, 100 or more—patience may be required.
If \( T_i \) is large for all groups, the bias of the unconditional fixed-effects estimator is not a concern, and we can confidently use \texttt{logit} with an indicator variable for each group (provided, of course, that the number of groups is held within a Stata matrix; see \[R\] Limits).

This command supports the clustered version of the Huber/White/sandwich estimator of the variance using \texttt{vce(robust)} and \texttt{vce(cluster clustvar)}. See \[P\] \_\texttt{robust}, particularly \textit{Maximum likelihood estimators} and \textit{Methods and formulas}. Specifying \texttt{vce(robust)} is equivalent to specifying \texttt{vce(cluster groupvar)}, where \texttt{groupvar} is the variable for the matched groups.

c\texttt{logit} also supports estimation with survey data. For details on VCEs with survey data, see \[SVY\] \textit{Variance estimation}.

</tr>
</tbody>
</table>

Unstarred statistics are available both in and out of sample; type `predict ... if e(sample) ... if wanted only for the estimation sample. Starred statistics are calculated only for the estimation sample, even when `if e(sample)` is not specified.

Starred statistics are available for multiple controls per case-matching design only. They are not available if `vce(robust), vce(cluster clustvar)`, or `pweights` were specified with `clogit`. `dbeta, dx2, gdbeta, gdx2, hat, and rstandard` are not available if `constraints()` was specified with `clogit`.

**Options for predict**

- **Main**
  - pc1, the default, calculates the probability of a positive outcome conditional on one positive outcome within group.
  - pu0 calculates the probability of a positive outcome, assuming that the fixed effect is zero.
  - xb calculates the linear prediction.
  - stdp calculates the standard error of the linear prediction.
dbeta calculates the Delta-\(\beta\) influence statistic, a standardized measure of the difference in the coefficient vector that is due to deletion of the observation.

dx2 calculates the Delta-\(\chi^2\) influence statistic, reflecting the decrease in the Pearson chi-squared that is due to deletion of the observation.

gdbeta calculates the approximation to the Pregibon stratum-specific Delta-\(\beta\) influence statistic, a standardized measure of the difference in the coefficient vector that is due to deletion of the entire stratum.

gdx2 calculates the approximation to the Pregibon stratum-specific Delta-\(\chi^2\) influence statistic, reflecting the decrease in the Pearson chi-squared that is due to deletion of the entire stratum.

hat calculates the Hosmer and Lemeshow leverage or the diagonal element of the hat matrix.

residuals calculates the Pearson residuals.

rstandard calculates the standardized Pearson residuals.

score calculates the equation-level score, \(\partial \ln L / \partial (x_{it}\beta)\).

nooffset is relevant only if you specified offset(varname) for clogit. It modifies the calculations made by predict so that they ignore the offset variable; the linear prediction is treated as \(x_j\beta\) rather than as \(x_j\beta + offset\). This option cannot be specified with dbeta, dx2, gdbeta, gdx2, hat, and rstandard.
margins

Description for margins

margins estimates margins of response for probabilities and linear predictions.

Menu for margins

Statistics > Postestimation

Syntax for margins

margins [marginlist] [ , options ]

</table>

Statistics not allowed with margins are functions of stochastic quantities other than e(b).

For the full syntax, see [R] margins.

Remarks and examples

predict may be used after clogit to obtain predicted values of the index $x_{it}\beta$. Predicted probabilities for conditional logistic regression must be interpreted carefully. Probabilities are estimated for each group as a whole, not for individual observations. Furthermore, the probabilities are conditional on the number of positive outcomes in the group (that is, the number of cases and the number of controls), or it is assumed that the fixed effect is zero. predict may also be used to obtain influence and lack of fit statistics for an individual observation and for the whole group, to compute Pearson, standardized Pearson residuals, and leverage values.

predict may be used for both within-sample and out-of-sample predictions.
Example 1

Suppose that we have $1:k_{2i}$ matched data and that we have previously fit the following model:

```
. use https://www.stata-press.com/data/r16/clogitid
. clogit y x1 x2, group(id)
(output omitted)
```

To obtain the predicted values of the index, we could type `predict idx, xb` to create a new variable called `idx`. From `idx`, we could then calculate the predicted probabilities. Easier, however, would be to type

```
. predict phat
(option `pc1 assumed; probability of success given one success within group')
```

`phat` would then contain the predicted probabilities.

As noted previously, the predicted probabilities are really predicted probabilities for the group as a whole (that is, they are the predicted probability of observing $y_{it} = 1$ and $y_{it'} = 0$ for all $t' \neq t$). Thus, if we want to obtain the predicted probabilities for the estimation sample, it is important that, when we make the calculation, predictions be restricted to the same sample on which we estimated the data. We cannot predict the probabilities and then just keep the relevant ones because the entire sample determines each probability. Thus, assuming that we are not attempting to make out-of-sample predictions, we type

```
. predict phat2 if e(sample)
(option `pc1 assumed; probability of success given one success within group')
```

Methods and formulas

Recall that $i = 1, \ldots, n$ denote the groups and $t = 1, \ldots, T_i$ denote the observations for the $i$th group.

`predict` produces probabilities of a positive outcome within group conditional on there being one positive outcome (`pc1`),

$$
\Pr(y_{it} = 1 \mid \sum_{t=1}^{T_i} y_{it} = 1) = \frac{\exp(x_{it}\beta)}{\sum_{t=1}^{T_i} \exp(x_{it}\beta)}
$$

or `predict` calculates the unconditional $pu0$:

$$
\Pr(y_{it} = 1) = \frac{\exp(x_{it}\beta)}{1 + \exp(x_{it}\beta)}
$$

Let $N = \sum_{j=1}^{n} T_j$ denote the total number of observations, $p$ denote the number of covariates, and $\hat{\theta}_{it}$ denote the conditional predicted probabilities of a positive outcome (`pc1`).

For the multiple control per case ($1:k_{2i}$) matching, *Hosmer, Lemeshow, and Sturdivant* (2013, 248–251) propose the following diagnostics:

The Pearson residual is

$$
r_{it} = \frac{(y_{it} - \hat{\theta}_{it})}{\sqrt{\hat{\theta}_{it}}}
$$
The leverage (hat) value is defined as

\[
h_{it} = \hat{\theta}_{it} \tilde{x}_{it}^T (\tilde{X}^T U \tilde{X})^{-1} \tilde{x}_{it}
\]

where \( \tilde{x}_{it} = x_{it} - \sum_{j=1}^{T_i} x_{ij} \hat{\theta}_{ij} \) is the \( 1 \times p \) row vector of centered by a weighted stratum-specific mean covariate values, \( U_N = \text{diag}\{\hat{\theta}_{it}\} \), and the rows of \( \tilde{X}_{N \times p} \) are composed of \( \tilde{x}_{it} \) values.

The standardized Pearson residual is

\[
r_{sit} = \frac{r_{it}}{\sqrt{1 - h_{it}}}
\]

The lack of fit and influence diagnostics for an individual observation are (respectively) computed as

\[
\Delta \chi^2_{it} = r_{sit}^2
\]

and

\[
\Delta \hat{\beta}_{it} = \Delta \chi^2_{it} \frac{h_{it}}{1 - h_{it}}
\]

The lack of fit and influence diagnostics for the groups are the group-specific totals of the respective individual diagnostics shown above.

[U] 20 Estimation and postestimation commands
cloglog fits a complementary log-log model for a binary dependent variable, typically with one of the outcomes rare relative to the other. It can also be used to fit a gompit model. cloglog can compute robust and cluster–robust standard errors and adjust results for complex survey designs.

Quick start

Complementary log-log model of \( y \) on \( x_1 \) and \( x_2 \)

\[
cloglog \ y \ x_1 \ x_2
\]

With robust standard errors

\[
cloglog \ y \ x_1 \ x_2, \ vce(robust)
\]

Adjust for complex survey design using \texttt{svyset} data

\[
svy: \ cloglog \ y \ x_1 \ x_2
\]
Syntax

cloglog  depvar  [  indepvars ]  [  if ]  [  in ]  [  weight ]  [  ,  options ]

options  Description

Model
noconstant  suppress constant term
offset(varname)  include varname in model with coefficient constrained to 1
asis  retain perfect predictor variables
constraints(constraints)  apply specified linear constraints

SE/Robust
vce(vcetype)  vcetype may be oim, robust, cluster clustvar, opg, bootstrap, or jackknife

Reporting
level(#)  set confidence level; default is level(95)
eform  report exponentiated coefficients
noconsreport  do not display constraints
display_options  control columns and column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling

Maximization
maximize_options  control the maximization process; seldom used
collinear  keep collinear variables
coefflegend  display legend instead of statistics

indevars  may contain factor variables; see [U] 11.4.3 Factor variables.
depvar  and indepvars  may contain time-series operators; see [U] 11.4.4 Time-series varlists.
bayes, bootstrap, by, fmm, fp, jackknife, mi estimate, nestreg, rolling, statsby, stepwise, and svy  are allowed; see [U] 11.1.10 Prefix commands.  For more details, see [BAYES] bayes: cloglog  and [FMM] fmm: cloglog.
vce(bootstrap)  and vce(jackknife)  are not allowed with the mi estimate prefix; see [MI] mi estimate.
Weights are not allowed with the bootstrap prefix; see [R] bootstrap.
vce()  and weights are not allowed with the svy prefix; see [SVY] svy.
fweights, iweights, and pweights  are allowed; see [U] 11.1.6 weight.
collinear  and coeflegend  do not appear in the dialog box.
See [U] 20 Estimation and postestimation commands  for more capabilities of estimation commands.

Options

noconstant, offset(varname); see [R] Estimation options.
asis  forces retention of perfect predictor variables and their associated perfectly predicted observations and may produce instabilities in maximization; see [R] probit.
constraints(constraints); see [R] Estimation options.
vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim, opg), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.

Reporting

level(#) ; see [R] Estimation options.

eform displays the exponentiated coefficients and corresponding standard errors and confidence intervals.

nocnsreport; see [R] Estimation options.

display_options: noci, nopvalues, noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(#), fvwrapon(style), cformat(%,fmt), pformat(%,fmt), sformat(%,fmt), and nolstretch; see [R] Estimation options.

Maximization

maximize_options: difficult, technique(algorithm_spec), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), 1tolerance(#), nrtolerance(#), nonrtolerance, and from(init_specs); see [R] Maximize. These options are seldom used.

Setting the optimization type to technique(bhhh) resets the default vcetype to vce(opg).

The following options are available with cloglog but are not shown in the dialog box:
collinear, coeflegend; see [R] Estimation options.

Remarks and examples

Remarks are presented under the following headings:

Introduction to complementary log-log regression
Robust standard errors

Introduction to complementary log-log regression

cloglog fits maximum likelihood models with dichotomous dependent variables coded as 0/1 (or, more precisely, coded as 0 and not 0).

Example 1

We have data on the make, weight, and mileage rating of 22 foreign and 52 domestic automobiles. We wish to fit a model explaining whether a car is foreign based on its weight and mileage. Here is an overview of our data:
. use https://www.stata-press.com/data/r16/auto
(1978 Automobile Data)
. keep make mpg weight foreign
. describe
Contains data from https://www.stata-press.com/data/r16/auto.dta
    obs:  74  1978 Automobile Data
    vars:  4  13 Apr 2018 17:45
  storage  display  value
variable name type format    label      variable label
  make    str18  %-18s    Make and Model
  mpg     int     %8.0g    Mileage (mpg)
  weight  int     %8.0gc   Weight (lbs.)
  foreign byte    %8.0g    origin     Car type
Sorted by: foreign
    Note: Dataset has changed since last saved.

. inspect foreign
foreign: Car type
(2 unique values)
    #      #      #      #      #      #
    #          Negative      Zero     Positive      #      #
    #          Total     74        74       -
    #          Missing    -        -        -
    0          1          74

foreign is labeled and all values are documented in the label.

The variable foreign takes on two unique values, 0 and 1. The value 0 denotes a domestic car, and 1 denotes a foreign car.

The model that we wish to fit is

$$ Pr(\text{foreign} = 1) = F(\beta_0 + \beta_1 \text{weight} + \beta_2 \text{mpg}) $$

where $$ F(z) = 1 - \exp\{- \exp(z)\} \).
To fit this model, we type

```
cloglog foreign weight mpg
```

Iteration 0: log likelihood = -34.054593
Iteration 1: log likelihood = -27.869915
Iteration 2: log likelihood = -27.742997
Iteration 3: log likelihood = -27.742769
Iteration 4: log likelihood = -27.742769

Complementary log-log regression

| Coef. | Std. Err. | z    | P>|z| | [95% Conf. Interval] |
|-------|-----------|------|------|---------------------|
| weight | -.0029153 | .0006974 | -4.18 | 0.000 | -.0042823 | -.0015483 |
| mpg    | -.1422911 | .076387 | -1.86 | 0.062 | -.2920069 | .0074247 |
| _cons  | 10.09694  | 3.351841 | 3.01  | 0.003 | 3.527448  | 16.66642 |

We find that heavier cars are less likely to be foreign and that cars yielding better gas mileage are also less likely to be foreign, at least when holding the weight of the car constant.

See [R] Maximize for an explanation of the output.

Technical note

Stata interprets a value of 0 as a negative outcome (failure) and treats all other values (except missing) as positive outcomes (successes). Thus, if your dependent variable takes on the values 0 and 1, 0 is interpreted as failure and 1 as success. If your dependent variable takes on the values 0, 1, and 2, 0 is still interpreted as failure, but both 1 and 2 are treated as successes.

If you prefer a more formal mathematical statement, when you type `cloglog y x`, Stata fits the model

\[
Pr(y_j \neq 0 \mid x_j) = 1 - \exp\{-\exp(x_j\beta)\}
\]

Robust standard errors

If you specify the `vce(robust)` option, `cloglog` reports robust standard errors, as described in [U] 20.22 Obtaining robust variance estimates. For the model of `foreign` on `weight` and `mpg`, the robust calculation increases the standard error of the coefficient on `mpg` by 44%:
. cloglog foreign weight mpg, vce(robust)
Iteration 0:  log pseudolikelihood = -34.054593
Iteration 1:  log pseudolikelihood = -27.869915
Iteration 2:  log pseudolikelihood = -27.742997
Iteration 3:  log pseudolikelihood = -27.742769
Iteration 4:  log pseudolikelihood = -27.742769

Without vce(robust), the standard error for the coefficient on mpg was reported to be 0.076, with a resulting confidence interval of \([-0.29, 0.01]\).

The vce(cluster clustvar) option can relax the independence assumption required by the complementary log-log estimator to being just independence between clusters. To demonstrate this ability, we will switch to a different dataset.

We are studying unionization of women in the United States by using the union dataset; see [XT] xt. We fit the following model, ignoring that women are observed an average of 5.9 times each in this dataset:

. use https://www.stata-press.com/data/r16/union, clear
(NLS Women 14-24 in 1968)
. cloglog union age grade not_smsa south##c.year

Complementary log-log regression

|                  | Coef. | Std. Err. | z     | P>|z|     | [95% Conf. Interval] |

The reported standard errors in this model are probably meaningless. Women are observed repeatedly, and so the observations are not independent. Looking at the coefficients, we find a large southern effect against unionization and a different time trend for the south. The `vce(cluster clustvar)` option provides a way to fit this model and obtains correct standard errors:

```stata
.cloglog union age grade not_smsa south##c.year, vce(cluster id) nolog
```

```
Complementary log-log regression
Number of obs = 26,200
Zero outcomes = 20,389
Nonzero outcomes = 5,811
Wald chi2(6) = 160.76
Log pseudolikelihood = -13540.607 Prob > chi2 = 0.0000
(Std. Err. adjusted for 4,434 clusters in idcode)
Robust
union Coef. Std. Err. z P>|z| [95% Conf. Interval]

_cons -1.488278 .4468005 -3.33 0.001 -2.363991 -.6125652
```

The coefficient estimates are similar, but these standard errors are smaller than those produced by `cloglog, vce(cluster clustvar)`. This finding is as we would expect. If the within-panel correlation assumptions are valid, the population-averaged estimator should be more efficient.
In addition to this estimator, we may use the `xtgee` command to fit a panel estimator (with complementary log-log link) and any number of assumptions on the within-idcode correlation.

`cloglog`, `vce(cluster clustvar)` is robust to assumptions about within-cluster correlation. That is, it inefficiently sums within cluster for the standard-error calculation rather than attempting to exploit what might be assumed about the within-cluster correlation (as do the `xtgee` population-averaged models).

### Stored results

`cloglog` stores the following in `e()`:

**Scalars**
- `e(N)`: number of observations
- `e(k)`: number of parameters
- `e(k_eq)`: number of equations in `e(b)`
- `e(k_eq_model)`: number of equations in overall model test
- `e(k_dv)`: number of dependent variables
- `e(N_eq)`: number of zero outcomes
- `e(N_s)`: number of nonzero outcomes
- `e(df_m)`: model degrees of freedom
- `e(ll)`: log likelihood
- `e(ll_0)`: log likelihood, constant-only model
- `e(df_m_0)`: log likelihood, constant-only model
- `e(1l)`: log likelihood
- `e(1l_0)`: log likelihood, constant-only model
- `e(N_clust)`: number of clusters
- `e(chi2)`: $\chi^2$
- `e(p)`: $p$-value for model test
- `e(rank)`: rank of `e(V)`
- `e(ic)`: number of iterations
- `e(rc)`: return code
- `e(converged)`: 1 if converged, 0 otherwise

**Macros**
- `e(cmd)`: `cloglog`
- `e(cmdline)`: command as typed
- `e(depvar)`: name of dependent variable
- `e(wtype)`: weight type
- `e(wexp)`: weight expression
- `e(title)`: title in estimation output
- `e(clustvar)`: name of cluster variable
- `e(offset)`: linear offset variable
- `e(chi2type)`: Wald or LR; type of model $\chi^2$ test
- `e(vcetype)`: `vcetype` specified in `vce()`
- `e(opt)`: type of optimization
- `e(ml_method)`: type of `ml` method
- `e(user)`: name of likelihood-evaluator program
- `e(technique)`: maximization technique
- `e(properties)`: `b V`
- `e(predict)`: program used to implement `predict`
- `e(marginsok)`: predictions allowed by `margins`
- `e(marginsnotok)`: predictions disallowed by `margins`
- `e(asbalanced)`: factor variables `fvset` as `asbalanced`
- `e(asobserved)`: factor variables `fvset` as `asobserved`
Matrices

- `e(b)` coefficient vector
- `e(Cns)` constraints matrix
- `e(ilog)` iteration log (up to 20 iterations)
- `e(gradient)` gradient vector
- `e(V)` variance–covariance matrix of the estimators
- `e(V_modelbased)` model-based variance

Functions

- `e(sample)` marks estimation sample

Methods and formulas

Complementary log-log analysis (related to the gompit model, so named because of its relationship to the Gompertz distribution) is an alternative to logit and probit analysis, but it is unlike these other estimators in that the transformation is not symmetric. Typically, this model is used when the positive (or negative) outcome is rare.

The log-likelihood function for complementary log-log is

$$\ln L = \sum_{j \in S} w_j \ln F(x_j \beta) + \sum_{j \notin S} w_j \ln \{1 - F(x_j \beta)\}$$

where $S$ is the set of all observations $j$ such that $y_j \neq 0$, $F(z) = 1 - \exp\{-\exp(z)\}$, and $w_j$ denotes the optional weights. $\ln L$ is maximized as described in [R] Maximize.

We can fit a gompit model by reversing the success–failure sense of the dependent variable and using `cloglog`.

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using `vce(robust)` and `vce(cluster clustvar)`, respectively. See [P] _robust, particularly Maximum likelihood estimators and Methods and formulas. The scores are calculated as $u_j = \frac{\exp(x_j \beta)\exp\{-\exp(x_j \beta)\}/F(x_j \beta)}{\exp(x_j \beta)}x_j$ for the positive outcomes and $\{-\exp(x_j \beta)\}x_j$ for the negative outcomes.

`cloglog` also supports estimation with survey data. For details on VCEs with survey data, see [SVY] Variance estimation.

Acknowledgment

We thank Joseph Hilbe (1944–2017) of Arizona State University for providing the inspiration for the `cloglog` command.

predict

Description for predict

predict creates a new variable containing predictions such as probabilities, linear predictions, standard errors, and equation-level scores.

Menu for predict

Statistics  >  Postestimation

Syntax for predict

```
predict [type] newvar [if] [in] [, statistic nooffset]
```

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Main</strong></td>
<td></td>
</tr>
<tr>
<td>pr</td>
<td>probability of a positive outcome; the default</td>
</tr>
<tr>
<td>xb</td>
<td>linear prediction</td>
</tr>
<tr>
<td>stdp</td>
<td>standard error of the linear prediction</td>
</tr>
<tr>
<td>score</td>
<td>first derivative of the log likelihood with respect to $x_j\beta$</td>
</tr>
</tbody>
</table>

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

Options for predict

- `pr`, the default, calculates the probability of a positive outcome.
- `xb` calculates the linear prediction.
- `stdp` calculates the standard error of the linear prediction.
- `score` calculates the equation-level score, $\partial \ln L / \partial (x_j \beta)$.
- `nooffset` is relevant only if you specified `offset(varname)` for cloglog. It modifies the calculations made by `predict` so that they ignore the offset variable; the linear prediction is treated as $x_j\beta$ rather than as $x_j\beta + \text{offset}_j$. 
margins

Description for margins

margins estimates margins of response for probabilities and linear predictions.

Menu for margins

Statistics > Postestimation

Syntax for margins

margins [marginlist] [ , options ]
margins [marginlist], predict(statistic ...)[predict(statistic ...) ...][options]

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>

</tr>
<tr>
<td>score</td>
<td>not allowed with margins</td>
</tr>
</tbody>
</table>

Statistics not allowed with margins are functions of stochastic quantities other than e(b).

For the full syntax, see [R] margins.

Remarks and examples

Once you have fit a model, you can obtain the predicted probabilities by using the predict command for both the estimation sample and other samples; see [U] 20 Estimation and postestimation commands and [R] predict. Here we will make only a few comments.

predict without arguments calculates the predicted probability of a positive outcome. With the xb option, it calculates the linear combination \( x_j b \), where \( x_j \) are the independent variables in the \( j \)th observation and \( b \) is the estimated parameter vector.

With the stdp option, predict calculates the standard error of the linear prediction, which is not adjusted for replicated covariate patterns in the data.
Example 1

In example 1 in [R] cloglog, we fit the complementary log-log model cloglog foreign weight mpg. To obtain predicted probabilities,

```
. use https://www.stata-press.com/data/r16/auto
(1978 Automobile Data)
. cloglog foreign weight mpg
(output omitted)
. predict p
(option pr assumed; Pr(foreign))
. summarize foreign p
```

<table>
<thead>
<tr>

Description

`cls` clears the Results window, causing all text to be removed. This operation cannot be undone.

Syntax

`cls`
**cnsreg — Constrained linear regression**

**Description**

cnsreg fits constrained linear regression models.

**Quick start**

Linear regression with coefficients for \(x_1\) and \(x_2\) constrained to equality

\[
\text{constraint 1 } x_1 = x_2 \\
\text{cnsreg } y \ x_1 \ x_2 \ x_3, \ 	ext{constraints(1)}
\]

Add constraint \(x_2 = x_3\) to impose \(x_1 = x_2 = x_3\)

\[
\text{constraint 2 } x_2 = x_3 \\
\text{cnsreg } y \ x_1 \ x_2 \ x_3, \ 	ext{constraints(1 2)}
\]

Constrain the coefficient for \(x_4\) to be \(-1\)

\[
\text{constraint 3 } x_4 = -1 \\
\text{cnsreg } y \ x_1 \ x_2 \ x_3 \ x_4, \ 	ext{constraints(1-3)}
\]

**Menu**

Statistics > Linear models and related > Constrained linear regression
Syntax

cnsreg  depvar  indepvars  [if]  [in]  [weight],  constraints(constraints)  [options]

options    Description

*constraints(constraints)    apply specified linear constraints
noconstant    suppress constant term

SE/Robust
vce(vcetype)    vcetype  may  be  ols,  robust,  cluster  clustvar,  bootstrap,  or  jackknife

Reporting
level(#)    set confidence level; default is level(95)
nocnsreport    do not display constraints
display_options    display  of  omitted  variables  and  base  and  empty  cells,  and  factor-variable  labeling

mse1    force MSE to be 1
collinear    keep collinear variables
coefflegend    display legend instead of statistics

*constraints(constraints)  is  required.
indepvars  may  contain  factor  variables;  see  [U]  11.4.3  Factor  variables.
depvar  and  indepvars  may  contain  time-series  operators;  see  [U]  11.4.4  Time-series  varlists.
bootstrap,  by,  fp,  jackknife,  mi  estimate,  rolling,  statsby,  and  svy  are  allowed;  see  [U]  11.1.10  Prefix commands.
vce(bootstrap)  and  vce(jackknife)  are  not  allowed  with  the  mi  estimate  prefix;  see  [MI]  mi  estimate.
With  the  fp  prefix  (see  [R]  fp),  constraints  cannot  be  specified  for  the  variable  containing  fractional  polynomial  terms.
Weights  are  not  allowed  with  the  bootstrap  prefix;  see  [R]  bootstrap.
aweights  are  not  allowed  with  the  jackknife  prefix;  see  [R]  jackknife.
vce(),  mse1,  and  weights  are  not  allowed  with  the  svy  prefix;  see  [SVY]  svy.
aweights,  fweights,  iweights,  and  pweights  are  allowed;  see  [U]  11.1.6  weight.
mse1,  collinear,  and  coefflegend  do  not  appear  in  the  dialog.
See  [U]  20  Estimation  and  postestimation  commands  for  more  capabilities  of  estimation  commands.

Options

Model

constraints(constraints),  noconstant;  see  [R]  Estimation  options.

SE/Robust

vce(vcetype)  specifies  the  type  of  standard  error  reported,  which  includes  types  that  are  derived  from  asymptotic  theory  (ols),  that  are  robust  to  some  kinds  of  misspecification  (robust),  that  allow  for  intragroup  correlation  (cluster  clustvar),  and  that  use  bootstrap  or  jackknife  methods  (bootstrap,  jackknife);  see  [R]  vce_option.

vce(ols),  the  default,  uses  the  standard  variance  estimator  for  ordinary  least-squares  regression.
level(#), nocnsreport; see [R] Estimation options.

display_options: noci, nopvalues, noomitted, vsquish, noemptycells, baselevels,
allbaselevels, nofvlabel, fvwrap(#), fvwrapon(style), cformat(%fmt), pformat(%fmt),
sformat(%fmt), and nolstretch; see [R] Estimation options.

The following options are available with cnsreg but are not shown in the dialog box:

mse1 is used only in programs and ado-files that use cnsreg to fit models other than constrained linear regression. mse1 sets the mean squared error to 1, thus forcing the variance–covariance matrix of the estimators to be \((X' DX)^{-1}\) (see Methods and formulas in [R] regress) and affecting calculated standard errors. Degrees of freedom for \(t\) statistics are calculated as \(n\) rather than \(n - p + c\), where \(p\) is the total number of parameters (prior to restrictions and including the constant) and \(c\) is the number of constraints.

mse1 is not allowed with the svy prefix.

collinear, coeflegend; see [R] Estimation options.

Remarks and examples

Example 1: One constraint

In principle, we can obtain constrained linear regression estimates by modifying the list of independent variables. For instance, if we wanted to fit the model

\[
mpg = \beta_0 + \beta_1 \text{price} + \beta_2 \text{weight} + u
\]

and constrain \(\beta_1 = \beta_2\), we could write

\[
mpg = \beta_0 + \beta_1 (\text{price} + \text{weight}) + u
\]

and run a regression of \(mpg\) on \(\text{price} + \text{weight}\). The estimated coefficient on the sum would be the constrained estimate of \(\beta_1\) and \(\beta_2\). Using cnsreg, however, is easier:

```
. use https://www.stata-press.com/data/r16/auto
(1978 Automobile Data)
. constraint 1 price = weight
. cnsreg mpg price weight, constraint(1)
Constrained linear regression
Number of obs = 74
F( 1, 72) = 37.59
Prob > F = 0.0000
Root MSE = 4.7220
( 1) price - weight = 0

mpg
Coef. Std. Err. t P>|t| [95% Conf. Interval]
price  -.0009875 .0001611 -6.13 0.000 -.0013086 -.0006664
weight  -.0009875 .0001611 -6.13 0.000 -.0013086 -.0006664
_cons 30.36718 1.577958 19.24 0.000 27.22158 33.51278
```
We define constraints by using the `constraint` command; see [R] `constraint`. We fit the model with `cnsreg` and specify the constraint number or numbers in the `constraints()` option.

Just to show that the results above are correct, here is the result of applying the constraint by hand:

\[
\text{. generate } x = \text{price} + \text{weight} \\
\text{. regress } \text{mpg} \ x
\]

\end{array}
\]

\[\text{Example 2: Multiple constraints}\]

Models can be fit subject to multiple simultaneous constraints. We simply define the constraints and then include the constraint numbers in the `constraints()` option. For instance, say that we wish to fit the model

\[
\text{mpg} = \beta_0 + \beta_1 \text{price} + \beta_2 \text{weight} + \beta_3 \text{displ} + \beta_4 \text{gear} \text{ratio} + \beta_5 \text{foreign} + \beta_6 \text{length} + u
\]

subject to the constraints

\[
\beta_1 = \beta_2 = \beta_3 = \beta_6 \\
\beta_4 = -\beta_5 = \beta_0/20
\]

(This model, like the one in example 1, is admittedly senseless.) We fit the model by typing

\[
\text{. constraint 1 price=weight} \\
\text{. constraint 2 displ=weight} \\
\text{. constraint 3 length=weight} \\

There are many ways we could have specified the constraints() option (which we abbreviated c() above). We typed c(1-3,5-6), meaning that we want constraints 1 through 3 and 5 and 6; those numbers correspond to the constraints we defined. The only reason we did not use the number 4 was to emphasize that constraints do not have to be consecutively numbered. We typed c(1-3,5-6), but we could have typed c(1,2,3,5,6) or c(1-3,5,6) or c(1-2,3,5,6) or even c(1-6), which would have worked as long as constraint 4 was not defined. If we had previously defined a constraint 4, then c(1-6) would have included it.

Stored results

cnsreg stores the following in e():

Scalars
  e(N) number of observations
  e(df_m) model degrees of freedom
  e(df_r) residual degrees of freedom
  e(F) \( F \) statistic
  e(p) \( p \)-value for model test
  e(rmse) root mean squared error
  e(ll) log likelihood
  e(N_clust) number of clusters
  e(rank) rank of \( e(V) \)

Macros
  e(cmd) \texttt{cnsreg}
  e(cmdline) command as typed
  e(depvar) name of dependent variable
  e(wtype) weight type
  e(wexp) weight expression
  e(title) title in estimation output
  e(clustvar) name of cluster variable
  e(vce) \texttt{vce} specified in \texttt{vce()}
  e(vcetype) title used to label Std. Err.
  e(properties) \texttt{b V}
  e(predict) program used to implement predict
Methods and formulas

Let \( n \) be the number of observations, \( p \) be the total number of parameters (prior to restrictions and including the constant), and \( c \) be the number of constraints. The coefficients are calculated as

\[
b' = T \{(T'X'WXT)^{-1} (T'X'Wy - T'X'WXa') \} + a',
\]

where \( T \) and \( a \) are as defined in \([P]\) makecns. \( W = I \) if no weights are specified. If weights are specified, let \( v: 1 \times n \) be the specified weights. If \( fweight \) frequency weights are specified, \( W = \text{diag}(v) \). If \( aweight \) analytic weights are specified, then \( W = \text{diag}[v/(1'v)(1'1)] \), meaning that the weights are normalized to sum to the number of observations.

The mean squared error is

\[
s^2 = (y'Wy - 2b'X'Wy + b'X'WXb)/(n - p + c).
\]

The variance–covariance matrix is \( s^2 T (T'X'WXT)^{-1} T' \).

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using \text{vce(robust)} and \text{vce(cluster clustvar)}, respectively. See \([P] \_robust\), particularly \text{Introduction} and \text{Methods and formulas}.

cnsreg also supports estimation with survey data. For details on VCEs with survey data, see \([SVY] \text{Variance estimation}\).

<td>E(y_j^<em>), y_j^</em> = max{a, min(y_j, b)}</td>
</tr>
<tr>
<td>score</td>
<td>equivalent to residuals</td>
</tr>
</tbody>
</table>

These statistics are available both in and out of sample; type predict ... if e(sample) ... if wanted only for the estimation sample.

stdf is not allowed with svy estimation results.

where a and b may be numbers or variables; a missing (a ≥ .) means −∞, and b missing (b ≥ .) means +∞; see [U] 12.2.1 Missing values.

Options for predict

xb, the default, calculates the linear prediction.

residuals calculates the residuals, that is, y_j − x_j * b.

stdp calculates the standard error of the prediction, which can be thought of as the standard error of the predicted expected value or mean for the observation’s covariate pattern. The standard error of the prediction is also referred to as the standard error of the fitted value.

stdf calculates the standard error of the forecast, which is the standard error of the point prediction for 1 observation. It is commonly referred to as the standard error of the future or forecast value. By construction, the standard errors produced by stdf are always larger than those produced by stdp; see Methods and formulas in [R] regress postestimation.
\texttt{pr}(a,b) \text{ calculates } \Pr(a < x_jb + u_j < b), \text{ the probability that } y_j|x_j \text{ would be observed in the interval } (a,b).

\textit{a} and \textit{b} may be specified as numbers or variable names; \textit{lb} and \textit{ub} are variable names;
\texttt{pr}(20,30) \text{ calculates } \Pr(20 < x_jb + u_j < 30);
\texttt{pr}(lb,ub) \text{ calculates } \Pr(lb < x_jb + u_j < ub); \text{ and }
\texttt{pr}(20,ub) \text{ calculates } \Pr(20 < x_jb + u_j < ub).

\textit{a} missing (\textit{a} \geq .) \text{ means } -\infty; \texttt{pr}(.,30) \text{ calculates } \Pr(-\infty < x_jb + u_j < 30);
\texttt{pr}(lb,30) \text{ calculates } \Pr(-\infty < x_jb + u_j < 30) \text{ in observations for which } lb \geq .
\text{ and calculates } \Pr(lb < x_jb + u_j < 30) \text{ elsewhere.}

\textit{b} missing (\textit{b} \geq .) \text{ means } +\infty; \texttt{pr}(20,. ) \text{ calculates } \Pr(+\infty > x_jb + u_j > 20);
\texttt{pr}(20,ub) \text{ calculates } \Pr(+\infty > x_jb + u_j > 20) \text{ in observations for which } ub \geq .
\text{ and calculates } \Pr(20 < x_jb + u_j < ub) \text{ elsewhere.}

\texttt{e}(a,b) \text{ calculates } E(x_jb + u_j | a < x_jb + u_j < b), \text{ the expected value of } y_j|x_j \text{ conditional on}
\textit{y}_j|x_j \text{ being in the interval } (a,b), \text{ meaning that } y_j|x_j \text{ is truncated. } \textit{a} \text{ and } \textit{b} \text{ are specified as they are for pr().}

\texttt{ystar}(a,b) \text{ calculates } E(y_j^*), \text{ where } y_j^* = a \text{ if } x_jb + u_j \leq a, y_j^* = b \text{ if } x_jb + u_j \geq b, \text{ and }
y_j^* = x_jb + u_j \text{ otherwise, meaning that } y_j^* \text{ is censored. } \textit{a} \text{ and } \textit{b} \text{ are specified as they are for pr().}

\texttt{score} \text{ is equivalent to residuals for linear regression models.}
margins

Description for margins

margins estimates margins of response for linear predictions, probabilities, and expected values.

Menu for margins

Statistics > Postestimation

Syntax for margins

[R] cnsreg — Constrained linear regression

[U] 20 Estimation and postestimation commands
constraint — Define and list constraints

Description

constraint defines, lists, and drops linear constraints. Constraints are for use by models that allow constrained estimation.

Constraints are defined by the constraint command. The currently defined constraints can be listed by either constraint list or constraint dir; both do the same thing. Existing constraints can be eliminated by constraint drop.

constraint get and constraint free are programmer’s commands. constraint get returns the contents of the specified constraint in macro r(contents) and returns in scalar r(defined) 0 or 1—1 being returned if the constraint was defined. constraint free returns the number of a free (unused) constraint in macro r(free).

Quick start

For single-equation models

Define constraint 1 to constrain the coefficient for x1 to 0
   constraint define 1 x1=0

Same as above
   constraint 1 x1

Constrain coefficients for x1 and x2 to 0
   constraint 2 x1 x2

Overwrite constraint 2 to constrain x2 and x3 to equality
   constraint 2 x2 = x3

Constrain the coefficients for factor indicators 2.a and 3.a to equality
   constraint 3 2.a = 3.a

Constrain the coefficient on x1 to equal 1
   constraint 4 x1 = 1

For multiple-equation models

Constrain coefficient for x4 to 0 in all equations
   constraint 11 x4

Constrain coefficients for x4 and x5 to equality in the equation for y2
   constraint 12 [y2]x4 = [y2]x5
Constrain the coefficient for $x_5$ to equality in equations for $y_1$ and $y_2$

\[ \text{constraint 13 [y1=y2] } x_5 \]

Constrain coefficient for $x_1$ to 0 in equation where the dependent variable equals $\text{cat2}$

\[ \text{constraint 14 [cat2] } x_1 \]

Constrain the coefficients for factor indicators $1.a$ and $1.b$ to equality in the equation for category $\text{cat3}$

\[ \text{constraint 15 [cat3]: 1.a = 1.b} \]

Constrain coefficients for $x_1$ to equality in the equations for categories $\text{cat2}$ and $\text{cat3}$

\[ \text{constraint 16 [cat2=cat3]: x1} \]

Listing constraints

List existing constraints

\[ \text{constraint dir} \]

Same as above

\[ \text{constraint list} \]

Menu

Statistics > Other > Manage constraints
Syntax

Define constraints

`constraint [define] # [exp=exp | coeflist]`

List constraints

`constraint dir [numlist | _all]`
`constraint list [numlist | _all]`

Drop constraints

`constraint drop {numlist | _all}`

Programmer’s commands

`constraint get #`
`constraint free`

where `coeflist` is as defined in [R] test and # is restricted to the range 1–1,999, inclusive.

Remarks and examples

Using constraints is discussed in [R] cnsreg, [R] mlogit, and [R] reg3; this entry is concerned only with practical aspects of defining and manipulating constraints.

Example 1

Constraints are numbered from 1 to 1,999, and we assign the number when we define the constraint:

```
. use https://www.stata-press.com/data/r16/sysdsn1
   (Health insurance data)
. constraint 2 [indemnity]2.site = 0
```

The currently defined constraints can be listed by `constraint list`:

```
. constraint list
   2: [indemnity]2.site = 0
```

`constraint drop` drops constraints:

```
. constraint drop 2
. constraint list
```

The empty list after `constraint list` indicates that no constraints are defined. Below we demonstrate the various syntaxes allowed by `constraint`:

```
. constraint 1 [Indemnity]
. constraint 10 [Indemnity]: 1.site 2.site
. constraint 11 [Indemnity]: 3.site
```
. constraint 21 [Prepaid=Uninsure]: nonwhite
. constraint 30 [Prepaid]
. constraint 31 [Insure]
. constraint list
   1: [Indemnity]
   10: [Indemnity]: 1.site 2.site
   11: [Indemnity]: 3.site
   21: [Prepaid=Uninsure]: nonwhite
   30: [Prepaid]
   31: [Insure]
. constraint drop 21-25, 31
. constraint list
   1: [Indemnity]
   10: [Indemnity]: 1.site 2.site
   11: [Indemnity]: 3.site
   30: [Prepaid]
. constraint drop _all
. constraint list

Technical note

The `constraint` command does not check the syntax of the constraint itself because a constraint can be interpreted only in the context of a model. Thus `constraint` is willing to define constraints that later will not make sense. Any errors in the constraints will be detected and mentioned at the time of estimation.

Reference

Also see

[R] `cnsreg` — Constrained linear regression

[P] `makecns` — Constrained estimation
**Description**

`contrast` tests linear hypotheses and forms contrasts involving factor variables and their interactions from the most recently fit model. The tests include ANOVA-style tests of main effects, simple effects, interactions, and nested effects. `contrast` can use named contrasts to decompose these effects into comparisons against reference categories, comparisons of adjacent levels, comparisons against the grand mean, orthogonal polynomials, and such. Custom contrasts may also be specified.

`contrast` can be used with `svy` estimation results; see [SVY] svy postestimation.

Contrasts can also be computed for margins of linear and nonlinear responses; see [R] margins, contrast.

**Quick start**

*Contrasts for one-way models*

Test the main effect of categorical variable `a` after `regress y i.a` or `anova y a`
```
contrast a
```
Reference category contrasts of cell means of `y` with the smallest value of `a` as the base category
```
contrast r.a
```
As above, but specify `a = 3` as the base category for comparisons
```
contrast rb3.a
```
Report tests instead of confidence intervals for each contrast
```
contrast r.a, pveffects
```
Report tests and confidence intervals for each contrast
```
contrast r.a, effects
```
Contrasts of the cell mean of `y` for each level of `a` with the grand mean of `y`
```
contrast g.a
```
As above, but compute grand mean as a weighted average of cell means with weights based on the number of observations for each level of `a`
```
contrast gw.a
```
User-defined contrast comparing the cell mean of `y` for `a = 1` with the average of the cell means for `a = 3` and `a = 4`
```
contrast {a -1 0 .5 .5}
```
Contrasts for two-way models

Test of the interaction effect after `regress y a##b` or `anova y a##b`
```
contrast a#b
```
Test of the main and interaction effects
```
contrast a b a#b
```
Same as above
```
contrast a##b
```
Individual reference category contrasts for the interaction of a and b
```
contrast r.a#r.b
```
Joint tests of the simple effects of a within each level of b
```
contrast a@b
```
Individual reference category contrasts for the simple effects of a within each level of b
```
contrast r.a@b
```
Orthogonal polynomial contrasts for a within each level of b
```
contrast p.a@b
```
Reference category contrasts of the marginal means of y for levels of a
```
contrast r.a
```
As above, but with marginal means for a computed as a weighted average of cell means, using the marginal frequencies of b rather than equal weights for each level
```
contrast r.a, asobserved
```
Contrasts of the marginal mean of y for each level of a with the previous level—reverse-adjacent contrasts
```
contrast ar.a
```

Contrasts for models with continuous covariates

Test of the interaction effect after `regress y a##c.x` or `anova y a##c.x`
```
contrast a#c.x
```
Reference category effects of a on the slope of x
```
contrast r.a#c.x
```
Reference category effects of a on the intercept
```
contrast r.a
```

Contrasts for nonlinear models

Orthogonal polynomial contrasts of log odds across levels of a after `logit y i.a`
```
contrast p.a
```
Test the main and interaction effects after `logit y a##b`
```
contrast a##b
```
Simple reference category effects for \(a\) within each level of \(b\)

\[
\text{contrast } r.a\@b
\]

**Contrasts for multiple-equation models**

Test the main and interaction effects in the equation for \(y_2\) after \texttt{mvreg} \(y_1\) \(y_2\) \(y_3\) = \(a\##b\)

\[
\text{contrast } a\#b, \text{ equation}(y_2)
\]

Reference category contrasts of estimated marginal means of \(y_3\) for levels of \(a\)

\[
\text{contrast } r.a, \text{ equation}(y_3)
\]

Test for a difference in the overall estimated marginal means of \(y_1\), \(y_2\), and \(y_3\)

\[
\text{contrast } _\text{eqns}
\]

Contrasts of estimated marginal means of \(y_2\) and \(y_3\) with \(y_1\)

\[
\text{contrast } r._\text{eqns}
\]

Test whether interaction effects differ across equations

\[
\text{contrast } a\#b\#_\text{eqns}
\]

**Menu**

</tbody>
</table>
A, B, C, and D represent any factor variable in the current estimation results.

\( x \) and \( y \) represent any continuous variable in the current estimation results.

\( r \). and \( g \). represent any contrast operator. See the table below.

c. specifies that a variable be treated as continuous; see \([U] 11.4.3 \text{ Factor variables}\).

Operators are allowed on any factor variable that does not appear to the right of \( @ \) or \( | \). Operators decompose the effects of the associated factor variable into one-degree-of-freedom effects (contrasts).

Higher-level interactions are allowed anywhere an interaction operator (\( \# \)) appears in the table.

Time-series operators are allowed if they were used in the estimation.

\_eqns\ designates the equations in \texttt{manova, mlogit, mprobit,} and \texttt{mvreg} and can be specified anywhere a factor variable appears.

/ is allowed only after \texttt{anova, cnsreg, manova, mvreg,} or \texttt{regress}.

\begin{tabular}{ll}
\textit{operators (op.)} & \textit{Description} \\
\hline
\texttt{r.} & differences from the reference (base) level; the default \\
\texttt{a.} & differences from the next level (adjacent contrasts) \\
\texttt{ar.} & differences from the previous level (reverse adjacent contrasts) \\
\texttt{g.} & differences from the balanced grand mean \\
\texttt{h.} & differences from the balanced mean of subsequent levels (Helmert contrasts) \\
\texttt{j.} & differences from the balanced mean of previous levels (reverse Helmert contrasts) \\
\texttt{p.} & orthogonal polynomial in the level values \\
\texttt{q.} & orthogonal polynomial in the level sequence \\
\hline
\texttt{gw.} & differences from the observation-weighted grand mean \\
\texttt{hw.} & differences from the observation-weighted mean of subsequent levels \\
\texttt{jw.} & differences from the observation-weighted mean of previous levels \\
\texttt{pw.} & observation-weighted orthogonal polynomial in the level values \\
\texttt{qw.} & observation-weighted orthogonal polynomial in the level sequence \\
\end{tabular}

One or more individual contrasts may be selected by using the \textit{op\#}. or \textit{op(numlist)}. syntax. For example, \texttt{a3.A} selects the adjacent contrast for level 3 of \( A \), and \texttt{p(1/2).B} selects the linear and quadratic effects of \( B \). Also see \textit{Orthogonal polynomial contrasts} and \textit{Beyond linear models}.

\begin{tabular}{ll}
\textit{Custom contrasts} & \textit{Description} \\
\hline
\{\texttt{A numlist}\} & user-defined contrast on the levels of factor \( A \) \\
\{\texttt{A#B numlist}\} & user-defined contrast on the levels of interaction between \( A \) and \( B \) \\
\hline
Custom contrasts may be part of a term, such as \{\texttt{A numlist}\}\#B, \{\texttt{A numlist}\}@B, \{\texttt{A numlist}\}|B, \{\texttt{A#B numlist}\}, and \{\texttt{A numlist}\}#{\texttt{B numlist}}. The same is true of higher-order custom contrasts, such as \{\texttt{A#B numlist}\}@C, \{\texttt{A#B numlist}\}#r.C, and \{\texttt{A#B numlist}\}#c.x.

Higher-order interactions with at most eight factor variables are allowed with custom contrasts.
### Options

**Main**
- `overall` specifies that a joint hypothesis test over all terms be performed.
- `asobserved` specifies that factor covariates be evaluated using the cell frequencies observed in the estimation sample. The default is to treat all factor covariates as though there were an equal number of observations in each level.
- `lincom` specifies that user-defined contrasts be treated as linear combinations. The default is to require that all user-defined contrasts sum to zero. (Summing to zero is part of the definition of a contrast.)

**Equations**
- `equation(eqspec)` specifies the equation from which contrasts are to be computed. The default is to compute contrasts from the first equation.
- `atequations` specifies that the contrasts be computed within each equation.

**Advanced**
- `emptycells(empspec)` specifies how empty cells are handled in interactions involving factor variables that are being treated as balanced.
  - `emptycells(strict)` is the default; it specifies that contrasts involving empty cells be treated as not estimable.
  - `emptycells(reweight)` specifies that the effects of the observed cells be increased to accommodate any missing cells. This makes the contrast estimable but changes its interpretation.
- `noestimcheck` specifies that contrast not check for estimability. By default, the requested contrasts are checked and those found not estimable are reported as such. Nonestimability is usually caused by empty cells. If `noestimcheck` is specified, estimates are computed in the usual way and reported even though the resulting estimates are manipulable, which is to say they can differ across equivalent models having different parameterizations.

**Reporting**
- `level(#)` specifies the confidence level, as a percentage, for confidence intervals. The default is `level(95)` or as set by `set level`; see [U] 20.8 Specifying the width of confidence intervals.
- `mcompare(method)` specifies the method for computing p-values and confidence intervals that account for multiple comparisons within a factor-variable term.

  Most methods adjust the comparisonwise error rate, $\alpha_c$, to achieve a prespecified experimentwise error rate, $\alpha_e$.

  $\alpha_c = \alpha_e$
contrast — Contrasts and linear hypothesis tests after estimation

mcompare(bonferroni) adjusts the comparisonwise error rate based on the upper limit of the Bonferroni inequality

$$\alpha_e \leq m \alpha_c$$

where $m$ is the number of comparisons within the term.

The adjusted comparisonwise error rate is

$$\alpha_c = \frac{\alpha_e}{m}$$

mcompare(sidak) adjusts the comparisonwise error rate based on the upper limit of the probability inequality

$$\alpha_e \leq 1 - (1 - \alpha_e)^m$$

where $m$ is the number of comparisons within the term.

The adjusted comparisonwise error rate is

$$\alpha_c = 1 - (1 - \alpha_e)^{1/m}$$

This adjustment is exact when the $m$ comparisons are independent.

mcompare(scheffe) controls the experimentwise error rate using the $F$ or $\chi^2$ distribution with degrees of freedom equal to the rank of the term.

mcompare(method adjustall) specifies that the multiple-comparison adjustments count all comparisons across all terms rather than performing multiple comparisons term by term. This leads to more conservative adjustments when multiple variables or terms are specified in marginslist. This option is compatible only with the bonferroni and sidak methods.

noeffects suppresses the table of individual contrasts with confidence intervals. This table is produced by default when the mcompare() option is specified or when a term in termlist implies all individual contrasts.

cieffects specifies that a table containing a confidence interval for each individual contrast be reported.

pveffects specifies that a table containing a $p$-value for each individual contrast be reported.

effects specifies that a single table containing a confidence interval and $p$-value for each individual contrast be reported.

nowald suppresses the table of Wald tests.

noatlevels indicates that only the overall Wald test be reported for each term containing within or nested ($@$ or $|$) operators.

nosvyadjust is for use with svy estimation commands. It specifies that the Wald test be carried out without the default adjustment for the design degrees of freedom. That is to say the test is carried out as $W/k \sim F(k, d)$ rather than as $(d - k + 1)W/(kd) \sim F(k, d - k + 1)$, where $k$ is the dimension of the test and $d$ is the total number of sampled PSUs minus the total number of strata.

sort specifies that the table of individual contrasts be sorted by the contrast values within each term.

post causes contrast to behave like a Stata estimation (e-class) command. contrast posts the vector of estimated contrasts along with the estimated variance–covariance matrix to $e()$, so you can treat the estimated contrasts just as you would results from any other estimation command. For example, you could use test to perform simultaneous tests of hypotheses on the contrasts, or you could use lincom to create linear combinations.

display_options: vsquish, nofvlabel, fwrap(#), fwrapon(style), cformat(‘fmt’), pformat(‘fmt’), sformat(‘fmt’), and nolstretch.
vspace specifies that the blank space separating factor-variable terms or time-series–operated variables from other variables in the model be suppressed.

nofvlabel displays factor-variable level values rather than attached value labels. This option overrides the fvlabel setting; see \[R\] set showbaselevels.

fvwrap(#) specifies how many lines to allow when long value labels must be wrapped. Labels requiring more than # lines are truncated. This option overrides the fvwrap setting; see \[R\] set showbaselevels.

fvwrapon(style) specifies whether value labels that wrap will break at word boundaries or break based on available space.

fvwrapon(word), the default, specifies that value labels break at word boundaries.

fvwrapon(width) specifies that value labels break based on available space.

This option overrides the fvwrapon setting; see \[R\] set showbaselevels.

cformat(\%fmt) specifies how to format contrasts, standard errors, and confidence limits in the table of estimated contrasts.

pformat(\%fmt) specifies how to format \(p\)-values in the table of estimated contrasts.

sformat(\%fmt) specifies how to format test statistics in the table of estimated contrasts.

nolstretch specifies that the width of the table of estimated contrasts not be automatically widened to accommodate longer variable names. The default, lstretch, is to automatically widen the table of estimated contrasts up to the width of the Results window. To change the default, use set lstretch off. nolstretch is not shown in the dialog box.

eform_option specifies that the contrasts table be displayed in exponentiated form. \(e^{\text{contrast}}\) is displayed rather than contrast. Standard errors and confidence intervals are also transformed. See \[R\] eform_option for the list of available options.

The following option is available with contrast but is not shown in the dialog box:

df(#) specifies that the \(t\) distribution with \# degrees of freedom be used for computing \(p\)-values and confidence intervals. The default is to use \(e(df_r)\) degrees of freedom or the standard normal distribution if \(e(df_r)\) is missing.

Introduction

contrast performs ANOVA-style tests of main effects, interactions, simple effects, and nested effects. It can easily decompose these tests into constituent contrasts using either named contrasts (codings) or user-specified contrasts. Comparing levels of factor variables—whether as main effects, interactions, or simple effects—is as easy as adding a contrast operator to the variable. The operators can compare each level with the previous level, each level with a reference level, each level with the mean of previous levels, and more.

contrast tests and estimates contrasts. A contrast of the parameters $\mu_1, \mu_2, \ldots, \mu_p$ is a linear combination $\sum_i c_i \mu_i$ whose $c_i$ sum to zero. A difference of population means such as $\mu_1 - \mu_2$ is a contrast, as are most other comparisons of population or model quantities (Coster 2005). Some contrasts may be estimated with \texttt{lincom}, but contrast is much more powerful. contrast can handle multiple contrasts simultaneously, and the command’s contrast operators make it easy to specify complicated linear combinations.

Both the contrast operation and the creation of the margins for comparison can be performed as though the data were balanced (typical for experimental designs) or using the observed frequencies in the estimation sample (typical for observational studies). contrast can perform these analyses on the results of almost all of Stata’s estimators, not just the linear-models estimators.
Most of contrast’s computations can be considered comparisons of estimated cell means from a model fit. Tests of interactions are tests of whether the cell means for the interaction are all equal. Tests of main effects are tests of whether the marginal cell means for the factor are all equal. More focused comparisons of cell means (for example, is level 2 equal to level 1) are specified using contrast operators. More formally, all of contrast's computations are comparisons of conditional expectations; cell means are one type of conditional expectation.

All contrasts can also easily be graphed; see [R] marginsplot.

contrast is a flexible tool for understanding the effects of categorical covariates. If your model contains categorical covariates, and especially if it contains interactions, you will want to use contrast.

One-way models

Suppose we have collected data on cholesterol levels for individuals from five age groups. To study the effect of age group on cholesterol, we can begin by fitting a one-way model using regress:

```
use https://www.stata-press.com/data/r16/cholesterol
(Artificial cholesterol data)
label list ages
ages:
   1 10-19
   2 20-29
   3 30-39
   4 40-59
   5 60-79
regress chol i.agegrp
```

```
<table>
<thead>

| 40-59 | 30.15067  | 3.771628  | 7.99    | 0.000    | 22.6284 37.67295  |
| 60-79 | 38.76221  | 3.771628  | 10.28   | 0.000    | 31.23993 46.28448  |
| _cons | 180.5198  | 2.666944  | 67.69   | 0.000    | 175.2007 185.8388  |
```
Estimated cell means

`margins` will show us the estimated cell means for each age group based on our fitted model:

```
margins agegrp
```

| agegrp  | Margin     | Std. Err. | t    | P>|t| | [95% Conf. Interval] |
|---------|------------|-----------|------|------|----------------------|
| 10-19   | 180.5198   | 2.666944  | 67.69| 0.000| 175.2007 185.8388    |
| 20-29   | 188.7233   | 2.666944  | 70.76| 0.000| 183.4043 194.0424    |
| 30-39   | 202.0608   | 2.666944  | 75.76| 0.000| 196.7418 207.3799    |
| 40-59   | 210.6704   | 2.666944  | 78.99| 0.000| 205.3514 215.9895    |
| 60-79   | 219.282    | 2.666944  | 82.22| 0.000| 213.9629 224.601     |

We can graph those means with `marginsplot`:

```
marginsplot
```

Variables that uniquely identify margins: `agegrp`
Testing equality of cell means

Are all the means equal? That is to say is there an effect of age group on cholesterol level? We can answer that by asking `contrast` to test whether the means of the age groups are identical.

```
. contrast agegrp
Contrasts of marginal linear predictions
Margins : asbalanced
                  df  F   P>F
agegrp           4  35.02 0.0000
Denominator      70
```

The means are clearly different. We could have obtained this same test directly had we fit our model using `anova` rather than `regress`.

```
. anova chol agegrp
Number of obs = 75  R-squared = 0.6668
    Root MSE = 10.329  Adj R-squared = 0.6477

Source | Partial SS   |  df |   MS    |     F   | Prob>F
-------|--------------|-----|---------|---------|--------
Model  | 14943.4      |  4  | 3735.8499 | 35.02   | 0.0000
agegrp | 14943.4      |  4  | 3735.8499 | 35.02   | 0.0000
Residual | 7468.2197  | 70  | 106.68885 |         |        
Total  | 22411.619    | 74  | 302.85972 |         |        
```

Achieving a more direct test result is why we recommend using `anova` instead of `regress` for models where our focus is on the categorical covariates. The models fit by `anova` and `regress` are identical; they merely parameterize the effects differently. The results of `contrast` will be identical regardless of which command is used to fit the model. If, however, we were fitting models whose responses are nonlinear functions of the covariates, such as logistic regression, then there would be no analogue to `anova`, and we would appreciate `contrast`’s ability to quickly test main effects and interactions.
### Reference category contrasts

Now that we know that the overall effect of age group is statistically significant, we can explore the effects of each age group. One way to do that is to use the reference category operator, `r`:

```
. contrast r.agegrp
Contras of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>agegrp</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>(20-29 vs 10-19)</td>
<td>1</td>
<td>4.73</td>
<td>0.0330</td>
</tr>
<tr>
<td>(30-39 vs 10-19)</td>
<td>1</td>
<td>32.62</td>
<td>0.0000</td>
</tr>
<tr>
<td>(40-59 vs 10-19)</td>
<td>1</td>
<td>63.91</td>
<td>0.0000</td>
</tr>
<tr>
<td>(60-79 vs 10-19)</td>
<td>1</td>
<td>105.62</td>
<td>0.0000</td>
</tr>
<tr>
<td>Joint</td>
<td>4</td>
<td>35.02</td>
<td>0.0000</td>
</tr>
<tr>
<td>Denominator</td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
```

The cell mean of each age group is compared against the base age group (ages 10–19). The first table shows that each difference is significant. The second table gives an estimate and confidence interval for each contrast. These are the comparisons that linear regression gives with a factor covariate and no interactions. The contrasts are identical to the coefficients from our linear regression.

### Reverse adjacent contrasts

We have far more flexibility with `contrast`. Age group is ordinal, so it is interesting to compare each age group with the preceding age group (rather than against one reference group). We specify that analysis by using the reverse adjacent operator, `ar`:

```
. contrast ar.agegrp
Contras of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>agegrp</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>(20-29 vs 10-19)</td>
<td>1</td>
<td>4.73</td>
<td>0.0330</td>
</tr>
<tr>
<td>(30-39 vs 20-29)</td>
<td>1</td>
<td>12.51</td>
<td>0.0007</td>
</tr>
<tr>
<td>(40-59 vs 30-39)</td>
<td>1</td>
<td>5.21</td>
<td>0.0255</td>
</tr>
<tr>
<td>(60-79 vs 40-59)</td>
<td>1</td>
<td>5.21</td>
<td>0.0255</td>
</tr>
<tr>
<td>Joint</td>
<td>4</td>
<td>35.02</td>
<td>0.0000</td>
</tr>
<tr>
<td>Denominator</td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
```
The 20–29 age group’s cholesterol level is 8.2 points higher than the 10–19 age group’s cholesterol level; the 30–39 age group’s level is 13.3 points higher than the 20–29 age group’s level; and so on. Each age group is statistically different from the preceding age group at the 5% level.

**Orthogonal polynomial contrasts**

The relationship between age group and cholesterol level looked almost linear in our graph. We can examine that relationship further by using the orthogonal polynomial operator, _p_.

```
. contrast p.agegrp, noeffects
Contrasts of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>agegrp</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>(linear)</td>
<td>1</td>
<td>139.11</td>
<td>0.0000</td>
</tr>
<tr>
<td>(quadratic)</td>
<td>1</td>
<td>0.15</td>
<td>0.6962</td>
</tr>
<tr>
<td>(cubic)</td>
<td>1</td>
<td>0.37</td>
<td>0.5448</td>
</tr>
<tr>
<td>(quartic)</td>
<td>1</td>
<td>0.43</td>
<td>0.5153</td>
</tr>
<tr>
<td>Joint</td>
<td>4</td>
<td>35.02</td>
<td>0.0000</td>
</tr>
<tr>
<td>Denominator</td>
<td>70</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
```

Only the linear effect is statistically significant.

We can even perform the joint test that all effects beyond linear are zero. We do that by selecting all polynomial contrasts above linear—that is, polynomial contrasts 2, 3, and 4.

```
. contrast p(2 3 4).agegrp, noeffects
Contrasts of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>agegrp</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>(quadratic)</td>
<td>1</td>
<td>0.15</td>
<td>0.6962</td>
</tr>
<tr>
<td>(cubic)</td>
<td>1</td>
<td>0.37</td>
<td>0.5448</td>
</tr>
<tr>
<td>(quartic)</td>
<td>1</td>
<td>0.43</td>
<td>0.5153</td>
</tr>
<tr>
<td>Joint</td>
<td>3</td>
<td>0.32</td>
<td>0.8129</td>
</tr>
<tr>
<td>Denominator</td>
<td>70</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
```

The joint test has three degrees of freedom and is clearly insignificant. A linear effect of age group seems adequate for this model.
Two-way models

Suppose we are investigating the effects of different dosages of a blood pressure medication and believe that the effects may be different for men and women. We can fit the following ANOVA model for \( \text{bpchange} \), the change in diastolic blood pressure. Change is defined as the after measurement minus the before measurement, so that negative values of \( \text{bpchange} \) correspond to decreases in blood pressure.

```
. use https://www.stata-press.com/data/r16/bpchange
(Artificial blood pressure data)
. label list gender
  gender:
      1 male
      2 female
. anova bpchange dose##gender
```

<table>
<thead>
<tr>
<th>Source</th>
<th>Partial SS</th>
<th>df</th>
<th>MS</th>
<th>F</th>
<th>Prob&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>Model</td>
<td>1411.9087</td>
<td>5</td>
<td>282.38174</td>
<td>131.09</td>
<td>0.0000</td>
</tr>
<tr>
<td>dose</td>
<td>963.48179</td>

<td>1463.608</td>
<td>29</td>
<td>50.46924</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Estimated interaction cell means

Everything is significant, including the interaction. So increasing dosage is effective and differs by gender. Let’s explore the effects. First, let’s look at the estimated cell mean of blood pressure change for each combination of gender and dosage.

```
. margins dose#gender
```

<table>
<thead>
<tr>
<th>dose#gender</th>
<th>Delta-method</th>
</tr>
</thead>
<tbody>
<tr>
<td>Margin</td>
<td>Std. Err.</td>
</tr>
<tr>
<td>250#male</td>
<td>-7.35384</td>
</tr>
<tr>
<td>250#female</td>
<td>3.706567</td>
</tr>
<tr>
<td>500#male</td>
<td>-13.73386</td>
</tr>
<tr>
<td>500#female</td>
<td>-6.584167</td>
</tr>
<tr>
<td>750#male</td>
<td>-16.82108</td>
</tr>
<tr>
<td>750#female</td>
<td>-14.38795</td>
</tr>
</tbody>
</table>

Our data are balanced, so these results will not be affected by the many different ways that `margins` can compute cell means. Moreover, because our model consists of only `dose` and `gender`, these are also the point estimates for each combination.
We can graph the results:

```
  . marginsplot
  Variables that uniquely identify margins: dose gender
```

The lines are not parallel, which we expected because the interaction term is significant. Males experience a greater decline in blood pressure at every dosage level, but the effect of increasing dosage is greater for females. In fact, it is not clear if we can tell the difference between male and female response at the maximum dosage.

**Simple effects**

We can contrast the male and female responses within dosage to see the simple effects of gender. Because there are only two levels in gender, the choice of contrast operator is largely irrelevant. Aside from orthogonal polynomials, all operators produce the same estimates, although the effects can change signs.

```
  . contrast r.gender@dose
  Contrasts of marginal linear predictions
  Margins : asbalanced

          df    F    P>F
  gender@dose
    (female vs male) 250  1  141.97  0.0000
    (female vs male) 500  1   59.33  0.0000
    (female vs male) 750  1   6.87  0.0150
         Joint  3   69.39  0.0000

  Denominator  24

          Contrast     Std. Err.      [95% Conf. Interval]
  gender@dose
    (female vs male) 250  11.06041    .9282533    9.144586    12.97623
    (female vs male) 500  7.149691    .9282533    5.23387    9.065512
    (female vs male) 750  2.433124    .9282533   .5173031    4.348944
```
The effect for males is about 11 points higher than for females at a dosage of 250, and that shrinks to 2.4 points higher at the maximum dosage of 750.

We can form the simple effects the other way by contrasting the effect of dose at each level of gender:

```
. contrast ar.dose@gender
Contrasts of marginal linear predictions
Margins      : asbalanced
                            df   F      P>F
---  -------------  ------  ------  ------
   dose@gender
  (500 vs 250) male   1  47.24   0.0000
  (500 vs 250) female 1 122.90   0.0000
  (750 vs 500) male   1  11.06   0.0028
  (750 vs 500) female 1  70.68   0.0000
  Joint               4 122.65   0.0000
---
Denominator       24
```

Here we use the ar. reverse adjacent contrast operator so that first we are comparing a dosage of 500 with a dosage of 250, and then we are comparing 750 with 500. We see that increasing the dosage has a larger effect on females—10.3 points when going from 250 to 500 compared with 6.4 points for males, and 7.8 points when going from 500 to 750 versus 3.1 points for males.

**Interaction effects**

By specifying contrast operators on both factors, we can decompose the interaction effect into separate interaction contrasts.

```
. contrast ar.dose#r.gender
Contrasts of marginal linear predictions
Margins      : asbalanced
                            df   F      P>F
---  -------------  ------  ------  ------
   dose#gender
  (500 vs 250) (female vs male) 1   8.87   0.0065
  (750 vs 500) (female vs male) 1  12.91   0.0015
  Joint               2  21.66   0.0000
---
Denominator       24
```
Contrast Std. Err. [95% Conf. Interval]

<table>
<thead>
<tr>
<th>dose#gender</th>
<th>Contrast</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>(500 vs 250)</td>
<td>-3.910716</td>
<td>1.312748</td>
<td>(-6.620095, -1.201336)</td>
</tr>
<tr>
<td>(female vs male)</td>
<td>-4.716567</td>
<td>1.312748</td>
<td>(-7.425947, -2.007187)</td>
</tr>
</tbody>
</table>

Look for departures from zero to indicate an interaction effect between dose and gender. Both contrasts are significantly different from zero. Of course, we already knew the overall interaction was significant from our ANOVA results. The effect of increasing dose from 250 to 500 is 3.9 points greater in females than in males, and the effect of increasing dose from 500 to 750 is 4.7 points greater in females than in males. The confidence intervals for both estimates easily exclude zero, meaning that there is an interaction effect.

The joint test of these two interaction effects reproduces the test of interaction effects in the anova output. We can see that the $F$ statistic of 21.66 matches the statistic from our original ANOVA results.

**Main effects**

We can perform tests of the main effects by listing each variable individually in contrast.

```
. contrast dose gender
Contrasts of marginal linear predictions
Margins : asbalanced
```

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>dose</td>
<td>2</td>
<td>223.64</td>
<td>0.0000</td>
</tr>
<tr>
<td>gender</td>
<td>1</td>
<td>164.85</td>
<td>0.0000</td>
</tr>
</tbody>
</table>

The $F$ tests are equivalent to the tests of main effects in the anova output. This is true only for linear models. contrast provides an easy way to obtain main effects and other ANOVA-style tests for models whose responses are not linear in the parameters—logistic, probit, glm, etc.

If we include contrast operators on the variables, we can also decompose the main effects into individual contrasts:

```
. contrast ar.dose r.gender
Contrasts of marginal linear predictions
Margins : asbalanced
```

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>dose (500 vs 250)</td>
<td>1</td>
<td>161.27</td>
<td>0.0000</td>
</tr>
<tr>
<td>dose (750 vs 500)</td>
<td>1</td>
<td>68.83</td>
<td>0.0000</td>
</tr>
<tr>
<td>Joint</td>
<td>2</td>
<td>223.64</td>
<td>0.0000</td>
</tr>
<tr>
<td>gender</td>
<td>1</td>
<td>164.85</td>
<td>0.0000</td>
</tr>
</tbody>
</table>

Denominator 24
By specifying the `ar.` operator on `dose`, we decompose the main effect for dose into two one-degree-of-freedom contrasts, comparing the marginal mean of blood pressure change for each dosage level with that of the previous level. Because `gender` has only two levels, we cannot decompose this main effect any further. However, specifying a contrast operator on `gender` allowed us to calculate the difference in the marginal means for women and men.

**Partial interaction effects**

At this point, we have looked at the total interaction effects and at the main effects of each variable. The partial interaction effects are a midpoint between these two types of effects where we collect the individual interaction effects along the levels of one of the variables and perform a joint test of those interactions. If we think of the interaction effects as forming a table, with the levels of one factor variable forming the rows and the levels of the other forming the columns, partial interaction effects are joint tests of the interactions in a row or a column. To perform these tests, we specify a contrast operator on only one of the variables in our interaction. For this particular model, these are not very interesting because our variables have only two and three levels. Therefore, the tests of the partial interaction effects reproduce the tests that we obtained for the total interaction effects. We specify a contrast operator only on `dose` to decompose the overall test for interaction effects into joint tests for each `ar.dose` contrast:

```
. contrast ar.dose#gender
Contrasts of marginal linear predictions
Margins : asbalanced
```

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>dose#gender</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>(500 vs 250) (joint)</td>
<td>1</td>
<td>8.87</td>
<td>0.0065</td>
</tr>
<tr>
<td>(750 vs 500) (joint)</td>
<td>1</td>
<td>12.91</td>
<td>0.0015</td>
</tr>
<tr>
<td>Joint</td>
<td>2</td>
<td>21.66</td>
<td>0.0000</td>
</tr>
<tr>
<td>Denominator</td>
<td>24</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

The first row is a joint test of all the interaction effects involving the (500 vs 250) comparison of dosages. The second row is a joint test of all the interaction effects involving the (750 vs 500) comparison. If we look back at our output in *Interaction effects*, we can see that there was only one of each of these interaction effects. Therefore, each test labeled (joint) has only one degree-of-freedom.

We could have instead included a contrast operator on `gender` to compute the partial interaction effects along the other dimension:
. contrast dose#r.gender
Contrasts of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>dose#gender</td>
<td>2</td>
<td>21.66</td>
<td>0.0000</td>
</tr>
<tr>
<td>Denominator</td>
<td>24</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Here we obtain a joint test of all the interaction effects involving the (female vs male) comparison for gender. Because gender has only two levels, the (female vs male) contrast is the only reference category contrast possible. Therefore, we obtain a single joint test of all the interaction effects.

Clearly, the partial interaction effects are not interesting for this particular model. However, if our factors had more levels, the partial interaction effects would produce tests that are not available in the total interaction effects. For example, if our model included factors for four dosage levels and three races, then typing

. contrast ar.dose#race

would produce three joint tests, one for each of the reverse adjacent contrasts for dosage. Each of these tests would be a two-degree-of-freedom test because race has three levels.

**Three-way and higher-order models**

All the contrasts and tests that we reviewed above for two-way models can be used with models that have more terms. For instance, we could fit a three-way full factorial model by using the anova command:

```
use https://www.stata-press.com/data/r16/cont3way
anova y race##sex##group
```

We could then test the simple effects of race within each level of the interaction between sex and group:

. contrast race@sex#group

To see the reference category contrasts that decompose these simple effects, type

. contrast r.race@sex#group

We could test the three-way interaction effects by typing

. contrast race#sex#group

or the interaction effects for the interaction of race and sex by typing

. contrast race#sex

To see the individual reference category contrasts that decompose this interaction effect, type

. contrast r.race#r.sex
We could even obtain joint tests for the interaction of race and sex within each level of group by typing

```
. contrast race#sex@group
```

For tests of the main effects of each factor, we can type

```
. contrast race sex group
```

We can calculate the individual reference category contrasts that decompose these main effects:

```
. contrast r.race r.sex r.group
```

For the partial interaction effects, we could type

```
. contrast r.race#group
```

to obtain a joint test of the two-way interaction effects of race and group for each of the individual r.race contrasts.

We could type

```
. contrast r.race#sex#group
```

to obtain a joint test of all the three-way interaction terms for each of the individual r.race contrasts.

### Contrast operators

contrast recognizes a set of contrast operators that are used to specify commonly used contrasts. When these operators are used, contrast will report a test for each individual contrast in addition to the joint test for the term. We have already seen a few of these, like r. and ar., in the previous examples. Here we will take a closer look at each of the unweighted operators.

Here we use the cholesterol dataset and the one-way ANOVA model from the example in One-way models:

```
. use https://www.stata-press.com/data/r16/cholesterol
(Artificial cholesterol data)
. anova chol agegrp
(output omitted)
```

The margins command reports the estimated cell means, $\hat{\mu}_1, \ldots, \hat{\mu}_5$, for each of the five age groups.

```
. margins agegrp
```

<table>
<thead>
<tr>
<th>Expression</th>
<th>Number of obs = 75</th>
</tr>
</thead>
<tbody>
<tr>
<td>Adjusted predictions</td>
<td></td>
</tr>
<tr>
<td>Delta-method</td>
<td>Std. Err.</td>

<tr>
<td>40-59</td>
<td>210.6704</td>
</tr>
<tr>
<td>60-79</td>
<td>219.282</td>
</tr>
</tbody>
</table>
Contrast operators provide an easy way to make certain types of comparisons of these cell means. We use the ordinal factor `agegrp` to demonstrate these operators because some types of contrasts are only meaningful when the levels of the factor have a natural ordering. We demonstrate these contrast operators using a one-way model; however, they are equally applicable to main effects, simple effects, and interactions for more complicated models.

Differences from a reference level (r.)

The `r.` operator specifies that each level of the attached factor variable be compared with a reference level. These are referred to as reference-level or reference-category contrasts (or effects), and `r.` is the reference-level operator.

In the following, we use the `r.` operator to test the effect of each category of age group when that category is compared with a reference category.

```
. contrast r.agegrp
Contrasts of marginal linear predictions
Margins    : asbalanced

<table>
<thead>
<tr>

<td>38.76221</td>
<td>3.771628</td>
<td>31.23993 46.28448</td>
</tr>
</tbody>
</table>
```

In the first table, the row labeled `(20-29 vs 10-19)` is a test of $\mu_2 = \mu_1$, a test that the mean cholesterol levels for the 10–19 age group and the 20–29 age group are equal. The tests in the next three rows are defined similarly. The row labeled `Joint` provides the joint test for these four hypotheses, which is just the test of the main effects of age group.

The second table provides the contrasts of each category with the reference category along with confidence intervals. The contrast in the row labeled `(20-29 vs 10-19)` is the difference in the cell means of the second age group and the first age group, $\hat{\mu}_2 - \hat{\mu}_1$.

The first level of a factor is the default reference level, but we can specify a different reference level by using the `b.` operator; see [U] 11.4.3.2 Base levels. Here we use the last age group, (60–79), instead of the first as the reference category. We also include the `nowald` option so that only the table of contrasts and their confidence intervals is produced.
. contrast rb5.agegrp, nowald
Contrasts of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th>agegrp</th>
<th>Contrast</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>(10-19 vs 60-79)</td>
<td>-38.76221</td>
<td>3.771628</td>
<td>-46.28448 -31.23993</td>
</tr>
<tr>
<td>(20-29 vs 60-79)</td>
<td>-30.55863</td>
<td>3.771628</td>
<td>-38.08091 -23.03636</td>
</tr>
<tr>
<td>(40-59 vs 60-79)</td>
<td>-8.611533</td>
<td>3.771628</td>
<td>-16.13381 -1.089257</td>
</tr>
</tbody>
</table>

Now the first row is labeled (10-19 vs 60-79) and is the difference in the cell means of the first and fifth age groups.

**Differences from the next level (a.)**

The `a.` operator specifies that each level of the attached factor variable be compared with the next level. These are referred to as adjacent contrasts (or effects), and `a.` is the adjacent operator. This operator is only meaningful with factor variables that have a natural ordering in the levels.

We can use the `a.` operator to perform tests that each level of age group differs from the next adjacent level.

. contrast a.agegrp
Contrasts of marginal linear predictions
Margins : asbalanced

</tr>
</tbody>
</table>

In the first table, the row labeled (10-19 vs 20-29) tests the effect of belonging to the 10–19 age group instead of the 20–29 age group. Likewise, the rows labeled (20-29 vs 30-39), (30-39 vs 40-59), and (40-59 vs 60-79) are tests for the effects of being in the younger of the two age groups instead of the older one.

In the second table, the contrast in the row labeled (10-19 vs 20-29) is the difference in the cell means of the first and second age groups, \( \hat{\mu}_1 - \hat{\mu}_2 \). The contrasts in the other rows are defined similarly.
Differences from the previous level (ar.)

The ar. operator specifies that each level of the attached factor variable be compared with the previous level. These are referred to as reverse adjacent contrasts (or effects), and ar. is the reverse adjacent operator. As with the a. operator, this operator is only meaningful with factor variables that have a natural ordering in the levels.

In the following, we use the ar. operator to report tests for the individual reverse adjacent effects of agegrp.

. contrast ar.agegrp

</tbody>
</table>

Here the Wald tests in the first table for the individual reverse adjacent effects are equivalent to the tests for the adjacent effects in the previous example. However, if we compare values of the contrasts in the bottom tables, we see the difference between the r. and the ar. operators. This time, the contrast in the first row is labeled (20–29 vs 10–19) and is the difference in the cell means of the second and first age groups, \( \hat{\mu}_2 - \hat{\mu}_1 \). This is the estimated effect of belonging to the 20–29 age group instead of the 10–19 age group. The remaining rows make similar comparisons to the previous level.

Differences from the grand mean (g.)

The g. operator specifies that each level of a factor variable be compared with the grand mean of all levels. For this operator, the grand mean is computed using a simple average of the cell means.
Here are the grand mean effects of `agegrp`:

```
. contrast g.agegrp
Contrasts of marginal linear predictions
Margins : asbalanced
```

Joint: 4, F: 35.02, P>F: 0.0000

There are five age groups in our estimation sample. Thus the row labeled (10-19 vs mean) tests $\mu_1 = (\mu_1 + \mu_2 + \mu_3 + \mu_4 + \mu_5)/5$. The row labeled (20-29 vs mean) tests $\mu_2 = (\mu_1 + \mu_2 + \mu_3 + \mu_4 + \mu_5)/5$. The remaining rows perform similar tests for the third, fourth, and fifth age groups. In our example, the means for all age groups except the 30–39 age group are statistically different from the grand mean.
The row labeled (10–19 vs >10–19) tests $\mu_1 = (\mu_2 + \mu_3 + \mu_4 + \mu_5)/4$, that is, that the cell mean for the youngest age group is equal to the average of the cell means for the older age groups. The row labeled (20–29 vs >20–29) tests $\mu_2 = (\mu_3 + \mu_4 + \mu_5)/3$. The tests in the other rows are defined similarly.

### Differences from the mean of previous levels (j.)

The j. operator specifies that each level of the attached factor variable be compared with the mean of the previous levels. These are referred to as reverse Helmert contrasts (or effects), and j. is the reverse Helmert operator. For this operator, the mean is computed using a simple average of the cell means. This operator is only meaningful with factor variables that have a natural ordering in the levels.

Here are the reverse Helmert contrasts of agegrp:

```
. contrast j.agegrp
Contrasts of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>

<td></td>
<td>70</td>
</tr>
</tbody>
</table>
```

The row labeled (20–29 vs 10–19) tests $\mu_2 = \mu_1$, that is, that the cell means for the 20–29 and the 10–19 age groups are equal. The row labeled (30–39 vs <30–29) tests $\mu_3 = (\mu_1 + \mu_2)/2$, that is, that the cell mean for the 30–39 age group is equal to the average of the cell means for the 10–19 and 20–29 age groups. The tests in the remaining rows are defined similarly.
Orthogonal polynomials (p. and q.)

The p. and q. operators specify that orthogonal polynomials be applied to the attached factor variable. Orthogonal polynomial contrasts allow us to partition the effects of a factor variable into linear, quadratic, cubic, and higher-order polynomial components. The p. operator applies orthogonal polynomials using the values of the factor variable. The q. operator applies orthogonal polynomials using the level indices. If the level values of the factor variable are equally spaced, as with our agegrp variable, then the p. and q. operators yield the same result. These operators are only meaningful with factor variables that have a natural ordering in the levels.

Because agegrp has five levels, contrast can test the linear, quadratic, cubic, and quartic effects of agegrp.

```
. contrast p.agegrp, noeffects
Contrasts of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>agegrp</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>(linear)</td>
<td>1</td>
<td>139.11</td>
<td>0.0000</td>
</tr>
<tr>
<td>(quadratic)</td>
<td>1</td>
<td>0.15</td>
<td>0.6962</td>
</tr>
<tr>

<td>4</td>
<td>35.02</td>
<td>0.0000</td>
</tr>
<tr>
<td>Denominator</td>
<td>70</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
```

The row labeled (linear) tests the linear effect of agegrp, the only effect that appears to be significant in this case.

The labels for our agegrp variable show the age ranges that correspond to each level.

```
. label list ages
ages:
  1 10-19
  2 20-29
  3 30-39
  4 40-59
  5 60-79
```

Notice that these groups do not have equal widths. Now let’s refit our model using the agemidpt variable. The values of agemidpt indicate the midpoint of each age group that was defined by the agegrp variable and are, therefore, not equally spaced.

```
. anova chol agemidpt
Number of obs = 75
Root MSE = 10.329
Adj R-squared = 0.6477

Source          Partial SS  df   MS    F     Prob>F
----------        -------   ---   ----    ----     ----
Model            14943.4    4  3735.8499  35.02   0.0000
agemidpt        14943.4    4  3735.8499  35.02   0.0000
Residual         7468.2197 70  106.68885
Total            22411.619 74  302.85972
```
Now if we use the `q.` operator, we will obtain the same results as above because the level indices of `agemidpt` are equivalent to the values of `agegrp`.

```
. contrast q.agemidpt, noeffects
Contrasts of marginal linear predictions
Margins : asbalanced
```

</tr>
</tbody>
</table>

Denominator 70

Using the values of the midpoints, the quadratic effect is also significant at the 5% level.

- **Technical note**
  
  We used the `noeffects` option when working with orthogonal polynomial contrasts. Apart from perhaps the sign of the contrast, the values of the individual contrasts are not meaningful for orthogonal polynomial contrasts. In addition, many textbooks provide tables with contrast coefficients that can be used to compute orthogonal polynomial contrasts where the levels of a factor are equally spaced. If we use these coefficients and calculate the contrasts manually with user-defined contrasts, as described below, the Wald tests for the polynomial terms will be equivalent, but the values of the individual contrasts will not necessarily match those that we obtain when using the polynomial contrast operator. When we use one of these contrast operators, an algorithm is used to calculate the coefficients of the polynomial contrast that will allow for unequal spacing in the levels of the factor as well as in the weights for the cell frequencies (when using `pw` or `qw`), as described in *Methods and formulas*.
User-defined contrasts

In the previous examples, we performed tests using contrast operators. When there is not a contrast operator available to calculate the contrast in which we are interested, we can specify custom contrasts.

Here we fit a one-way model for cholesterol on the factor `race`, which has three levels:

```
. label list race
race:
   1 black
   2 white
   3 other
. anova chol race
```

<table>
<thead>
<tr>
<th>Source</th>
<th>Partial SS</th>
<th>df</th>
<th>MS</th>
<th>F</th>
<th>Prob&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>Model</td>
<td>669.27823</td>
<td>2</td>
<td>334.63912</td>
<td>1.11</td>
<td>0.3357</td>
</tr>
<tr>
<td>race</td>
<td>669.27823</td>
<td>2</td>
<td>334.63912</td>
<td>1.11</td>
<td>0.3357</td>
</tr>
<tr>
<td>Residual</td>
<td>21742.341</td>
<td>72</td>
<td>301.97696</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Total</td>
<td>22411.619</td>
<td>74</td>
<td>302.85972</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

`margins` calculates the estimated cell mean cholesterol level for each race:

```
. margins race
```

Adjusted predictions Number of obs = 75
Expression : Linear prediction, predict()

| race | Delta-method Margin Std. Err. t P>|t| [95% Conf. Interval] |
|------|---------------------|--------------------|-------|---------------------|
| black| 204.4279 3.475497 58.82 0.000 | 197.4996 211.3562 |
| white| 197.6132 3.475497 56.86 0.000 | 190.6849 204.5415 |
| other| 198.7127 3.475497 57.18 0.000 | 191.7844 205.6409 |

Suppose we want to test the following linear combination:

\[
\sum_{i=1}^{3} c_i \mu_i
\]

where \( \mu_i \) is the cell mean of `chol` when `race` is equal to its \( i \)th level (the means estimated using `margins` above). Assuming the \( c_i \) elements sum to zero, this linear combination is a contrast. We can specify this type of custom contrast by using the following syntax:

```
{race c_1 c_2 c_3}
```

The null hypothesis for the test of the main effects of `race` is

\[ H_{0\text{race}}: \mu_1 = \mu_2 = \mu_3 \]
Although $H_{0_{\text{race}}}$ can be tested using any of several different contrasts on the cell means, we will test it by comparing the second and third cell means with the first. To test that the cell means for blacks and whites are equal, $\mu_1 = \mu_2$, we can specify the contrast

\[
\{\text{race } -1 \ 1 \ 0\}
\]

To test that the cell means for blacks and other races are equal, $\mu_1 = \mu_3$, we can specify the contrast

\[
\{\text{race } -1 \ 0 \ 1\}
\]

We can use both in a single call to `contrast`.

\[
. \text{ contrast } \{\text{race } -1 \ 1 \ 0\} \{\text{race } -1 \ 0 \ 1\}
\]

Contrasts of marginal linear predictions

<table>
<thead>
<tr>

</tbody>
</table>

Denominator

The row labeled (1) is the test for $\mu_1 = \mu_2$, the first specified contrast. The row labeled (2) is the test for $\mu_1 = \mu_3$, the second specified contrast. The row labeled Joint is the overall test for the main effects of race.

Now let’s fit a model with two factors, race and age group:

\[
. \text{ anova chol race##agegrp}
\]

Number of obs = 75 R-squared = 0.7524
Root MSE = 9.61785 Adj R-squared = 0.6946

<table>
<thead>
<tr>
<th>Source</th>
<th>Partial SS</th>
<th>df</th>
<th>MS</th>
<th>F</th>
<th>Prob&gt;F</th>
</tr>
</thead>
<tbody>
<tr>

<td>8</td>
<td>156.09501</td>
<td>1.69</td>
<td>0.1201</td>
</tr>
<tr>
<td>Residual</td>
<td>5550.1814</td>
<td>60</td>
<td>92.503024</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Total</td>
<td>22411.619</td>
<td>74</td>
<td>302.85972</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

The null hypothesis for the test of the main effects of race is now

\[
H_{0_{\text{race}}} : \mu_{1i} = \mu_{2i} = \mu_{3i}.
\]

where $\mu_{it}$ is the marginal mean of chol when race is equal to its $i$th level.
We can use the same syntax as above to perform this test by specifying contrasts on the marginal means of `race`:

```
. contrast {race -1 1 0} {race -1 0 1}
```

Contras of marginal linear predictions

<table>

</tr>
</tbody>
</table>

Custom contrasts may be specified on the cell means of interactions, too. Here we use `margins` to calculate the mean of `chol` for each cell in the interaction of `race` and `agegrp`:

```
. margins race#agegrp
```

Adjusted predictions Number of obs = 75
Expression : Linear prediction, predict()

|        | Delta-method | Margin | Std. Err. | t     | P>|t|  | [95% Conf. Interval] |
|--------|--------------|--------|-----------|-------|------|----------------------|
| race#agegrp |              |        |           |       |      |                      |
| black#10-19 | 179.2309     | 4.301233 | 41.67     | 0.000 | 170.6271 | 187.8346 |
| black#20-29 | 196.4777     | 4.301233 | 45.68     | 0.000 | 187.874  | 205.0814 |
| black#30-39 | 210.6694     | 4.301233 | 48.98     | 0.000 | 202.0656 | 219.2731 |
| black#40-59 | 214.097      | 4.301233 | 49.78     | 0.000 | 205.4933 | 222.7008 |

| white#30-39 | 196.2633     | 4.301233 | 45.63     | 0.000 | 187.6595 | 204.867 |
| white#40-59 | 209.9953     | 4.301233 | 48.82     | 0.000 | 201.3916 | 218.5991 |
| white#60-79 | 211.0633     | 4.301233 | 49.07     | 0.000 | 202.4595 | 219.667 |
| other#10-19 | 176.2556     | 4.301233 | 40.98     | 0.000 | 167.6519 | 184.8594 |
| other#20-29 | 185.0209     | 4.301233 | 43.02     | 0.000 | 176.4172 | 193.6247 |
| other#30-39 | 199.2498     | 4.301233 | 46.32     | 0.000 | 190.646  | 207.8535 |
| other#40-59 | 207.9189     | 4.301233 | 48.34     | 0.000 | 199.3152 | 216.5227 |
| other#60-79 | 225.118      | 4.301233 | 52.34     | 0.000 | 216.5143 | 233.7218 |

Now we are interested in testing the following linear combination of these cell means:

\[
\sum_{i=1}^{3} \sum_{j=1}^{5} c_{ij} \mu_{ij}
\]
We can specify this type of custom contrast using the following syntax:

\[
\{\text{race#agegrp } c_{11} c_{12} \ldots c_{15} c_{21} c_{22} \ldots c_{25} c_{31} c_{32} \ldots c_{35}\}
\]

Because the marginal means of chol for each level of race are linear combinations of the cell means, we can compose the test for the main effects of race in terms of the cell means directly. The constraint that the marginal means for blacks and whites are equal, \(\mu_1 = \mu_2\), translates to the following constraint on the cell means:

\[
\frac{1}{5}(\mu_{11} + \mu_{12} + \mu_{13} + \mu_{14} + \mu_{15}) = \frac{1}{5}(\mu_{21} + \mu_{22} + \mu_{23} + \mu_{24} + \mu_{25})
\]

Ignoring the common factor, we can specify this contrast as

\[
\{\text{race#agegrp } -1 -1 -1 -1 -1 1 1 1 1 1 0 0 0 0 0\}
\]

contrast will fill in the trailing zeros for us if we neglect to specify them, so

\[
\{\text{race#agegrp } -1 -1 -1 -1 -1 0 0 0 0 0 1 1 1 1 1\}
\]

is also allowed. The other constraint, \(\mu_1 = \mu_3\), translates to

\[
\frac{1}{5}(\mu_{11} + \mu_{12} + \mu_{13} + \mu_{14} + \mu_{15}) = \frac{1}{5}(\mu_{31} + \mu_{32} + \mu_{33} + \mu_{34} + \mu_{35})
\]

This can be specified to contrast as

\[
\{\text{race#agegrp } -1 -1 -1 -1 -1 0 0 0 0 0 1 1 1 1 1\}
\]

The following call to contrast yields the same test results as above.

```
. contrast {race#agegrp -1 -1 -1 -1 -1 1 1 1 1 1 1 1 1 1 1}
> {race#agegrp -1 -1 -1 -1 -1 0 0 0 0 0 1 1 1 1 1}, noeffects
```

Contrasts of marginal linear predictions

<table>
<thead>
<tr>
<th>Margins</th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>race#agegrp</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>(1) (1)</td>
<td>1</td>
<td>6.28</td>
<td>0.0150</td>
</tr>
<tr>
<td>(2) (2)</td>
<td>1</td>
<td>4.41</td>
<td>0.0399</td>

<td>2</td>
<td>3.62</td>
<td>0.0329</td>
</tr>
<tr>
<td>Denominator</td>
<td>60</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

The row labeled (1) (1) is the test for

\[
\mu_{11} + \mu_{12} + \mu_{13} + \mu_{14} + \mu_{15} = \mu_{21} + \mu_{22} + \mu_{23} + \mu_{24} + \mu_{25}
\]

It was the first specified contrast. The row labeled (2) (2) is the test for

\[
\mu_{11} + \mu_{12} + \mu_{13} + \mu_{14} + \mu_{15} = \mu_{31} + \mu_{32} + \mu_{33} + \mu_{34} + \mu_{35}
\]

It was the second specified contrast. The row labeled Joint tests (1) (1) and (2) (2) simultaneously.
We used the `noeffects` option above to suppress the table of contrasts. We can omit the $1/5$ from the equations for $\mu_1 = \mu_2$ and $\mu_1 = \mu_3$ and still obtain the appropriate tests. However, if we want to calculate the differences in the marginal means, we must include the $1/5 = 0.2$ on each of the contrast coefficients as follows:

```
. contrast {race#agegrp -0.2 -0.2 -0.2 -0.2 -0.2 ///
          0.2 0.2 0.2 0.2 0.2} ///
{race#agegrp -0.2 -0.2 -0.2 -0.2 -0.2 ///
          0 0 0 0 0 ///
          0.2 0.2 0.2 0.2 0.2}
```

So far, we have reproduced the reference category contrasts by specifying user-defined contrasts on the marginal means and then on the cell means. For this test, it would have been easier to use the `r. contrast` operator:

```
. contrast r.race, noeffects
```

```
Contrasts of marginal linear predictions

In most cases, we can use contrast operators to perform tests. However, if we want to compare, for instance, the second and third age groups with the fourth and fifth age groups with the test

\[
\frac{1}{2}(\mu_2 + \mu_3) = \frac{1}{2}(\mu_4 + \mu_5)
\]

there is not a contrast operator that corresponds to this particular contrast. A custom contrast is necessary.

```
. contrast {agegrp 0 -0.5 -0.5 0.5 0.5}
```

```

Empty cells

An empty cell is a combination of the levels of factor variables that is not observed in the estimation sample. In the previous examples, we have seen data with three levels of race, five levels of agegrp, and all level combinations of race and agegrp present. Suppose there are no observations for white individuals in the second age group (ages 20–29).

```

```
Now let’s use `contrast` to test the main effects of `race`:

```plaintext
. contrast race
Contrasts of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>race</td>
<td></td>
<td></td>
<td>(not testable)</td>
</tr>
<tr>
<td>Denominator</td>
<td></td>
<td>56</td>
<td></td>
</tr>
</tbody>
</table>
```

By “not testable”, `contrast` means that it cannot form a test for the main effects of `race` based on estimable functions of the model coefficients. `agegrp` has five levels, so `contrast` constructs an estimate of the \( i \)th margin for `race` as

\[
\hat{\mu}_i = \frac{1}{5} \sum_{j=1}^{5} \hat{\mu}_{ij} = \hat{\mu}_0 + \hat{\alpha}_i + \frac{1}{5} \sum_{j=1}^{5} \left\{ \hat{\beta}_j + (\hat{\alpha}\hat{\beta})_{ij} \right\}
\]

but \((\alpha\beta)_{22}\) was constrained to zero because of the empty cell, so \(\hat{\mu}_2\) is not an estimable function of the model coefficients.

See Estimable functions in Methods and formulas of \([R]\) `margins` for a technical description of estimable functions. The `emptycells(reweight)` option causes `contrast` to estimate \(\mu_2\) by

\[
\hat{\mu}_2 = \frac{\hat{\mu}_{21} + \hat{\mu}_{23} + \hat{\mu}_{24} + \hat{\mu}_{25}}{4}
\]

which is an estimable function of the model coefficients.

```plaintext
. contrast race, emptycells(reweight)
Contrasts of marginal linear predictions
Margins : asbalanced
Empty cells : reweight

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>race</td>
<td>2</td>
<td>3.17</td>
<td>0.0498</td>
</tr>
<tr>
<td>Denominator</td>
<td></td>
<td>56</td>
<td></td>
</tr>
</tbody>
</table>
```
We can reconstruct the effect of the `emptycells(reweight)` option by using custom contrasts.

```
. contrast {race#agegrp -4 -4 -4 -4 -4 5 0 5 5 5} >
   {race#agegrp -1 -1 -1 -1 -1 0 0 0 0 0 1 1 1 1 1}, noeffects
```

Contrasts of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>race#agegrp</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>(1) (1)</td>
<td>1</td>
<td>1.06</td>
<td>0.3080</td>
</tr>
<tr>
<td>(2) (2)</td>
<td>1</td>
<td>2.37</td>
<td>0.1291</td>
</tr>
<tr>
<td>Joint</td>
<td>2</td>
<td>3.17</td>
<td>0.0498</td>
</tr>
<tr>
<td>Denominator</td>
<td>56</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

The row labeled (1) (1) is the test for

\[
\frac{1}{5}(\mu_{11} + \mu_{12} + \mu_{13} + \mu_{14} + \mu_{15}) = \frac{1}{4}(\mu_{21} + \mu_{23} + \mu_{24} + \mu_{25})
\]

It was the first specified contrast. The row labeled (2) (2) is the test for

\[
\mu_{11} + \mu_{12} + \mu_{13} + \mu_{14} + \mu_{15} = \mu_{31} + \mu_{32} + \mu_{33} + \mu_{34} + \mu_{35}
\]

It was the second specified contrast. The row labeled Joint is the overall test of the main effects of race.

Empty cells, ANOVA style

Let's refit the linear model from the previous example with `anova` to compare with `contrast`'s test for the main effects of `race`.

```
. anova chol race##agegrp
```

<table>
<thead>
<tr>
<th>Source</th>
<th>Partial SS</th>
<th>df</th>
<th>MS</th>
<th>F</th>
<th>Prob&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>Model</td>
<td>15751.611</td>
<td>13</td>
<td>1211.6624</td>
<td>13.51</td>
<td>0.0000</td>
</tr>
<tr>
<td>race</td>
<td>305.49046</td>
<td>2</td>
<td>152.74523</td>
<td>1.70</td>
<td>0.1914</td>
</tr>
<tr>
<td>agegrp</td>
<td>14387.856</td>
<td>4</td>
<td>3596.964</td>
<td>40.10</td>
<td>0.0000</td>
</tr>
<tr>
<td>race#agegrp</td>
<td>795.80757</td>
<td>7</td>
<td>113.6868</td>
<td>1.27</td>
<td>0.2831</td>
</tr>
<tr>
<td>Residual</td>
<td>5022.7156</td>
<td>56</td>
<td>89.69135</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Total</td>
<td>20774.327</td>
<td>69</td>
<td>301.0772</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

`contrast` and `anova` handled the empty cell differently; the $F$ statistic reported by `contrast` was 3.17, but `anova` reported 1.70. To see how they differ, consider the following table of the cell means and margins for our situation.
For testing the main effects of \textit{race}, we know that we will be testing the equality of the marginal means for rows 1 and 3, that is, $\mu_1 = \mu_3$. This translates into the following constraint:

$$\mu_{11} + \mu_{12} + \mu_{13} + \mu_{14} + \mu_{15} = \mu_{31} + \mu_{32} + \mu_{33} + \mu_{34} + \mu_{35}$$

Because row 2 contains an empty cell in column 2, \textit{anova} dropped column 2 and tested the equality of the marginal mean for row 2 with the average of the marginal means from rows 1 and 3, using only the remaining cell means. This translates into the following constraint:

$$2(\mu_{21} + \mu_{23} + \mu_{24} + \mu_{25}) = \mu_{11} + \mu_{13} + \mu_{14} + \mu_{15} + \mu_{31} + \mu_{33} + \mu_{34} + \mu_{35} \quad (1)$$

Now that we know the constraints that \textit{anova} used to test for the main effects of \textit{race}, we can use custom contrasts to reproduce the \textit{anova} test result.

\begin{verbatim}
> . contrast {race#agegrp -1 -1 -1 -1 -1 0 0 0 0 0 1 1 1 1 1}
> {race#agegrp 1 0 1 1 1 -2 0 -2 -2 -2 1 0 1 1 1}, noeffects

Contrasts of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th>race#agegrp</th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>(1) (1)</td>
<td>1</td>
<td>2.37</td>
<td>0.1291</td>
</tr>
<tr>
<td>(2) (2)</td>
<td>1</td>
<td>1.03</td>
<td>0.3138</td>
</tr>
<tr>
<td>Joint</td>
<td>2</td>
<td>1.70</td>
<td>0.1914</td>
</tr>
<tr>
<td>Denominator</td>
<td></td>
<td>56</td>
<td></td>
</tr>
</tbody>
</table>
\end{verbatim}

The row labeled (1) (1) is the test for $\mu_1 = \mu_3$; it was the first specified contrast. The row labeled (2) (2) is the test for the constraint in (1); it was the second specified contrast. The row labeled Joint is an overall test for the main effects of \textit{race}.

### Nested effects

\texttt{contrast} has the | operator for computing simple effects when the levels of one factor are nested within the levels of another. Here is a fictional example where we are interested in the effect of five methods of teaching algebra on students’ scores for the math portion of the SAT. Suppose three algebra classes are randomly sampled from classes using each of the five methods so that \texttt{class} is nested in \texttt{method} as demonstrated in the following tabulation.
. use https://www.stata-press.com/data/r16/sat
(Fictional SAT data)
. tabulate class method

<table>

<td>75</td>
</tr>
</tbody>
</table>

We will consider `method` as fixed and `class` nested in `method` as random. To use `class` nested in `method` as the error term for `method`, we can specify the following `anova` model:

```
. anova score method / class|method /
```

```
Number of obs = 75  R-squared = 0.7599
Root MSE = 71.8517  Adj R-squared = 0.7039
```

<table>
<thead>
<tr>
<th>Source</th>
<th>Partial SS</th>
<th>df</th>
<th>MS</th>
<th>F</th>
<th>Prob&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>Model</td>
<td>980312</td>
<td>14</td>
<td>70022.286</td>
<td>13.56</td>
<td>0.0000</td>
</tr>
<tr>
<td>method</td>
<td>905872</td>
<td>4</td>
<td>226468</td>
<td>30.42</td>
<td>0.0000</td>
</tr>
<tr>
<td>class</td>
<td>method</td>
<td>74440</td>
<td>10</td>
<td>7444</td>
<td>1.44</td>
</tr>
<tr>
<td>class</td>
<td>method</td>
<td>74440</td>
<td>10</td>
<td>7444</td>
<td>1.44</td>
</tr>
<tr>
<td>Residual</td>
<td>309760</td>
<td>60</td>
<td>5162.6667</td>
<td>1.44</td>
<td>0.1845</td>
</tr>
<tr>
<td>Total</td>
<td>1290072</td>
<td>74</td>
<td>17433.405</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Like `anova`, `contrast` allows the `|` operator, which specifies that one variable is nested in the levels of another. We can use `contrast` to test the main effects of `method` and the simple effects of `class` within `method`.

Like `anova`, `contrast` allows the `|` operator, which specifies that one variable is nested in the levels of another. We can use `contrast` to test the main effects of `method` and the simple effects of `class` within `method`.
Although `contrast` was able to perform the individual tests for the simple effects of `class` within `method`, empty cells in the interaction between `method` and `class` prevented `contrast` from testing for a main effect of `method`. Here we add the `emptycells(reweight)` option so that `contrast` can take the empty cells into account when computing the marginal means for `method`.

```
. contrast method class|method, emptycells(reweight)
Contrasts of marginal linear predictions
Margins : asbalanced
Empty cells : reweight

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>method</td>
<td></td>
<td>(not testable)</td>
<td></td>
</tr>
<tr>
<td>class</td>
<td>method</td>
<td></td>
<td></td>
</tr>
<tr>
<td>1</td>
<td>2</td>
<td>2.80</td>
<td>0.0687</td>
</tr>
<tr>
<td>2</td>
<td>2</td>
<td>0.91</td>
<td>0.4089</td>
</tr>
<tr>
<td>3</td>
<td>2</td>
<td>1.10</td>
<td>0.3390</td>
</tr>
<tr>
<td>4</td>
<td>2</td>
<td>0.22</td>
<td>0.8025</td>
</tr>
<tr>
<td>5</td>
<td>2</td>
<td>2.18</td>
<td>0.1221</td>
</tr>
<tr>
<td>Joint</td>
<td>10</td>
<td>1.44</td>
<td>0.1845</td>
</tr>
</tbody>
</table>

Now `contrast` does report a test for the main effects of `method`. However, if we compare this with the `anova` results, we will see that the results are different. They are different because `contrast` uses the residual error term to compute the $F$ test by default. Using notation similar to `anova`, we can use the `/` operator to specify a different error term for the test. Therefore, we can reproduce the test of main effects from our `anova` command by typing
Multiple comparisons

We have seen that \texttt{contrast} can report the individual linear combinations that make up the requested effects. Depending upon the specified option, \texttt{contrast} will report confidence intervals, \textit{p}-values, or both in the effects table. By default, the reported confidence intervals and \textit{p}-values are not adjusted for multiple comparisons. Use the \texttt{mcompare()} option to adjust the confidence intervals and \textit{p}-values for multiple comparisons of the individual effects.

Let's compute the grand mean effects of \texttt{race} using the \texttt{g.} operator. We also specify the \texttt{mcompare(bonferroni)} option to compute \textit{p}-values and confidence intervals using Bonferroni’s adjustment.

\begin{verbatim}
. use https://www.stata-press.com/data/r16/cholesterol (Artificial cholesterol data)
. anova chol race##agegrp
(output omitted)
. contrast g.race, mcompare(bonferroni)
Contrasts of marginal linear predictions
Margins         : asbalanced

\begin{tabular}{lcc}
                  & df  & F     & P>F  \\
\textit{race}    &     &       &      \\
(black vs mean)  & 1   & 7.07  & 0.0100 & 0.0301 \\
(white vs mean)  & 1   & 2.82  & 0.0982 & 0.2947 \\
(other vs mean)  & 1   & 0.96  & 0.3312 & 0.9936 \\
Joint            & 2   & 3.62  & 0.0329 & \\
Denominator      & 60  &       &        & \\
\end{tabular}

Note: Bonferroni-adjusted \textit{p}-values are reported for tests on individual contrasts only.
\end{verbatim}
The last table reports a Bonferroni-adjusted confidence interval for each individual contrast. (Use the `effects` option to add $p$-values to the last table.) The first table includes a Bonferroni-adjusted $p$-value for each test that is not a joint test.

Joint tests are never adjusted for multiple comparisons. For example,

```
. contrast race@agegrp, mcompare(bonferroni)
Contrasts of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>race@agegrp</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>10-19</td>
<td>2</td>
<td>1.37</td>
<td>0.2620</td>
</tr>
<tr>
<td>20-29</td>
<td>2</td>
<td>2.44</td>
<td>0.0958</td>
</tr>
<tr>
<td>30-39</td>
<td>2</td>
<td>3.12</td>
<td>0.0512</td>
</tr>
<tr>
<td>40-59</td>
<td>2</td>
<td>0.53</td>
<td>0.5889</td>
</tr>
<tr>
<td>60-79</td>
<td>2</td>
<td>2.90</td>
<td>0.0628</td>
</tr>
<tr>
<td>Joint</td>
<td>10</td>
<td>2.07</td>
<td>0.0409</td>
</tr>
<tr>
<td>Denominator</td>
<td></td>
<td>60</td>
<td></td>
</tr>
</tbody>
</table>
```

Note: Bonferroni-adjusted $p$-values are reported for tests on individual contrasts only.
Here we have five tests of simple effects with two degrees of freedom each. No Bonferroni-adjusted \( p \)-values are available for these tests, but the confidence intervals for the individual contrasts are adjusted.

### Unbalanced data

By default, `contrast` treats all factors as balanced when computing marginal means. By balanced, we mean that `contrast` assumes an equal number of observations in each level of each factor and an equal number of observations in each cell of each interaction. If our data are balanced, there is no issue. If, however, our data are not balanced, we might prefer that `contrast` use the actual cell frequencies from our data in computing marginal means. We instruct `contrast` to use observed frequencies by adding the `asobserved` option.

Even if our data are unbalanced, we might still want `contrast` to compute balanced marginal means. It depends on what we want to test and what our data represent. If we have data from a designed experiment that started with an equal number of males and females but the data became unbalanced because the data from a few males were unusable, we might still want our margins computed as though the data were balanced. If, however, we have a representative sample of individuals from Los Angeles with 40% of European descent, 34% African-American, 25% Hispanic, and 1% Australian, we probably want our margins computed using these representative frequencies. We do not want Australians receiving the same weight as Europeans.

The following examples will use an unbalanced version of our dataset.

```
. use https://www.stata-press.com/data/r16/cholesterol3
(Artificial cholesterol data, unbalanced)

. tab race agegrp
```

<table>
<thead>
<tr>
<th>race@agegrp</th>
<th>10-19</th>
<th>20-29</th>
<th>30-39</th>
<th>40-59</th>
<th>60-79</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>black</td>
<td>1</td>
<td>5</td>
<td>5</td>
<td>4</td>
<td>3</td>
<td>18</td>
</tr>
<tr>
<td>white</td>
<td>4</td>
<td>5</td>
<td>7</td>
<td>4</td>
<td>4</td>
<td>24</td>

</tr>
<tr>
<td>Total</td>
<td>8</td>
<td>17</td>
<td>18</td>
<td>13</td>
<td>11</td>
<td>67</td>
</tr>
</tbody>
</table>

The row labeled `Total` gives observed cell frequencies for age group. These can be obtained by summing frequencies from the cells in the corresponding column. In this respect, we can also refer to them as marginal frequencies. We use the terms marginal frequencies and cell frequencies interchangeably below.
We begin by fitting the two-factor model with an interaction.

\[ \text{. anova chol race##agegrp} \]

Using observed cell frequencies

Recall that the marginal means are computed from the cell means. Treating the factors as balanced yields the following marginal means for \( \text{race} \):

\[ \eta_1 = \frac{1}{5}(\mu_{11} + \mu_{12} + \mu_{13} + \mu_{14} + \mu_{15}) \]

\[ \eta_2 = \frac{1}{5}(\mu_{21} + \mu_{22} + \mu_{23} + \mu_{24} + \mu_{25}) \]

\[ \eta_3 = \frac{1}{5}(\mu_{31} + \mu_{32} + \mu_{33} + \mu_{34} + \mu_{35}) \]

If we have a fixed population and unbalanced cells, then the \( \eta_i \) do not represent population means. If, however, our data are representative of the population, we can use the frequencies from our estimation sample to estimate the population marginal means, denoted \( \mu_i \).

Here are the results of testing for a main effect of \( \text{race} \), treating all the factors as balanced.

\[ \text{. contrast r.race} \]

Contrasts of marginal linear predictions

<table>

</tr>
</tbody>
</table>
The row labeled (white vs black) is the test for \( \eta_2 = \eta_1 \). The row labeled (other vs black) is the test for \( \eta_3 = \eta_1 \).

If the observed marginal frequencies are representative of the distribution of the levels of \texttt{agegrp}, we can use them to form the marginal means of \texttt{chol} for each of the levels of \texttt{race} from the cell means.

\[
\mu_1 = \frac{1}{67}(8\mu_{11} + 17\mu_{12} + 18\mu_{13} + 13\mu_{14} + 11\mu_{15})
\]

\[
\mu_2 = \frac{1}{67}(8\mu_{21} + 17\mu_{22} + 18\mu_{23} + 13\mu_{24} + 11\mu_{25})
\]

\[
\mu_3 = \frac{1}{67}(8\mu_{31} + 17\mu_{32} + 18\mu_{33} + 13\mu_{34} + 11\mu_{35})
\]

Here are the results of testing for the main effects of \texttt{race}, using the observed marginal frequencies:

```
. contrast r.race, asobserved
Contrasts of marginal linear predictions
Margins : asobserved

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>

<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th></th>
<th>Contrast Std. Err. [95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>race</td>
<td></td>
</tr>
<tr>
<td>(white vs black)</td>
<td>-7.232433 2.686089 -12.62246 -1.842402</td>
</tr>
<tr>
<td>(other vs black)</td>
<td>-5.231198 2.651203 -10.55123 .0888295</td>
</tr>
</tbody>
</table>
```

The row labeled (white vs black) is the test for \( \mu_2 = \mu_1 \). The row labeled (other vs black) is the test for \( \mu_3 = \mu_1 \). Both tests were insignificant when we tested the cell means resulting from balanced frequencies; however, when we tested the cell means from observed frequencies, the first test is significant beyond the 5% level (and the second test is nearly so).

Here we reproduce the results of the \texttt{asobserved} option with custom contrasts. Because we are modifying the way that the marginal means are constructed from the cell means, we will specify the contrasts on the predicted cell means. We use macro expansion, \texttt{=exp}, to evaluate the fractions instead of approximating them with decimals. Macro expansion guarantees that the contrast coefficients sum to zero. For more information, see \texttt{Macro expansion operators and function} in \texttt{[P] macro}. 
contrast provides observation-weighted versions of five of the contrast operators—gw., hw., jw., pw., and qw.. The first three of these operators perform comparisons of means across cells, and like the marginal means just discussed, these means can be computed in two ways: 1) as though the cell frequencies were equal or 2) using the observed cell frequencies from the estimation sample. The weighted operators provide versions of the standard (as balanced) operators that weight these means by their cell frequencies. The two orthogonal polynomial operators involve similar adjustments for weighting.

Let’s examine what this means by using the gw. operator. The gw. operator is a weighted version of the g. operator. The gw. operator computes the grand mean using the cell frequencies for race obtained from the model fit.

Here we test the effects of race, comparing each level with the weighted grand mean but otherwise treating the factors as balanced in the marginal mean calculations.
Contrast Std. Err. [95% Conf. Interval]
\[
\begin{array}{cccc}
\text{race} & \text{Contrast} & \text{Std. Err.} & [95\% \text{ Conf. Interval}] \\
\text{(black vs mean)} & 3.24931 & 1.948468 & -0.6605779 \quad 7.159198 \\
\text{(white vs mean)} & -2.074944 & 1.44618 & -4.976915 \quad 0.8270276 \\
\text{(other vs mean)} & -0.347557 & 1.414182 & -3.18532 \quad 2.490206 \\
\end{array}
\]

The observed marginal frequencies of race are 18, 24, and 25. Thus the row labeled (black vs mean) tests \(\eta_1 = \frac{(18\eta_1 + 24\eta_2 + 25\eta_3)}{67}\); the row labeled (white vs mean) tests \(\eta_2 = \frac{(18\eta_1 + 24\eta_2 + 25\eta_3)}{67}\); and the row labeled (other vs mean) tests \(\eta_3 = \frac{(18\eta_1 + 24\eta_2 + 25\eta_3)}{67}\).

Now we reproduce the above results using custom contrasts. We are weighting the calculation of the grand mean from the marginal means for each of the races, but we are not weighting the calculation of the marginal means themselves. Therefore, we can specify the custom contrast on the marginal means for race instead of on the cell means.

```
. contrast \{race \='49/67' -='24/67' -='25/67'}
> \{race -='18/67' \='43/67' -='25/67'}
> \{race -='18/67' -='24/67' \='42/67'}
```

Contrasts of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>race</td>

<td>1</td>
<td>2.78</td>
<td>0.1014</td>
</tr>
<tr>
<td>(2)</td>
<td>1</td>
<td>2.06</td>
<td>0.1573</td>
</tr>
<tr>
<td>(3)</td>
<td>1</td>
<td>0.06</td>
<td>0.8068</td>
</tr>
<tr>
<td>Joint</td>
<td>2</td>
<td>1.64</td>
<td>0.2029</td>
</tr>
<tr>
<td>Denominator</td>
<td>52</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Contrast Std. Err. [95% Conf. Interval]
\[
\begin{array}{cccc}
\text{race} & \text{Contrast} & \text{Std. Err.} & [95\% \text{ Conf. Interval}] \\
(1) & 3.24931 & 1.948468 & -0.6605779 \quad 7.159198 \\
(2) & -2.074944 & 1.44618 & -4.976915 \quad 0.8270276 \\
(3) & -0.347557 & 1.414182 & -3.18532 \quad 2.490206 \\
\end{array}
\]

Now we will test for each race the difference between the marginal mean and the weighted grand mean, treating the factors as observed in the marginal mean calculations.
. contrast gw.race, asobserved wald ci

Contrasts of marginal linear predictions
Margins : asobserved

<table>
<thead>
<tr>

<tr>
<td>(white vs mean)</td>
<td>-2.689771 1.39142 -5.481859 .1023172</td>
</tr>
<tr>
<td>(other vs mean)</td>
<td>-.6885363 1.341261 -3.379973 2.002901</td>
</tr>
</tbody>
</table>

The row labeled (black vs mean) tests $\mu_1 = (18\mu_1 + 24\mu_2 + 25\mu_3)/67$; the row labeled (white vs mean) tests $\mu_2 = (18\mu_1 + 24\mu_2 + 25\mu_3)/67$; and the row labeled (other vs mean) tests $\mu_3 = (18\mu_1 + 24\mu_2 + 25\mu_3)/67$.

Here we use a custom contrast to reproduce the above result testing $\mu_1 = (18\mu_1 + 24\mu_2 + 25\mu_3)/67$. Because both the calculation of the marginal means and the calculation of the grand mean are adjusted, we specify the custom contrast on the cell means.

Contrasts of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th></th>
<th>Contrast Std. Err. [95% Conf. Interval]</th>

</tr>
<tr>
<td>(1) (1)</td>
<td>4.542662 1.740331 1.050432 8.034891</td>
</tr>
</tbody>
</table>

The Helmert and reverse Helmert contrasts also involve calculating averages of the marginal means; therefore, weighted versions of these parameters are available as well. The hw. operator is a weighted version of the h. operator that computes the mean of the subsequent levels using the cell frequencies obtained from the model fit. The jw. operator is a weighted version of the j. operator that computes the mean of the previous levels using the cell frequencies obtained from the model fit.

For orthogonal polynomials, we can use the pw. and qw. operators, which are the weighted versions of the p. and q. operators. In this case, the cell frequencies from the model fit are used in the calculation of the orthogonal polynomial contrast coefficients.
Testing factor effects on slopes

For linear models where the independent variables are all factor variables, the linear prediction at fixed levels of the factor variables turns out to be a cell mean. With these models, `contrast` computes and tests the effects of the factor variables on the expected mean of the dependent variable. When factor variables are interacted with continuous variables, `contrast` distinguishes factor effects on the intercept from factor effects on the slope.

Here we have 1980 census data including information on the birth rate (`brate`), the median age (`medage`), and the region of the country (`region`) for each of the 50 states. We can fit an ANCOVA model for `brate` using main effects of the factor variable `region` and the continuous variable `medage`.

```
. use https://www.stata-press.com/data/r16/census3
(1980 Census data by state)
. label list cenreg
cenreg:
   1 NE
   2 NCentral
   3 South
   4 West
. anova brate i.region c.medage
```

<table>
<thead>
<tr>
<th>Source</th>
<th>Partial SS</th>
<th>df</th>
<th>MS</th>
<th>F</th>
<th>Prob&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>Model</td>
<td>34872.859</td>
<td>4</td>
<td>8718.2147</td>
<td>53.57</td>
<td>0.0000</td>
</tr>
<tr>
<td>region</td>
<td>2197.7545</td>
<td>3</td>
<td>732.58484</td>
<td>4.50</td>
<td>0.0076</td>
</tr>
<tr>
<td>medage</td>
<td>15327.423</td>
<td>1</td>
<td>15327.423</td>
<td>94.18</td>
<td>0.0000</td>
</tr>
<tr>
<td>Residual</td>
<td>7323.9611</td>
<td>45</td>
<td>162.75469</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Total</td>
<td>42196.82</td>
<td>49</td>
<td>861.15959</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

For those more comfortable with linear regression, this is equivalent to the regression model

```
. regress brate i.region c.medage
```

You may use either.

We can use `contrast` to compute reference category effects for `region`. These contrasts compare the adjusted means of NCentral, South, and West regions with the adjusted mean of the NE region.

```
. contrast r.region
```

| Margins : asbalanced
<table>
<thead>
<tr>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>region</td>
<td></td>
<td></td>
</tr>
<tr>
<td>(NCentral vs NE)</td>
<td>1</td>
<td>2.24</td>
</tr>
<tr>
<td>(South vs NE)</td>
<td>1</td>
<td>0.78</td>
</tr>
<tr>
<td>(West vs NE)</td>
<td>1</td>
<td>10.33</td>
</tr>
<tr>
<td>Joint</td>
<td>3</td>
<td>4.50</td>
</tr>
<tr>
<td>Denominator</td>
<td>45</td>
<td></td>
</tr>
</tbody>
</table>
Let’s add the interaction between `region` and `medage` to the model.

```stata
. anova brate region##c.medage
```

The parameterization for the expected value of `brate` as a function of `region` and `medage` is given by

\[
E(brate|region = i, medage) = \alpha_0 + \alpha_i + \beta_0 medage + \beta_i medage
\]

where \(\alpha_0\) is the intercept and \(\beta_0\) is the slope of `medage`. We are modeling the effects of `region` in two different ways. The \(\alpha_i\) parameters measure the effect of `region` on the intercept, and the \(\beta_i\) parameters measure the effect of `region` on the slope of `medage`.

`contrast` computes and tests effects on slopes separately from effects on intercepts. First, we will compute the reference category effects of `region` on the intercept:

```stata
. contrast r.region
```

### Contrasts of marginal linear predictions

<table>
<thead>
<tr>
<th>region</th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>(NCentral vs NE)</td>
<td>1</td>
<td>0.09</td>
<td>0.7691</td>
</tr>
<tr>
<td>(South vs NE)</td>
<td>1</td>
<td>0.01</td>
<td>0.9389</td>
</tr>
<tr>
<td>(West vs NE)</td>
<td>1</td>
<td>8.50</td>
<td>0.0057</td>
</tr>
<tr>
<td>Joint</td>
<td>3</td>
<td>11.30</td>
<td>0.0000</td>
</tr>
<tr>
<td>Denominator</td>
<td>42</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>region</th>
<th>Contrast</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>(NCentral vs NE)</td>
<td>-49.38396</td>
<td>167.1281</td>
<td>-386.6622 287.8942</td>
</tr>
<tr>
<td>(South vs NE)</td>
<td>-9.058983</td>
<td>117.424</td>
<td>-246.0302 227.9123</td>
</tr>
<tr>
<td>(West vs NE)</td>
<td>343.0024</td>
<td>117.6547</td>
<td>105.5656 580.4393</td>
</tr>
</tbody>
</table>

| Contrast Std. Err. [95% Conf. Interval] |
Now we will compute the reference category effects of region on the slope of medage:

```
. contrast r.region#c.medage
Contrasts of marginal linear predictions
Margins : asbalanced
```

<table>
<thead>
<tr>
<th>region#c.medage</th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>(NCentral vs NE)</td>
<td>1</td>
<td>0.16</td>
<td>0.6917</td>
</tr>
<tr>
<td>(South vs NE)</td>
<td>1</td>
<td>0.03</td>
<td>0.8558</td>
</tr>
<tr>
<td>(West vs NE)</td>
<td>1</td>
<td>8.18</td>
<td>0.0066</td>
</tr>
<tr>
<td>Joint</td>
<td>3</td>
<td>10.29</td>
<td>0.0000</td>
</tr>
<tr>
<td>Denominator</td>
<td></td>
<td>42</td>
<td></td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Contrast</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>region#c.medage</td>
<td></td>
<td></td>
</tr>
<tr>
<td>(NCentral vs NE)</td>
<td>2.208539</td>
<td>-8.953432 13.37051</td>
</tr>
<tr>
<td>(South vs NE)</td>
<td>.6928008</td>
<td>-6.953175 8.338777</td>
</tr>
<tr>
<td>(West vs NE)</td>
<td>-10.94649</td>
<td>-18.67041 -3.22257</td>
</tr>
</tbody>
</table>

At the 5% level, the slope of medage for the West region differs from that of the NE region, but at that level of significance, we cannot say that the slope for the NCentral or the South region differs from that of the NE region.

This model is simple enough that the reference category contrasts reproduce the coefficients for region and for the interactions in an equivalent model fit by regress.

```
. regress brate region##c.medage
```

| West           | -10.94649 | 3.827357  | -2.86 | 0.007| -18.67041 -3.22257   |
| _cons          | 411.8268  | 108.2084  | 3.81  | 0.000| 193.4533 630.2002    |

This will not be the case for models that are more complicated.
Chow tests

Now let’s suppose we are fitting a model for birth rates on median age and marriage rate. We are also interested in whether the regression coefficients differ for states in the east versus states in the west. We use census divisions to create a new variable, *west*, that indicates which states are in the western half of the United States.

```
. generate west = inlist(division, 4, 7, 8, 9)
```

We fit a model that includes a separate intercept for *west* as well as an interaction between *west* and each of the other variables in our model.

```
. regress brate i.west##c.medage i.west##c.mrgrate
```

<table>
<thead>
<tr>

<tr>
<td>Total</td>
<td>42196.82</td>
<td>49</td>
<td>861.159592</td>
<td>Root MSE = 9.146</td>
</tr>
</tbody>
</table>

We can test the effects of *west* on the intercept and on the slopes of *medage* and *mrgrate*. We will specify all of these effects in a single `contrast` command and include the `overall` option to obtain a joint test of effects, that is, a test that the coefficients for eastern states and for western states are equal.

```
. contrast west west#c.medage west#c.mrgrate, overall
```

<table>
<thead>
<tr>
<th>Margins : asbalanced</th>
</tr>
</thead>
<tbody>
<tr>

</tr>
<tr>
<td>west</td>
</tr>
<tr>
<td>west#c.medage</td>
</tr>
<tr>
<td>west#c.mrgrate</td>
</tr>
<tr>
<td>Overall</td>
</tr>
</tbody>
</table>

This overall test is referred to as a Chow test in econometrics (Chow 1960).
Beyond linear models

contrast may be used after almost any estimation command, with the added benefit that contrast provides direct support for testing main and interaction effects that is not available in most estimation commands. To illustrate, we will use contrast with results from a logistic regression. Stata’s logit command fits logistic regression models, reporting the fitted regression coefficients. The logistic command fits the same models but reports odds ratios. Although contrast can report odds ratios for the computed effects, the tests are all computed from linear combinations of the model coefficients regardless of which estimation command we used.

Suppose we have data on patient satisfaction for three hospitals in a city. Let’s begin by fitting a model for satisfied, whether the patient was satisfied with his or her treatment, using the main effects of hospital:

. use https://www.stata-press.com/data/r16/hospital, clear
(Artificial hospital satisfaction data)
. logit satisfied i.hospital
Iteration 0: log likelihood = -393.72216
Iteration 1: log likelihood = -387.55736
Iteration 2: log likelihood = -387.4768
Iteration 3: log likelihood = -387.47679
Logistic regression
Number of obs = 802
LR chi2(2) = 12.49
Prob > chi2 = 0.0019
Log likelihood = -387.47679
Pseudo R2 = 0.0159

| satisfied | Coef. | Std. Err. | z    | P>|z| | [95% Conf. Interval] |
|-----------|-------|-----------|------|------|----------------------|
| hospital  |       |           |      |      |                      |
| 2         | .5348129 | .2136021 | 2.50 | 0.012 | .1161604 .9534654   |
| 3         | .7354519 | .2221929 | 3.31 | 0.001 | .2999618 1.170942   |
| _cons     | 1.034708 | .1391469 | 7.44 | 0.000 | .7619855 1.307431   |

Because there are no other independent variables in this model, the reference category effects of hospital computed by contrast will match the fitted model coefficients, assuming a common reference level.

. contrast r.hospital
Contrasts of marginal linear predictions
Margins : asbalanced

|          | df | chi2  | P>|chi2|
|----------|----|-------|-------|
| hospital |    |       |       |
| 2 vs 1   | 1  | 6.27  | 0.0123|
| 3 vs 1   | 1  | 10.96 | 0.0009|
| Joint    | 2  | 12.55 | 0.0019|

</tbody>
</table>
We see that the reference category effects are equal to the fitted coefficients. They also have the same interpretation, the difference in log odds from the reference category. The top table also provides a joint test of these effects, a test of the main effects of hospital.

We also have information on the condition for which each patient is being treated in the variable illness. Here we fit a logistic regression using a two-way crossed model of hospital and illness.

```
. label list illness
illness:
   1 heart attack
   2 stroke
   3 pneumonia
   4 lung disease
   5 kidney failure

. logistic satisfied hospital##illness

```

Note: _cons estimates baseline odds.

Using contrast, we can obtain an ANOVA-style table of tests for the main effects and interaction effects of hospital and illness.
Our interaction effect is significant, so we decide to evaluate the simple reference category effects of hospital within illness. We are particularly interested in patient satisfaction when being treated for a heart attack or stroke, so we will use the `i.` operator to limit our output to simple effects within the first two illnesses.

```
. contrast r.hospital@i(1 2).illness, nowald
```

The row labeled (2 vs 1) heart attack estimates simple effects on the log odds when comparing hospital 2 with hospital 1 for patients having heart attacks. These effects are differences in the cell means of the linear predictions.

We can add the `or` option to report an odds ratio for each of these simple effects:

```
. contrast r.hospital@i(1 2).illness, nowald or
```

These odds ratios are just the exponentiated version of the contrasts in the previous table.

For contrasts of the margins of nonlinear predictions, such as predicted probabilities, see `[R] margins, contrast`. 

```

contrast — Contrasts and linear hypothesis tests after estimation 357

Multiple equations

contrast works with models containing multiple equations. Commands such as intreg and gnbreg allow their ancillary parameters to be modeled as functions of independent variables, and contrast can compute and test effects within these equations. In addition, contrast allows a special pseudofactor for equation—called _eqns—when working with results from manova, mvreg, mlogit, and mprobit.

In example 4 of [MV] manova, we fit a two-way MANOVA model using data from Woodard (1931). Here we will fit this model using mvreg. The data represent patients with jaw fractures. y1 is the patient’s age, y2 is blood lymphocytes, and y3 is blood polymorphonuclears. Two factor variables, gender and fracture, are used as independent variables.

. use https://www.stata-press.com/data/r16/jaw
(Table 4.6 Two-Way Unbalanced Data for Fractures of the Jaw -- Rencher (1998))
. mvreg y1 y2 y3 = gender##fracture, vsquish nofvlabel

contrast computes Wald tests using the coefficients from the first equation by default.
Here we use the `equation()` option to compute the Wald tests in the y2 equation:

```
. contrast gender##fracture, equation(y2)
```

```
Contrasts of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>y2</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>gender</td>
<td>1</td>
<td>5.41</td>
<td>0.0301</td>
</tr>
<tr>
<td>fracture</td>
<td>2</td>
<td>7.97</td>
<td>0.0027</td>
</tr>
<tr>
<td>gender#fracture</td>
<td>2</td>
<td>5.97</td>
<td>0.0088</td>
</tr>
<tr>
<td>Denominator</td>
<td>21</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
```

Here we use the equation index to compute the Wald tests in the third equation:

```
. contrast gender##fracture, equation(#3)
```

```
Contrasts of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>

</thead>
<tbody>
<tr>
<td>y3</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>gender</td>
<td>1</td>
<td>2.33</td>
<td>0.1502</td>
</tr>
<tr>
<td>fracture</td>
<td>2</td>
<td>6.36</td>
<td>0.0069</td>
</tr>
<tr>
<td>gender#fracture</td>
<td>2</td>
<td>6.66</td>
<td>0.0058</td>
</tr>
<tr>
<td>Denominator</td>
<td>21</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
```

Here we use the `atequations` option to compute Wald tests for each equation in the model. We also use the `vsquish` option to suppress the extra blank lines between terms.
. contrast gender#fracture, atrigations vsquish
Contrasts of marginal linear predictions

| gender#fracture | 2  | 6.66  | 0.0058 |

Denominator 21

Because we are investigating the results from `mvreg`, we can use the special `_eqns` factor to test for a marginal effect on the means among the dependent variables:

. contrast `_eqns`
Contrasts of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>_eqns</code></td>
<td>2</td>
<td>49.19</td>
<td>0.0000</td>
</tr>
</tbody>
</table>

Denominator 21

Here we test whether the main effects of `gender` differ among the dependent variables:

. contrast `gender#_eqns`
Contrasts of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>gender#_eqns</td>
<td>2</td>
<td>3.61</td>
<td>0.0448</td>
</tr>
</tbody>
</table>

Denominator 21
Although it is not terribly interesting in this case, we can even calculate contrasts across equations:

```
. contrast gender#r._eqns
Contrasts of marginal linear predictions
Margins : asbalanced

          |   df  |     F    |   P>F  
----------|-------|----------|--------
gender#_eqns          
  (joint) (2 vs 1)  |   1   |  5.82    | 0.0251
  (joint) (3 vs 1)  |   1   |  0.40    | 0.5352
  Joint             |   2   |  3.61    | 0.0448
  Denominator      |  21   |          |        
```

**Video example**

Introduction to contrasts in Stata: One-way ANOVA

**Stored results**

contrast stores the following in r():

Scalars
- r(df_r) variance degrees of freedom
- r(k_terms) number of terms in `termlist`
- r(level) confidence level of confidence intervals

Macros
- r(cmd) contrast
- r(cmdline) command as typed
- r(est_cmd) e(cmd) from original estimation results
- r(est_cmdline) e(cmdline) from original estimation results
- r(title) title in output
- r(overall) overall or empty
- r(empyspec) empspec from emptycells()
- r(method) method from mcompare()
- r(mctitle) title for method from mcompare()
- r(mcadjustall) adjustall or empty
- r(margin_method) asbalanced or asobserved

Matrices
- r(b) contrast estimates
- r(V) variance-covariance matrix of the contrast estimates
- r(error) contrast estimability codes; 0 means estimable, 8 means not estimable
- r(L) matrix of contrasts applied to the model coefficients
- r(table) matrix containing the contrasts with their standard errors, test statistics, p-values, and confidence intervals
- r(F) vector of F statistics; r(df_r) present
- r(chi2) vector of \( \chi^2 \) statistics; r(df_r) not present
- r(p) vector of p-values corresponding to r(F) or r(chi2)
- r(df) vector of degrees of freedom corresponding to r(p)
- r(df2) vector of denominator degrees of freedom corresponding to r(F)
contrast with the post option stores the following in e():

Scalars
- \( e(\text{df}_r) \) variance degrees of freedom
- \( e(k\_\text{terms}) \) number of terms in \textit{termlist}

Macros
- \( e(\text{cmd}) \) contrast
- \( e(\text{cmdline}) \) command as typed
- \( e(\text{properties}) \) \( b \ V \)
- \( e(\text{est}_\text{cmd}) \) \( e(\text{cmd}) \) from original estimation results
- \( e(\text{est}_\text{cmdline}) \) \( e(\text{cmdline}) \) from original estimation results
- \( e(\text{title}) \) title in output
- \( e(\text{overall}) \) overall or empty
- \( e(\text{emptycells}) \) \textit{empspec} from \textit{emptycells()}
- \( e(\text{margin\_method}) \) \textit{asbalanced} or \textit{asobserved}
- \( e(\text{asbalanced}) \) factor variables \textit{fvset} as \textit{asbalanced}
- \( e(\text{asobserved}) \) factor variables \textit{fvset} as \textit{asobserved}

Matrices
- \( e(b) \) contrast estimates
- \( e(V) \) variance–covariance matrix of the contrast estimates
- \( e(\text{error}) \) contrast estimability codes; 0 means estimable, 8 means not estimable
- \( e(L) \) matrix of contrasts applied to the model coefficients
- \( e(F) \) vector of unadjusted \( F \) statistics; \( e(\text{df}_r) \) present
- \( e(\text{chi2}) \) vector of \( \chi^2 \) statistics; \( e(\text{df}_r) \) not present
- \( e(p) \) vector of unadjusted \textit{p}-values corresponding to \( e(F) \) or \( e(\text{chi2}) \)
- \( e(\text{df}) \) vector of degrees of freedom corresponding to \( e(p) \)
- \( e(\text{df2}) \) vector of denominator degrees of freedom corresponding to \( e(F) \)

Methods and formulas

Methods and formulas are presented under the following headings:

- Marginal linear predictions
- Contrast operators
  - Reference level contrasts
  - Adjacent contrasts
  - Grand mean contrasts
  - Helmert contrasts
  - Reverse Helmert contrasts
  - Orthogonal polynomial contrasts
- Contrasts within interactions
- Multiple comparisons

Marginal linear predictions

\textit{contrast} treats intercept effects separately from slope effects. To illustrate, consider the following parameterization for a quadratic regression of \( y \) on \( x \) that also models the effects of two factor variables \( A \) and \( B \), where the levels of \( A \) are indexed by \( i = 1, \ldots, k_a \) and the levels of \( B \) are indexed by \( j = 1, \ldots, k_b \).
\[
E(y|A = i, B = j, x) = \eta_{0ij} + \eta_{1ij}x + \eta_{2ij}x^2
\]

\[
\eta_{0ij} = \eta_0 + \alpha_{0i} + \beta_{0j} + (\alpha\beta)_{0ij}
\]

\[
\eta_{1ij} = \eta_1 + \alpha_{1i} + \beta_{1j} + (\alpha\beta)_{1ij}
\]

\[
\eta_{2ij} = \eta_2 + \alpha_{2i} + \beta_{2j} + (\alpha\beta)_{2ij}
\]

We have partitioned the coefficients into three groups of parameters: \(\eta_{0ij}\) is a cell prediction for the intercept, \(\eta_{1ij}\) is a cell prediction for the slope on \(x\), and \(\eta_{2ij}\) is a cell prediction for the slope on \(x^2\). For the intercept parameters, \(\eta_0\) is the intercept, \(\alpha_{0i}\) represents a main effect for factor \(A\) at its \(i\)th level, \(\beta_{0j}\) represents a main effect for factor \(B\) at its \(j\)th level, and \((\alpha\beta)_{0ij}\) represents an effect for the interaction of \(A\) and \(B\) at the \(ij\)th level. The individual coefficients in \(\eta_{1ij}\) and \(\eta_{2ij}\) have similar interpretations, but the effects are on the slopes of \(x\) and \(x^2\), respectively.

The marginal intercepts for \(A\) are given by

\[
\eta_{0i} = \sum_{j=1}^{k_b} f_{ij} \eta_{0ij}
\]

where \(f_{ij}\) is a marginal relative frequency of the \(j\)th level of \(B\) and is controlled by the asobserved and emptycells(reweight) options according to

\[
\begin{cases} 
1/k_b, & \text{default} \\
 w_{..}/w_{i.}, & \text{asobserved} \\
 1/(k_b - e_{i.}), & \text{emptycells(reweight)} \\
 w_{ij}/w_{i.}, & \text{emptycells(reweight) and asobserved}
\end{cases}
\]

Above, \(w_{ij}\) is the number of individuals with \(A\) at its \(i\)th level and \(B\) at its \(j\)th,

\[
w_{i.} = \sum_{j=1}^{k_b} w_{ij}
\]

\[
w_{.j} = \sum_{i=1}^{k_a} w_{ij}
\]

\[
w_{..} = \sum_{i=1}^{k_a} \sum_{j=1}^{k_b} w_{ij}
\]

and \(e_{i.}\) is the number of empty cells where \(A\) is at its \(i\)th level. The marginal intercepts for \(B\) and marginal slopes on \(x\) and \(x^2\) are similarly defined.

Estimates for the cell intercepts and slopes are computed using the corresponding linear combination of the coefficients from the fitted model. For example, the estimated cell intercepts are computed using

\[
\hat{\eta}_{0ij} = \hat{\eta}_0 + \hat{\alpha}_{0i} + \hat{\beta}_{0j} + (\hat{\alpha}\hat{\beta})_{0ij}
\]
and the estimated marginal intercepts for $A$ are computed as

$$
\hat{\eta}_{0i} = \sum_{j=1}^{k_b} f_{ij} \hat{\eta}_{0ij}
$$

### Contrast operators

`contrast` performs Wald tests using linear combinations of marginal linear predictions. For example, the following linear combination can be used to test for a specific effect of factor $A$ on the marginal intercepts.

$$
\sum_{i=1}^{k_a} c_i \hat{\eta}_{0i}.
$$

If the $c_i$ elements sum to zero, the linear combination is called a contrast. If the factor $A$ is represented by a variable named `A`, then we specify this contrast using the following syntax:

```
{A c_1 c_2 \ldots c_{k_a}}
```

Similarly, the following linear combination can be used to test for a specific interaction effect of factors $A$ and $B$ on the marginal slope of $x$.

$$
\sum_{i=1}^{k_a} \sum_{j=1}^{k_b} c_{ij} \eta_{1ij}
$$

If the factor $B$ is represented by a variable named `B`, then we specify this contrast using the following syntax:

```
{A#B c_{11} c_{12} \ldots c_{1k_b} c_{21} \ldots c_{k_a k_b}}
```

`contrast` has variable operators for several commonly used contrasts. Each contrast operator specifies a matrix of linear combinations that yield the requested set of contrasts to be applied to the marginal linear predictions associated with the attached factor variable.

### Reference level contrasts

The `r.` operator compares each level with a reference level. Let $R$ be the corresponding contrast matrix for factor $A$, and then $R$ is a $(k_a - 1) \times k_a$ matrix with elements

$$
R_{ij} = \begin{cases} 
-1, & \text{if } j \text{ is the reference level} \\
1, & \text{if } i = j \text{ and } j \text{ is less than the reference level} \\
1, & \text{if } i + 1 = j \text{ and } j \text{ is greater than the reference level} \\
0, & \text{otherwise}
\end{cases}
$$
If \( k_a = 5 \) and the reference level is the third level of \( A \) (specified as \( \text{rb(#3)} \cdot A \)), then

\[
R = \begin{pmatrix}
1 & 0 & -1 & 0 & 0 \\
0 & 1 & -1 & 0 & 0 \\
0 & 0 & -1 & 1 & 0 \\
0 & 0 & -1 & 0 & 1
\end{pmatrix}
\]

**Adjacent contrasts**

The \( \text{a.} \) operator compares each level with the next level. Let \( A \) be the corresponding contrast matrix for factor \( A \), and then \( A \) is a \( (k_a - 1) \times k_a \) matrix with elements

\[
A_{ij} = \begin{cases}
1, & \text{if } i = j \\
-1, & \text{if } i + 1 = j \\
0, & \text{otherwise}
\end{cases}
\]

If \( k_a = 5 \), then

\[
A = \begin{pmatrix}
1 & -1 & 0 & 0 & 0 \\
0 & 1 & -1 & 0 & 0 \\
0 & 0 & 1 & -1 & 0 \\
0 & 0 & 0 & 1 & -1
\end{pmatrix}
\]

The \( \text{ar.} \) operator compares each level with the previous level. If \( A \) is the contrast matrix for the \( \text{a.} \) operator, then \(-A\) is the corresponding contrast matrix for the \( \text{ar.} \) operator.

**Grand mean contrasts**

The \( \text{g.} \) operator compares each level with the mean of all the levels. Let \( G \) be the corresponding contrast matrix for factor \( A \), and then \( G \) is a \( k_a \times k_a \) matrix with elements

\[
G_{ij} = \begin{cases}
1 - 1/k_a, & \text{if } i = j \\
-1/k_a, & \text{if } i \neq j
\end{cases}
\]

If \( k_a = 5 \), then

\[
G = \begin{pmatrix}
4/5 & -1/5 & -1/5 & -1/5 & -1/5 \\
-1/5 & 4/5 & -1/5 & -1/5 & -1/5 \\
-1/5 & -1/5 & 4/5 & -1/5 & -1/5 \\
-1/5 & -1/5 & -1/5 & 4/5 & -1/5 \\
-1/5 & -1/5 & -1/5 & -1/5 & 4/5
\end{pmatrix}
\]

The \( \text{gw.} \) operator compares each level with the weighted mean of all the levels. The weights are taken from the observed weighted cell frequencies in the estimation sample of the fitted model. Let \( G_w \) be the corresponding contrast matrix for factor \( A \), and then \( G_w \) is a \( k_a \times k_a \) matrix with elements
\[ G_{ij} = \begin{cases} 1 - \frac{w_i}{w}, & \text{if } i = j \\ - \frac{w_j}{w}, & \text{if } i \neq j \end{cases} \]

where \( w_i \) is a marginal weight representing the number of individuals with \( A \) at its \( i \)th level and \( w = \sum_i w_i \).

**Helmert contrasts**

The \( h. \) operator compares each level with the mean of the subsequent levels. Let \( H \) be the corresponding contrast matrix for factor \( A \), and then \( H \) is a \((k_a - 1) \times k_a\) matrix with elements

\[ H_{ij} = \begin{cases} 1, & \text{if } i = j \\ - \frac{1}{(k_a - i)}, & \text{if } i < j \\ 0, & \text{otherwise} \end{cases} \]

If \( k_a = 5 \), then

\[ H = \begin{pmatrix} 1 & -1/4 & -1/4 & -1/4 & -1/4 \\ 0 & 1 & -1/3 & -1/3 & -1/3 \\ 0 & 0 & 1 & -1/2 & -1/2 \\ 0 & 0 & 0 & 1 & -1 \end{pmatrix} \]

The \( hw. \) operator compares each level with the weighted mean of the subsequent levels. Let \( H_w \) be the corresponding contrast matrix for factor \( A \), and then \( H_w \) is a \((k_a - 1) \times k_a\) matrix with elements

\[ H_{wij} = \begin{cases} 1, & \text{if } i = j \\ - \frac{w_j}{\sum_{l=j}^{k_a} w_l}, & \text{if } i < j \\ 0, & \text{otherwise} \end{cases} \]

**Reverse Helmert contrasts**

The \( j. \) operator compares each level with the mean of the previous levels. Let \( J \) be the corresponding contrast matrix for factor \( A \), and then \( J \) is a \((k_a - 1) \times k_a\) matrix with elements

\[ J_{ij} = \begin{cases} 1, & \text{if } i + 1 = j \\ - \frac{1}{i}, & \text{if } j \leq i \\ 0, & \text{otherwise} \end{cases} \]

If \( k_a = 5 \), then

\[ H = \begin{pmatrix} -1 & 1 & 0 & 0 & 0 \\ -1/2 & -1/2 & 1 & 0 & 0 \\ -1/3 & -1/3 & -1/3 & 1 & 0 \\ -1/4 & -1/4 & -1/4 & -1/4 & 1 \end{pmatrix} \]
The jw. operator compares each level with the weighted mean of the previous levels. Let $J_w$ be the corresponding contrast matrix for factor $A$, and then $J_w$ is a $(k_a - 1) \times k_a$ matrix with elements

$$J_{wij} = \begin{cases} 1, & \text{if } i + 1 = j \\ -w_j / \sum_{l=1}^i w_l, & \text{if } i \leq j \\ 0, & \text{otherwise} \end{cases}$$

Orthogonal polynomial contrasts

The p. operator applies orthogonal polynomial contrasts using the level values of the attached factor variable. The q. operator applies orthogonal polynomial contrasts using the level indices of the attached factor variable. These two operators are equivalent when the level values of the attached factor are equally spaced. The pw. and qw. operators are weighted versions of p. and q., where the weights are taken from the observed weighted cell frequencies in the estimation sample of the fitted model. contrast uses the Christoffel–Darboux recurrence formula for computing orthogonal polynomial contrasts (Abramowitz and Stegun 1964). The elements of the contrasts are normalized such that

$$Q'WQ = \frac{1}{w} I$$

where $W$ is a diagonal matrix of the marginal cell weights $w_1, w_2, \ldots, w_k$ of the attached factor variable (all 1 for p. and q.), and $w.$ is the sum of the weights (the number of levels $k$ for p. and q.).

Contrasts within interactions

Contrast operators are allowed to be specified on factor variables participating in interactions. In such cases, contrast applies the proper matrix product of the contrast matrices to the cell margins of the interacted factor variables.

For example, consider the contrasts implied by specifying r.A#h.B. Let $M$ be the matrix of estimated cell margins for the levels of $A$ and $B$, where the rows of $M$ are indexed by the levels of $A$ and the columns are indexed by the levels of $B$. contrast puts the estimated cell margins in the following vector form:

$$v = \text{vec}(M') = \begin{pmatrix} M_{11} \\ M_{12} \\ \vdots \\ M_{1k_b} \\ M_{21} \\ M_{22} \\ \vdots \\ M_{2k_b} \\ \vdots \\ M_{k_a k_b} \end{pmatrix}$$
The individual contrasts are then given by the elements of

$$(R \otimes H)v$$

where $\otimes$ denotes the Kronecker direct product.

**Multiple comparisons**

See [R] `pwcompare` for details on the methods and formulas used to adjust $p$-values and confidence intervals for multiple comparisons. The formulas for Bonferroni’s method and Šidák’s method are presented with $m = k(k − 1)/2$, the number of pairwise comparisons for a factor term with $k$ levels. For contrasts, $m$ is instead the number of contrasts being performed on the factor term; often, $m = k − 1$ for a term with $k$ levels.

</tr>
<tr>
<td>test</td>
<td>Wald tests of simple and composite linear hypotheses</td>
</tr>
<tr>
<td>testnl</td>
<td>Wald tests of nonlinear hypotheses</td>
</tr>
</tbody>
</table>

Remarks and examples

In *Orthogonal polynomial contrasts* in [R] contrast, we used the p. operator to test the orthogonal polynomial effects of age group.

```
. contrast p.agegrp, noeffects
```

We then used a second contrast command,

```
. contrast p(2 3 4).agegrp, noeffects
```

selecting levels to test whether the quadratic, cubic, and quartic contrasts were jointly significant.

We can perform the same joint test by using the test command after specifying the post option with our first contrast command.
. use https://www.stata-press.com/data/r16/cholesterol
(Artificial cholesterol data)
. anova chol agegrp
(output omitted)
. contrast p.agegrp, noeffects post
Contrasts of marginal linear predictions

Description

copyright presents copyright notifications concerning tools, libraries, etc., used in the construction of Stata.

Syntax

copyright

Remarks and examples

The correct form for a copyright notice is

Copyright dates by author/owner

The word “Copyright” is spelled out. You can use the © symbol, but “(C)” has never been given legal recognition. The phrase “All Rights Reserved” was historically required but is no longer needed.

Currently, most works are copyrighted from the moment they are written, and no copyright notice is required. Copyright concerns the protection of the expression and structure of facts and ideas, not the facts and ideas themselves. Copyright concerns the ownership of the expression and not the name given to the expression, which is covered under trademark law.

Copyright law as it exists today began in England in 1710 with the Statute of Anne, An Act for the Encouragement of Learning, by Vesting the Copies of Printed Books in the Authors or Purchases of Such Copies, during the Times therein mentioned. In 1672, Massachusetts introduced the first copyright law in what was to become the United States. After the Revolutionary War, copyright was introduced into the U.S. Constitution in 1787 and went into effect on May 31, 1790. On June 9, 1790, the first copyright in the United States was registered for The Philadelphia Spelling Book by John Barry.

There are significant differences in the understanding of copyright in the English- and non–English-speaking world. The Napoleonic or Civil Code, the dominant legal system in the non–English-speaking world, splits the rights into two classes: the author’s economic rights and the author’s moral rights. Moral rights are available only to “natural persons”. Legal persons (corporations) have economic rights but not moral rights.

Apache License
Version 2.0, January 2004

http://www.apache.org/licenses/

TERMS AND CONDITIONS FOR USE, REPRODUCTION, AND DISTRIBUTION

1. Definitions.

“License” shall mean the terms and conditions for use, reproduction, and distribution as defined by Sections 1 through 9 of this document.

“Licensor” shall mean the copyright owner or entity authorized by the copyright owner that is granting the License.

“Legal Entity” shall mean the union of the acting entity and all other entities that control, are controlled by, or are under common control with that entity. For the purposes of this definition, “control” means (i) the power, direct or indirect, to cause the direction or management of such entity, whether by contract or otherwise, or (ii) ownership of fifty percent (50%) or more of the outstanding shares, or (iii) beneficial ownership of such entity.

“You” (or “Your”) shall mean an individual or Legal Entity exercising permissions granted by this License.

“Source” form shall mean the preferred form for making modifications, including but not limited to software source code, documentation source, and configuration files.

“Object” form shall mean any form resulting from mechanical transformation or translation of a Source form, including but not limited to compiled object code, generated documentation, and conversions to other media types.

“Work” shall mean the work of authorship, whether in Source or Object form, made available under the License, as indicated by a copyright notice that is included in or attached to the work (an example is provided in the Appendix below).

“Derivative Works” shall mean any work, whether in Source or Object form, that is based on (or derived from) the Work and for which the editorial revisions, annotations, elaborations, or other modifications represent, as a whole, an original work of authorship. For the purposes of this License, Derivative Works shall not include works that remain separable from, or merely link (or bind by name) to the interfaces of, the Work and Derivative Works thereof.
“Contribution” shall mean any work of authorship, including the original version of the Work and any modifications or additions to that Work or Derivative Works thereof, that is intentionally submitted to Licensor for inclusion in the Work by the copyright owner or by an individual or Legal Entity authorized to submit on behalf of the copyright owner. For the purposes of this definition, “submitted” means any form of electronic, verbal, or written communication sent to the Licensor or its representatives, including but not limited to communication on electronic mailing lists, source code control systems, and issue tracking systems that are managed by, or on behalf of, the Licensor for the purpose of discussing and improving the Work, but excluding communication that is conspicuously marked or otherwise designated in writing by the copyright owner as “Not a Contribution.”

“Contributor” shall mean Licensor and any individual or Legal Entity on behalf of whom a Contribution has been received by Licensor and subsequently incorporated within the Work.

2. Grant of Copyright License. Subject to the terms and conditions of this License, each Contributor hereby grants to You a perpetual, worldwide, non-exclusive, no-charge, royalty-free, irrevocable copyright license to reproduce, prepare Derivative Works of, publicly display, publicly perform, sublicense, and distribute the Work and such Derivative Works in Source or Object form.

3. Grant of Patent License. Subject to the terms and conditions of this License, each Contributor hereby grants to You a perpetual, worldwide, non-exclusive, no-charge, royalty-free, irrevocable (except as stated in this section) patent license to make, have made, use, offer to sell, sell, import, and otherwise transfer the Work, where such license applies only to those patent claims licensable by such Contributor that are necessarily infringed by their Contribution(s) alone or by combination of their Contribution(s) with the Work to which such Contribution(s) was submitted. If You institute patent litigation against any entity (including a cross-claim or counterclaim in a lawsuit) alleging that the Work or a Contribution incorporated within the Work constitutes direct or contributory patent infringement, then any patent licenses granted to You under this License for that Work shall terminate as of the date such litigation is filed.

4. Redistribution. You may reproduce and distribute copies of the Work or Derivative Works thereof in any medium, with or without modifications, and in Source or Object form, provided that You meet the following conditions:

You must give any other recipients of the Work or Derivative Works a copy of this License; and

You must cause any modified files to carry prominent notices stating that You changed the files; and

You must retain, in the Source form of any Derivative Works that You distribute, all copyright, patent, trademark, and attribution notices from the Source form of the Work, excluding those notices that do not pertain to any part of the Derivative Works; and

If the Work includes a “NOTICE” text file as part of its distribution, then any Derivative Works that You distribute must include a readable copy of the attribution notices contained within such NOTICE file, excluding those notices that do not pertain to any part of the Derivative Works, in at least one of the following places: within a NOTICE text file distributed as part of the Derivative Works; within the Source form or documentation, if provided along with the Derivative Works; or, within a display generated by the Derivative Works, if and wherever such third-party notices normally appear. The contents of the NOTICE file are for informational purposes only and do not modify the License. You may
add Your own attribution notices within Derivative Works that You distribute, alongside or as an addendum to the NOTICE text from the Work, provided that such additional attribution notices cannot be construed as modifying the License. You may add Your own copyright statement to Your modifications and may provide additional or different license terms and conditions for use, reproduction, or distribution of Your modifications, or for any such Derivative Works as a whole, provided Your use, reproduction, and distribution of the Work otherwise complies with the conditions stated in this License.

5. Submission of Contributions. Unless You explicitly state otherwise, any Contribution intentionally submitted for inclusion in the Work by You to the Licensor shall be under the terms and conditions of this License, without any additional terms or conditions. Notwithstanding the above, nothing herein shall supersede or modify the terms of any separate license agreement you may have executed with Licensor regarding such Contributions.

6. Trademarks. This License does not grant permission to use the trade names, trademarks, service marks, or product names of the Licensor, except as required for reasonable and customary use in describing the origin of the Work and reproducing the content of the NOTICE file.

7. Disclaimer of Warranty. Unless required by applicable law or agreed to in writing, Licensor provides the Work (and each Contributor provides its Contributions) on an “AS IS” BASIS, WITHOUT WARRANTIES OR CONDITIONS OF ANY KIND, either express or implied, including, without limitation, any warranties or conditions of TITLE, NON-INFRINGEMENT, MERCHANTABILITY, or FITNESS FOR A PARTICULAR PURPOSE. You are solely responsible for determining the appropriateness of using or redistributing the Work and assume any risks associated with Your exercise of permissions under this License.

8. Limitation of Liability. In no event and under no legal theory, whether in tort (including negligence), contract, or otherwise, unless required by applicable law (such as deliberate and grossly negligent acts) or agreed to in writing, shall any Contributor be liable to You for damages, including any direct, indirect, special, incidental, or consequential damages of any character arising as a result of this License or out of the use or inability to use the Work (including but not limited to damages for loss of goodwill, work stoppage, computer failure or malfunction, or any and all other commercial damages or losses), even if such Contributor has been advised of the possibility of such damages.

9. Accepting Warranty or Additional Liability. While redistributing the Work or Derivative Works thereof, You may choose to offer, and charge a fee for, acceptance of support, warranty, indemnity, or other liability obligations and/or rights consistent with this License. However, in accepting such obligations, You may act only on Your own behalf and on Your sole responsibility, not on behalf of any other Contributor, and only if You agree to indemnify, defend, and hold each Contributor harmless for any liability incurred by, or claims asserted against, such Contributor by reason of your accepting any such warranty or additional liability.

END OF TERMS AND CONDITIONS

APPENDIX: How to apply the Apache License to your work

To apply the Apache License to your work, attach the following boilerplate notice, with the fields enclosed by brackets “[]” replaced with your own identifying information. (Don’t include the brackets!) The text should be enclosed in the appropriate comment syntax for the file format. We also recommend that a file or class name and description of purpose be included on the same “printed page” as the copyright notice for easier identification within third-party archives.

Description

Stata uses portions of JAXB with the express permission of the authors, pursuant to the terms of the Common Development and Distribution License (CDDL) version 1.1.

COMMON DEVELOPMENT AND DISTRIBUTION LICENSE (CDDL) Version 1.1
1. Definitions.
1.1. “Contributor” means each individual or entity that creates or contributes to the creation of Modifications.
1.2. “Contributor Version” means the combination of the Original Software, prior Modifications used by a Contributor (if any), and the Modifications made by that particular Contributor.
1.3. “Covered Software” means (a) the Original Software, or (b) Modifications, or (c) the combination of files containing Original Software with files containing Modifications, in each case including portions thereof.
1.4. “Executable” means the Covered Software in any form other than Source Code.
1.5. “Initial Developer” means the individual or entity that first makes Original Software available under this License.
1.6. “Larger Work” means a work which combines Covered Software or portions thereof with code not governed by the terms of this License.
1.7. “License” means this document.
1.8. “Licensable” means having the right to grant, to the maximum extent possible, whether at the time of the initial grant or subsequently acquired, any and all of the rights conveyed herein.
1.9. “Modifications” means the Source Code and Executable form of any of the following:
   A. Any file that results from an addition to, deletion from or modification of the contents of a file containing Original Software or previous Modifications;
   B. Any new file that contains any part of the Original Software or previous Modification; or
   C. Any new file that is contributed or otherwise made available under the terms of this License.
1.10. “Original Software” means the Source Code and Executable form of computer software code that is originally released under this License.
1.11. “Patent Claims” means any patent claim(s), now owned or hereafter acquired, including without limitation, method, process, and apparatus claims, in any patent Licensable by grantor.
1.12. “Source Code” means (a) the common form of computer software code in which modifications are made and (b) associated documentation included in or with such code.

1.13. “You” (or “Your”) means an individual or a legal entity exercising rights under, and complying with all of the terms of, this License. For legal entities, “You” includes any entity which controls, is controlled by, or is under common control with You. For purposes of this definition, “control” means (a) the power, direct or indirect, to cause the direction or management of such entity, whether by contract or otherwise, or (b) ownership of more than fifty percent (50%) of the outstanding shares or beneficial ownership of such entity.

2. License Grants.

2.1. The Initial Developer Grant.

Conditioned upon Your compliance with Section 3.1 below and subject to third party intellectual property claims, the Initial Developer hereby grants You a world-wide, royalty-free, non-exclusive license:

(a) under intellectual property rights (other than patent or trademark) Licensable by Initial Developer, to use, reproduce, modify, display, perform, sublicense and distribute the Original Software (or portions thereof), with or without Modifications, and/or as part of a Larger Work; and

(b) under Patent Claims infringed by the making, using or selling of Original Software, to make, have made, use, practice, sell, and offer for sale, and/or otherwise dispose of the Original Software (or portions thereof).

(c) The licenses granted in Sections 2.1(a) and (b) are effective on the date Initial Developer first distributes or otherwise makes the Original Software available to a third party under the terms of this License.

(d) Notwithstanding Section 2.1(b) above, no patent license is granted: (1) for code that You delete from the Original Software, or (2) for infringements caused by: (i) the modification of the Original Software, or (ii) the combination of the Original Software with other software or devices.

2.2. Contributor Grant.

Conditioned upon Your compliance with Section 3.1 below and subject to third party intellectual property claims, each Contributor hereby grants You a world-wide, royalty-free, non-exclusive license:

(a) under intellectual property rights (other than patent or trademark) Licensable by Contributor to use, reproduce, modify, display, perform, sublicense and distribute the Modifications created by such Contributor (or portions thereof), either on an unmodified basis, with other Modifications, as Covered Software and/or as part of a Larger Work; and

(b) under Patent Claims infringed by the making, using, or selling of Modifications made by that Contributor either alone and/or in combination with its Contributor Version (or portions of such combination), to make, use, sell, offer for sale, have made, and/or otherwise dispose of: (1) Modifications made by that Contributor (or portions thereof); and (2) the combination of Modifications made by that Contributor with its Contributor Version (or portions of such combination).
(c) The licenses granted in Sections 2.2(a) and 2.2(b) are effective on the date Contributor first distributes or otherwise makes the Modifications available to a third party.

(d) Notwithstanding Section 2.2(b) above, no patent license is granted: (1) for any code that Contributor has deleted from the Contributor Version; (2) for infringements caused by: (i) third party modifications of Contributor Version, or (ii) the combination of Modifications made by that Contributor with other software (except as part of the Contributor Version) or other devices; or (3) under Patent Claims infringed by Covered Software in the absence of Modifications made by that Contributor.

3. Distribution Obligations.

3.1. Availability of Source Code.

Any Covered Software that You distribute or otherwise make available in Executable form must also be made available in Source Code form and that Source Code form must be distributed only under the terms of this License. You must include a copy of this License with every copy of the Source Code form of the Covered Software You distribute or otherwise make available. You must inform recipients of any such Covered Software in Executable form as to how they can obtain such Covered Software in Source Code form in a reasonable manner on or through a medium customarily used for software exchange.

3.2. Modifications.

The Modifications that You create or to which You contribute are governed by the terms of this License. You represent that You believe Your Modifications are Your original creation(s) and/or You have sufficient rights to grant the rights conveyed by this License.

3.3. Required Notices.

You must include a notice in each of Your Modifications that identifies You as the Contributor of the Modification. You may not remove or alter any copyright, patent or trademark notices contained within the Covered Software, or any notices of licensing or any descriptive text giving attribution to any Contributor or the Initial Developer.

3.4. Application of Additional Terms.

You may not offer or impose any terms on any Covered Software in Source Code form that alters or restricts the applicable version of this License or the recipients’ rights hereunder. You may choose to offer, and to charge a fee for, warranty, support, indemnity or liability obligations to one or more recipients of Covered Software. However, you may do so only on Your own behalf, and not on behalf of the Initial Developer or any Contributor. You must make it absolutely clear that any such warranty, support, indemnity or liability obligation is offered by You alone, and You hereby agree to indemnify the Initial Developer and every Contributor for any liability incurred by the Initial Developer or such Contributor as a result of warranty, support, indemnity or liability terms You offer.

3.5. Distribution of Executable Versions.

You may distribute the Executable form of the Covered Software under the terms of this License or under the terms of a license of Your choice, which may contain terms different from this License, provided that You are in compliance with the terms of
this License and that the license for the Executable form does not attempt to limit or alter the recipient’s rights in the Source Code form from the rights set forth in this License. If You distribute the Covered Software in Executable form under a different license, You must make it absolutely clear that any terms which differ from this License are offered by You alone, not by the Initial Developer or Contributor. You hereby agree to indemnify the Initial Developer and every Contributor for any liability incurred by the Initial Developer or such Contributor as a result of any such terms You offer.

You may create a Larger Work by combining Covered Software with other code not governed by the terms of this License and distribute the Larger Work as a single product. In such a case, You must make sure the requirements of this License are fulfilled for the Covered Software.

4. Versions of the License.
4.1. New Versions.
Oracle is the initial license steward and may publish revised and/or new versions of this License from time to time. Each version will be given a distinguishing version number. Except as provided in Section 4.3, no one other than the license steward has the right to modify this License.

4.2. Effect of New Versions.
You may always continue to use, distribute or otherwise make the Covered Software available under the terms of the version of the License under which You originally received the Covered Software. If the Initial Developer includes a notice in the Original Software prohibiting it from being distributed or otherwise made available under any subsequent version of the License, You must distribute and make the Covered Software available under the terms of the version of the License under which You originally received the Covered Software. Otherwise, You may also choose to use, distribute or otherwise make the Covered Software available under the terms of any subsequent version of the License published by the license steward.

4.3. Modified Versions.
When You are an Initial Developer and You want to create a new license for Your Original Software, You may create and use a modified version of this License if You: (a) rename the license and remove any references to the name of the license steward (except to note that the license differs from this License); and (b) otherwise make it clear that the license contains terms which differ from this License.

5. DISCLAIMER OF WARRANTY.
COVERED SOFTWARE IS PROVIDED UNDER THIS LICENSE ON AN “AS IS” BASIS, WITHOUT WARRANTY OF ANY KIND, EITHER EXPRESSED OR IMPLIED, INCLUDING, WITHOUT LIMITATION, WARRANTIES THAT THE COVERED SOFTWARE IS FREE OF DEFECTS, MERCHANTABILITY, FIT FOR A PARTICULAR PURPOSE OR NON-INFRINGEMENT. THE ENTIRE RISK AS TO THE QUALITY AND PERFORMANCE OF THE COVERED SOFTWARE IS WITH YOU. SHOULD ANY COVERED SOFTWARE PROVE DEFECTIVE IN ANY RESPECT, YOU (NOT THE INITIAL DEVELOPER OR ANY OTHER CONTRIBUTOR) ASSUME THE COST OF ANY NECESSARY SERVICING, REPAIR OR CORRECTION. THIS DISCLAIMER OF WARRANTY CONSTITUTES AN ESSENTIAL PART OF
6. TERMINATION.

6.1. This License and the rights granted hereunder will terminate automatically if You fail to comply with terms herein and fail to cure such breach within 30 days of becoming aware of the breach. Provisions which, by their nature, must remain in effect beyond the termination of this License shall survive.

6.2. If You assert a patent infringement claim (excluding declaratory judgment actions) against Initial Developer or a Contributor (the Initial Developer or Contributor against whom You assert such claim is referred to as “Participant”) alleging that the Participant Software (meaning the Contributor Version where the Participant is a Contributor or the Original Software where the Participant is the Initial Developer) directly or indirectly infringes any patent, then any and all rights granted directly or indirectly to You by such Participant, the Initial Developer (if the Initial Developer is not the Participant) and all Contributors under Sections 2.1 and/or 2.2 of this License shall, upon 60 days notice from Participant terminate prospectively and automatically at the expiration of such 60 day notice period, unless if within such 60 day period You withdraw Your claim with respect to the Participant Software against such Participant either unilaterally or pursuant to a written agreement with Participant.

6.3. If You assert a patent infringement claim against Participant alleging that the Participant Software directly or indirectly infringes any patent where such claim is resolved (such as by license or settlement) prior to the initiation of patent infringement litigation, then the reasonable value of the licenses granted by such Participant under Sections 2.1 or 2.2 shall be taken into account in determining the amount or value of any payment or license.

6.4. In the event of termination under Sections 6.1 or 6.2 above, all end user licenses that have been validly granted by You or any distributor hereunder prior to termination (excluding licenses granted to You by any distributor) shall survive termination.

7. LIMITATION OF LIABILITY.

UNDER NO CIRCUMSTANCES AND UNDER NO LEGAL THEORY, WHETHER TORT (INCLUDING NEGLIGENCE), CONTRACT, OR OTHERWISE, SHALL YOU, THE INITIAL DEVELOPER, ANY OTHER CONTRIBUTOR, OR ANY DISTRIBUTOR OF COVERED SOFTWARE, OR ANY SUPPLIER OF ANY OF SUCH PARTIES, BE LIABLE TO ANY PERSON FOR ANY INDIRECT, SPECIAL, INCIDENTAL, OR CONSEQUENTIAL DAMAGES OF ANY CHARACTER INCLUDING, WITHOUT LIMITATION, DAMAGES FOR LOSS OF GOODWILL, WORK STOPPAGE, COMPUTER FAILURE OR MALFUNCTION, OR ANY AND ALL OTHER COMMERCIAL DAMAGES OR LOSSES, EVEN IF SUCH PARTY SHALL HAVE BEEN INFORMED OF THE POSSIBILITY OF SUCH DAMAGES. THIS LIMITATION OF LIABILITY SHALL NOT APPLY TO LIABILITY FOR DEATH OR PERSONAL INJURY RESULTING FROM SUCH PARTY’S NEGLIGENCE TO THE EXTENT APPLICABLE LAW PROHIBITS SUCH LIMITATION. SOME JURISDICTIONS DO NOT ALLOW THE EXCLUSION OR LIMITATION OF INCIDENTAL OR CONSEQUENTIAL DAMAGES, SO THIS EXCLUSION AND LIMITATION MAY NOT APPLY TO YOU.
8. U.S. GOVERNMENT END USERS.

The Covered Software is a “commercial item,” as that term is defined in 48 C.F.R. 2.101 (Oct. 1995), consisting of “commercial computer software” (as that term is defined at 48 C.F.R. §252.227-7014(a)(1)) and “commercial computer software documentation” as such terms are used in 48 C.F.R. 12.212 (Sept. 1995). Consistent with 48 C.F.R. 12.212 and 48 C.F.R. 227.7202-1 through 227.7202-4 (June 1995), all U.S. Government End Users acquire Covered Software with only those rights set forth herein. This U.S. Government Rights clause is in lieu of, and supersedes, any other FAR, DFAR, or other clause or provision that addresses Government rights in computer software under this License.

9. MISCELLANEOUS.

This License represents the complete agreement concerning subject matter hereof. If any provision of this License is held to be unenforceable, such provision shall be reformed only to the extent necessary to make it enforceable. This License shall be governed by the law of the jurisdiction specified in a notice contained within the Original Software (except to the extent applicable law, if any, provides otherwise), excluding such jurisdiction’s conflict-of-law provisions. Any litigation relating to this License shall be subject to the jurisdiction of the courts located in the jurisdiction and venue specified in a notice contained within the Original Software, with the losing party responsible for costs, including, without limitation, court costs and reasonable attorneys’ fees and expenses. The application of the United Nations Convention on Contracts for the International Sale of Goods is expressly excluded. Any law or regulation which provides that the language of a contract shall be construed against the drafter shall not apply to this License. You agree that You alone are responsible for compliance with the United States export administration regulations (and the export control laws and regulation of any other countries) when You use, distribute or otherwise make available any Covered Software.

10. RESPONSIBILITY FOR CLAIMS.

As between Initial Developer and the Contributors, each party is responsible for claims and damages arising, directly or indirectly, out of its utilization of rights under this License and You agree to work with Initial Developer and Contributors to distribute such responsibility on an equitable basis. Nothing herein is intended or shall be deemed to constitute any admission of liability.

<td></td>
</tr>
</tbody>
</table>

**Description**

The `correlate` command displays the correlation matrix or covariance matrix for a group of variables. If `varlist` is not specified, the matrix is displayed for all variables in the dataset.

`pwcorr` displays all the pairwise correlation coefficients between the variables in `varlist` or, if `varlist` is not specified, all the variables in the dataset.

**Quick start**

Correlation matrix for variables v1, v2, and v3

```
correlate v1 v2 v3
```

As above, but display covariances instead of correlations

```
correlate v1 v2 v3, covariance
```

Pairwise correlation coefficients between v1, v2, and v3

```
pwcorr v1 v2 v3
```

Also print significance level of each correlation coefficient

```
pwcorr v1 v2 v3, sig
```

As above, but star correlation coefficients significant at the 5% level

```
pwcorr v1 v2 v3, sig star(.05)
```

As above, but use Bonferroni-adjusted significance levels

```
pwcorr v1 v2 v3, sig star(.05) bonferroni
```

**Menu**

**correlate**

Statistics > Summaries, tables, and tests > Summary and descriptive statistics > Correlations and covariances

**pwcorr**

Statistics > Summaries, tables, and tests > Summary and descriptive statistics > Pairwise correlations
correlate — Correlations of variables

Syntax

Display correlation matrix or covariance matrix

    correlate [varlist] [if] [in] [weight] [ , correlate_options ]

Display all pairwise correlation coefficients

    pwcorr [varlist] [if] [in] [weight] [ , pwcorr_options ]

correlate_options    Description

Options

    means      display means, standard deviations, minimums, and maximums with matrix
    noformat   ignore display format associated with variables
    covariance display covariances
    wrap       allow wide matrices to wrap

pwcorr_options    Description

Main

    obs        print number of observations for each entry
    sig        print significance level for each entry
    listwise   use listwise deletion to handle missing values
    casewise   synonym for listwise
    print(#)   significance level for displaying coefficients
    star(#)    significance level for displaying with a star
    bonferroni use Bonferroni-adjusted significance level
    sidak      use Šidák-adjusted significance level

varlist may contain time-series operators; see [U] 11.4.4 Time-series varlists.
by is allowed with correlate and pwcorr; see [D] by.
aweights and fweights are allowed; see [U] 11.1.6 weight.

Options for correlate

    means     displays summary statistics (means, standard deviations, minimums, and maximums) with the matrix.
    noformat  displays the summary statistics requested by the means option in g format, regardless of the display formats associated with the variables.
    covariance displays the covariances rather than the correlation coefficients.
    wrap      requests that no action be taken on wide correlation matrices to make them readable. It prevents Stata from breaking wide matrices into pieces to enhance readability. You might want to specify this option if you are displaying results in a window wider than 80 characters. Then you may need to set linesize to however many characters you can display across a line; see [R] log.
Options for pwcrr

- **Main**
  - **obs** adds a line to each row of the matrix reporting the number of observations used to calculate the correlation coefficient.
  - **sig** adds a line to each row of the matrix reporting the significance level of each correlation coefficient.
  - **listwise** handles missing values through listwise deletion, meaning that the entire observation is omitted from the estimation sample if any of the variables in varlist is missing for that observation. By default, pwcrr handles missing values by pairwise deletion; all available observations are used to calculate each pairwise correlation without regard to whether variables outside that pair are missing.
  - **correlate** uses listwise deletion. Thus listwise allows users of pwcrr to mimic correlate’s treatment of missing values while retaining access to pwcrr’s features.
  - **casewise** is a synonym for listwise.

- **print(#)** specifies the significance level of correlation coefficients to be printed. Correlation coefficients with larger significance levels are left blank in the matrix. Typing pwcrr, print(.10) would list only correlation coefficients significant at the 10% level or better.

- **star(#)** specifies the significance level of correlation coefficients to be starred. Typing pwcrr, star(.05) would star all correlation coefficients significant at the 5% level or better.

- **bonferroni** makes the Bonferroni adjustment to calculated significance levels. This option affects printed significance levels and the **print()** and **star()** options. Thus pwcrr, print(.05) bonferroni prints coefficients with Bonferroni-adjusted significance levels of 0.05 or less.

- **sidak** makes the Šidák adjustment to calculated significance levels. This option affects printed significance levels and the **print()** and **star()** options. Thus pwcrr, print(.05) sidak prints coefficients with Šidák-adjusted significance levels of 0.05 or less.

Remarks and examples

Remarks are presented under the following headings:

- **correlate**
- **pwcrr**
- **Video example**

**correlate**

Typing **correlate** by itself produces a correlation matrix for all variables in the dataset. If you specify the **varlist**, a correlation matrix for just those variables is displayed.
Example 1

We have state data on demographic characteristics of the population. To obtain a correlation matrix, we type

```
use https://www.stata-press.com/data/r16/census13
(1980 Census data by state)
correlate
(obs=50)
```

<table>
<thead>
<tr>
<th></th>
<th>state</th>
<th>brate</th>
<th>pop</th>
<th>medage</th>
<th>division</th>
<th>region</th>
<th>mrgrate</th>
</tr>
</thead>
<tbody>
<tr>
<td>state</td>
<td>1.0000</td>
<td>0.0208</td>
<td>-0.0540</td>
<td>-0.0624</td>
<td>-0.1345</td>
<td>-0.1339</td>
<td>0.0509</td>
</tr>
<tr>
<td>brate</td>
<td></td>
<td></td>
<td>-0.2830</td>
<td>-0.8800</td>
<td>0.6356</td>
<td>0.6086</td>
<td>0.0677</td>
</tr>
<tr>
<td>pop</td>
<td></td>
<td></td>
<td>1.0000</td>
<td>0.3294</td>
<td>-0.1081</td>
<td>-0.5207</td>
<td>0.2280</td>
</tr>
<tr>
<td>medage</td>
<td></td>
<td></td>
<td></td>
<td>1.0000</td>
<td>-0.5292</td>
<td>0.9688</td>
<td>0.5522</td>
</tr>
<tr>
<td>division</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td>-0.5292</td>
<td>1.0000</td>
<td>0.2490</td>
</tr>
<tr>
<td>region</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td>0.9688</td>
<td>0.2490</td>
<td>1.0000</td>
</tr>
<tr>
<td>mrgrate</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>dvcrate</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>medagesq</td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Because we did not specify the `wrap` option, Stata did its best to make the result readable by breaking the table into two parts.

To obtain the correlations between `mrgrate`, `dvcrate`, and `medage`, we type

```
correlate mrgrate dvcrate medage
(obs=50)
```

<table>
<thead>
<tr>
<th></th>
<th>mrgrate</th>
<th>dvcrate</th>
<th>medage</th>
</tr>
</thead>
<tbody>
<tr>
<td>mrgrate</td>
<td>1.0000</td>
<td></td>
<td></td>
</tr>
<tr>
<td>dvcrate</td>
<td>0.7700</td>
<td>1.0000</td>
<td></td>
</tr>
<tr>
<td>medage</td>
<td>-0.0177</td>
<td>-0.2229</td>
<td>1.0000</td>
</tr>
</tbody>
</table>

Example 2

The `pop` variable in example 1 represents the total population of the state. Thus, to obtain population-weighted correlations among `mrgrate`, `dvcrate`, and `medage`, we type

```
correlate mrgrate dvcrate medage [w=pop]
(analytic weights assumed)
(sum of wgt is 225,907,472)
(obs=50)
```

<table>
<thead>
<tr>
<th></th>
<th>mrgrate</th>
<th>dvcrate</th>
<th>medage</th>
</tr>
</thead>
<tbody>
<tr>
<td>mrgrate</td>
<td>1.0000</td>
<td></td>
<td></td>
</tr>
<tr>
<td>dvcrate</td>
<td>0.5854</td>
<td>1.0000</td>
<td></td>
</tr>
<tr>
<td>medage</td>
<td>-0.1316</td>
<td>-0.2833</td>
<td>1.0000</td>
</tr>
</tbody>
</table>

With the covariance option, `correlate` can be used to obtain covariance matrices, as well as correlation matrices, for both weighted and unweighted data.
Example 3

To obtain the matrix of covariances between \textit{mrgrate}, \textit{dvcrate}, and \textit{medage}, we type \texttt{correlate mrgrate dvcrate medage, covariance}:

\begin{verbatim}
. correlate mrgrate dvcrate medage, covariance (obs=50)

<table>
<thead>
<tr>
<th></th>
<th>mrgrate</th>
<th>dvcrate</th>
<th>medage</th>
</tr>
</thead>
<tbody>
<tr>
<td>mrgrate</td>
<td>0.000662</td>
<td></td>
<td></td>
</tr>
<tr>
<td>dvcrate</td>
<td>0.000063</td>
<td>1.0e-05</td>
<td></td>
</tr>
<tr>
<td>medage</td>
<td>-.000769</td>
<td>-.001191</td>
<td>2.86775</td>
</tr>
</tbody>
</table>
\end{verbatim}

We could have obtained the \textit{pop}-weighted covariance matrix by typing \texttt{correlate mrgrate dvcrate medage \[w=pop\], covariance}.

\texttt{pwcorr}

correlate calculates correlation coefficients by using casewise deletion; when you request correlations of variables \(x_1, x_2, \ldots, x_k\), any observation for which any of \(x_1, x_2, \ldots, x_k\) is missing is not used. Thus if \(x_3\) and \(x_4\) have no missing values, but \(x_2\) is missing for half the data, the correlation between \(x_3\) and \(x_4\) is calculated using only the half of the data for which \(x_2\) is not missing. Of course, you can obtain the correlation between \(x_3\) and \(x_4\) by using all the data by typing \texttt{correlate \(x_3\) \(x_4\)}.

\texttt{pwcorr} makes obtaining such pairwise correlation coefficients easier.

Example 4

Using \texttt{auto.dta}, we investigate the correlation between several of the variables.

\begin{verbatim}
. use https://www.stata-press.com/data/r16/auto1
(Automobile Models)
. pwcorr mpg price rep78 foreign, obs sig

<table>
<thead>
<tr>
<th></th>
<th>mpg</th>
<th>price</th>
<th>rep78</th>
<th>foreign</th>
</tr>
</thead>
<tbody>
<tr>
<td>mpg</td>
<td>1.0000</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>price</td>
<td>-0.4594</td>
<td>1.0000</td>
<td></td>
<td></td>
</tr>
<tr>
<td>rep78</td>
<td>0.3739</td>
<td>0.0066</td>
<td>1.0000</td>
<td></td>
</tr>
<tr>
<td>foreign</td>
<td>0.3613</td>
<td>0.0487</td>
<td>0.5922</td>
<td>1.0000</td>
</tr>
<tr>
<td></td>
<td>74</td>
<td>74</td>
<td>69</td>
<td>74</td>
</tr>
</tbody>
</table>
\end{verbatim}
The correlate command will report the correlation matrix of the data, but there are occasions when you need the matrix stored as a Stata matrix so that you can further manipulate it. You can obtain the matrix by typing

```
. matrix accum R = varlist, noconstant deviations
. matrix R = corr(R)
```

The first line places the cross-product matrix of the data in matrix R. The second line converts that to a correlation matrix. Also see [P] matrix define and [P] matrix accum.

### Video example

Pearson’s correlation coefficient in Stata

### Stored results

correlate stores the following in r():

**Scalars**
- r(N)    number of observations
- r(rho)  \( \rho \) (first and second variables)
- r(cov_12) covariance (covariance only)
- r(Var_1) variance of first variable (covariance only)
- r(Var_2) variance of second variable (covariance only)
- r(sum_w) sum of weights

**Matrices**
- r(C)    correlation or covariance matrix
`pwcorr` stores the following in `r()`:

Scalars
- `r(N)` number of observations (first and second variables)
- `r(rho)` $\rho$ (first and second variables)

Matrices
- `r(C)` pairwise correlation matrix
- `r(sig)` significance level of each correlation coefficient

Methods and formulas

For a discussion of correlation, see, for instance, Snedecor and Cochran (1989, 177–195); for an introductory explanation using Stata examples, see Acock (2018, 205–210).

According to Snedecor and Cochran (1989, 180), the term “co-relation” was first proposed by Galton (1888). The product-moment correlation coefficient is often called the Pearson product-moment correlation coefficient because Pearson (1896) and Pearson and Filon (1898) were partially responsible for popularizing its use. See Stigler (1986) for information on the history of correlation.

The estimate of the product-moment correlation coefficient, $\rho$, is

$$\hat{\rho} = \frac{\sum_{i=1}^{n} w_i (x_i - \bar{x})(y_i - \bar{y})}{\sqrt{\sum_{i=1}^{n} w_i (x_i - \bar{x})^2} \sqrt{\sum_{i=1}^{n} w_i (y_i - \bar{y})^2}}$$

where $w_i$ are the weights, if specified, or $w_i = 1$ if weights are not specified. $\bar{x} = (\sum w_i x_i) / (\sum w_i)$ is the mean of $x$, and $\bar{y}$ is similarly defined.

The unadjusted significance level is calculated by `pwcorr` as

$$p = 2 \times ttail(n-2, |\hat{\rho}| \sqrt{n-2} / \sqrt{1-\hat{\rho}^2})$$

Let $v$ be the number of variables specified so that $k = v(v-1)/2$ correlation coefficients are to be estimated. If `bonferroni` is specified, the adjusted significance level is $p' = \min(1, kp)$. If `sidak` is specified, $p' = \min\{1, 1-(1-p)^k\}$. In both cases, see Methods and formulas in [R] oneway for a more complete description of the logic behind these adjustments.
Carlo Emilio Bonferroni (1892–1960) was born in Bergamo, Italy, in 1892. Before enrolling in the mathematics department at the University of Turin, he studied conducting and the piano at the Music Conservatory of Turin. Bonferroni, like many men of his generation, fought in World War I, during which he was part of The Engineer Corps of the Italian Army.

After the war, Bonferroni was appointed as an assistant professor at the Polytechnic University of Turin. He taught geometry, mechanics, and analysis. In 1923, he moved to Bari and began teaching at the Economics Institute, where he got to teach financial mathematics, a topic that was of great interest to him. In 1933, Bonferroni moved to Florence, where he was chair of the mathematics department until his death in 1960.

Bonferroni’s interests had a large breadth. He published on actuarial mathematics, probability, statistics, analysis, geometry, and mechanics. His work on probability inequalities has been applied to simultaneous statistical inference. However, the application of Bonferroni’s theory to the construction of confidence intervals is the work of Olive Jean Dunn.

Olive Jean Dunn (1915–2008) was born in the United States in 1915. She obtained her bachelor’s degree in 1936, her master’s degree in 1951, and her PhD in 1956, all from the University of California in Los Angeles (UCLA). After spending one year as an assistant professor at Iowa State College, she returned to UCLA to serve in the biostatistics and preventive medicine and health departments. She remained at UCLA for the rest of her career. Dunn died in 2008.

Dunn is best known for her application of Bonferroni’s inequalities to construct corrections to confidence intervals for multiple comparisons. Although the literature refers to it as the Bonferroni correction, it is Dunn who developed the application we use today.

Dunn is also well known for her textbooks Basic Statistics: A Primer for the Biomedical Sciences, written in 1977 with later editions coauthored with Virginia A. Clark, and Applied Statistics: An Analysis of Variance and Regression, which was also coauthored with Clark.

In 1968, Dunn became a Fellow of the American Statistical Association. She also was a fellow of the American Public Health Association and the American Association for the Advancement of Science. In 1974, she was awarded the honor of UCLA Woman of Science.
Florence Nightingale David (1909–1993) was born in Ivington, England, to parents who were friends with Florence Nightingale, David’s namesake. She began her studies in statistics under the direction of Karl Pearson at University College London and continued her studies under the direction of Jerzy Neyman. After receiving her doctorate in statistics in 1938, David became a senior statistician for various departments within the British military. She developed statistical models to forecast the toll on life and infrastructure that would occur if a large city were bombed. In 1938, she also published her book *Tables of the Correlation Coefficient*, dealing with the distributions of correlation coefficients. After the war, she returned to University College London, serving as a lecturer until her promotion to professor in 1962. In 1967, David joined the University of California–Riverside, eventually becoming chair of the Department of Statistics. One of her most well-known works is the book *Games, Gods and Gambling: The Origins and History of Probability and Statistical Ideas from the Earliest Times to the Newtonian Era*, a history of statistics. David published over 100 papers on topics including combinatorics, symmetric functions, the history of statistics, and applications of statistics, including ecological diversity. She published under the name F. N. David to avoid revealing her gender in a male-dominated profession.

Karl Pearson (1857–1936) studied mathematics at Cambridge. He was professor of applied mathematics (1884–1911) and eugenics (1911–1933) at University College London. His publications include literary, historical, philosophical, and religious topics. Statistics became his main interest in the early 1890s after he learned about its application to biological problems. His work centered on distribution theory, the method of moments, correlation, and regression. Pearson introduced the chi-squared test and the terms coefficient of variation, contingency table, heteroskedastic, histogram, homoskedastic, kurtosis, mode, random sampling, random walk, skewness, standard deviation, and truncation. Despite many strong qualities, he also fell into prolonged disagreements with others, most notably, William Bateson and R. A. Fisher.

Zbynˇek ˇSid´ak (1933–1999) was a notable Czech statistician and probabilist. He worked on Markov chains, rank tests, multivariate distribution theory and multiple-comparison methods, and he served as the chief editor of *Applications of Mathematics*.

Title

cpoisson — Censored Poisson regression

Description

cpoisson fits a Poisson model of a count dependent variable with some censored values. The command can be used when the dependent variable is left-censored (has a lower limit), is right-censored (has an upper limit), or is interval-censored (has a lower and an upper limit).

Quick start

Censored Poisson regression of \( y \) on \( x \) without options \( ll() \) and \( ul() \), equivalent to Poisson regression
\[
cpoisson y x
\]
Add categorical variable \( a \) using factor-variable syntax, and specify censoring at an upper limit of 4
\[
cpoisson y x i.a, ul(4)
\]
Also specify a lower-censoring limit that varies across observations by using the variable \( lower \)
\[
cpoisson y x i.a, ul(4) ll(lower)
\]
Add offset variable \( v \), and report results as incidence-rate ratios
\[
cpoisson y x i.a, ul(4) ll(lower) offset(v) irr
\]
Constrain the coefficient for \( x \) to 2
\[
constraint define 1 \( x=2 \)
cpoisson y x i.a, ul(4) constraints(1)
\]

```

**Options**

```
noconstant; see [R] Estimation options.
```

```
ll((varname | #)) and ul((varname | #)) indicate the lower and upper limits for censoring, respectively. Observations with depvar <= ll() are left-censored; observations with depvar >= ul() are right-censored; and remaining observations are not censored. You do not have to specify the censoring values. If you specify ll, the lower limit is the minimum of depvar. If you specify ul, the upper limit is the maximum of depvar.
```
exposure(varname_e), offset(varname_o), constraints(constraints); see [R] Estimation options.

vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim, opg), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.

level(#) ; see [R] Estimation options.

irr reports estimated coefficients transformed to incidence-rate ratios, that is, $e^{\beta_i}$ rather than $\beta_i$. Standard errors and confidence intervals are similarly transformed. This option affects how results are displayed, not how they are estimated. irr may be specified at estimation or when replaying previously estimated results.

nocnsreport ; see [R] Estimation options.

display_options: noci, nopvalues, noomitted, vsquish, noemptycells, baselevels, allbaselevels, nobrlabel, fvwrap(#), fvwrapon(style), cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch; see [R] Estimation options.

maximize_options: difficult, technique(algorithm_spec), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#) , ltolerance(#), nrtolerance(#), nonrtolerance, and from(init_specs); see [R] Maximize. These options are seldom used.

The following options are available with cpoisson but are not shown in the dialog box: collinear, coeflegend; see [R] Estimation options.

Remarks and examples

Censored Poisson regression is a method for analyzing censored count data. One of the most common sources of censored count data is top coding, data that record only the value $x$ when $x$ or greater is observed. Not observing subjects for a sufficient period of time is another common cause.

Censored count data models have been studied by Terza (1985) and Brännäs (1992), among others. For an introduction to censored Poisson regression, see Cameron and Trivedi (2005, 2013) and Winkelmann (2008). Raciborski (2011) discusses a command for right-censored Poisson regression and presented Monte Carlo results indicating that the estimator performs well in finite samples. See Creel and Loomis (1990) and Gurmu and Trivedi (1996) for some examples of survey applications with top coding.

Censored data can be right-censored, left-censored, or interval-censored. Right-censoring occurs when we observe the covariates but only observe that the dependent variable is greater than or equal to an upper limit. Left-censoring occurs when we observe the covariates but only observe that the dependent variable is less than or equal to a lower limit.

When the dependent variable is censored, we must use estimation methods that account for this limitation. If we do not account for censoring when our data are censored, our estimates will not converge to the true values. More formally, failure to control for censoring when it exists leads to inconsistent parameter estimation.
Censored Poisson regression provides an alternative to standard Poisson regression that produces consistent estimates when the dependent variable is censored. If the dependent variable is not censored, standard Poisson regression may be more appropriate; see \texttt{[R] poisson}.

Censoring differs from truncation. For censored observations, we observe complete covariate information but only a censored value of the dependent variable. When the data are truncated, we do not observe either the dependent variable or the covariates. Different research designs can give rise to censored data or truncated data.

For example, consider a study about the use of national parks. We could ask a random sample of people in the population how many national parks each has visited in the past year. Suppose we decide to record three for those individuals who visited three or more parks. In this case, individuals who visit four or more parks will have observations that are right-censored at three visits. Now suppose that instead of sending out surveys to a random sample from the population, we ask questions only of individuals who come to parks. We will have no information about individuals who do not visit at least one park, and the data will be truncated at zero visits.

Censoring and truncation are different statistical phenomenon and require different analytic methods. See \texttt{[R] tpoisson} for information on truncated Poisson regression.

\textbf{Example 1: Poisson model with top-coded data}

Imagine that we have collected survey data about how many times a household has visited the ABC amusement park from a random sample of households in the state in which ABC is located. Respondents were asked about the number of visits to the park in the last year (trips), their income (income), and the number of children in the household (children). The number of trips recorded in trips was top coded at “three or more” visits.

We model right-censored trips as a function of income and children.

\begin{verbatim}
. use https://www.stata-press.com/data/r16/trips
(Visits to the ABC amusement park)
. cpoisson trips income children, ul(3)
initial: log likelihood = -620.68749
rescale: log likelihood = -620.68749
Iteration 0: log likelihood = -620.68749
Iteration 1: log likelihood = -600.96763
Iteration 2: log likelihood = -600.78416
Iteration 3: log likelihood = -600.78415
Censored Poisson regression
Number of obs = 500
Uncensored = 278
Limits: lower = 0 Left-censored = 0
upper = 3 Right-censored = 222
LR chi2(2) = 49.29
Log likelihood = -600.78415 Prob > chi2 = 0.000

Coef. Std. Err. z P>|z| [95% Conf. Interval]
income .0740477 .0137653 5.38 0.000 .0470683 .1010272
children .1346922 .028617 4.71 0.000 .078604 .1907805
_cons .0033918 .1455473 0.02 0.981 -.2818756 .2886592
\end{verbatim}

Both income and the number of children have positive effects on the expected number of trips to the amusement park. The estimated parameters provide the sign, but not the magnitude of the effect, because the model is nonlinear; see \texttt{[R] cpoisson postestimation}.
cpoisson stores the following in `e()`:  

Scalars

- `e(N)`: number of observations
- `e(N_unc)`: number of uncensored observations
- `e(N_lc)`: number of left-censored observations
- `e(N_rc)`: number of right-censored observations
- `e(k)`: number of parameters
- `e(k_eq)`: number of equations in `e(b)`
- `e(k_eq_model)`: number of equations in overall model test
- `e(dv)`: number of dependent variables
- `e(ll)`: log likelihood
- `e(ll_0)`: log likelihood, constant-only model
- `e(N_clust)`: number of clusters
- `e(chi2)`: $\chi^2$ value
- `e(p)`: p-value for model test
- `e(rank)`: rank of `e(V)`
- `e(ic)`: number of iterations
- `e(rc)`: return code
- `e(converged)`: 1 if converged, 0 otherwise

Macros

- `e(cmd)`: cpoisson
- `e(cmdline)`: command as typed
- `e(depvar)`: name of dependent variable
- `e(ll_opt)`: contents of `ll()`, if specified
- `e(u_opt)`: contents of `ul()`, if specified
- `e(wtype)`: weight type
- `e(wexp)`: weight expression
- `e(title)`: title in estimation output
- `e(clustvar)`: name of cluster variable
- `e(offset)`: linear offset variable
- `e(chi2type)`: Wald or LR; type of model $\chi^2$ test
- `e(vce)`: vcetype specified in `vce()`
- `e(vcetype)`: title used to label Std. Err.
- `e(opt)`: type of optimization
- `e(which)`: max or min; whether optimizer is to perform maximization or minimization
- `e(ml_method)`: type of ml method
- `e(user)`: name of likelihood-evaluator program
- `e(technique)`: maximization technique
- `e(properties)`: b V
- `e(predict)`: program used to implement predict
- `e(marginsok)`: predictions allowed by margins
- `e(marginsnotok)`: predictions disallowed by margins
- `e(asbalanced)`: factor variables fvset as asbalanced
- `e(asobserved)`: factor variables fvset as asobserved

Matrices

- `e(b)`: coefficient vector
- `e(Cns)`: constraints matrix
- `e(iter)`: iteration log (up to 20 iterations)
- `e(gradient)`: gradient vector
- `e(V)`: variance–covariance matrix of the estimators
- `e(V_modelbase)`: model-based variance

Functions

- `e(sample)`: marks estimation sample
Methods and formulas

We let $y_j$ be the observed, interval-censored dependent variable for observation $j$ and let $y_j^*$ be the uncensored, latent dependent variable. When $y_j$ is not censored, it is the same as $y_j^*$. When $y_j$ is censored, only the censoring point is observed. Letting $L_j$ denote the left-censoring point (lower limit) and $U_j$ denote the right-censoring point (upper limit), we see that

$$y_j = \begin{cases} 
L_j & \text{if } y_j^* \leq L_j \\
y_j^* & \text{if } L_j < y_j^* < U_j \\
U_j & \text{if } y_j^* \geq U_j 
\end{cases}$$

Note that $L_j$ and $U_j$ may vary over the observations so that individuals may have different left- and right-censoring points.

Although \texttt{cpoisson} may be used with data that are left-censored, right-censored, or censored from both sides (which is known as interval-censored), we present the formulas for the interval-censored case because it applies to all three cases.

Let $f(y_j|x_j)$ denote the probability mass function of the Poisson distribution. Defining $\xi_j = x_j\beta + \text{offset}_j$ implies that the conditional mean of the uncensored variable is given by $E(y_j^*|x_j) = \exp(\xi_j)$. The log likelihood for observation $j$ is given by

$$l_j = w_j \left[ d_j \{-\exp(\xi_j) + y_j \xi_j - \ln(y_j !)\} + (1 - d_j) \ln \left( 1 - \sum_{k=0}^{U_j-1} f(k|x_j) + \sum_{k=0}^{L_j} f(k|x_j) \right) \right]$$

where $d_j$ equals 1 when $L_j < y_j^* < U_j$ and equals 0 when $y_j^* \leq L_j$ or $y_j^* \geq U_j$. The log likelihood is thus

$$\ln L = \sum_{j=1}^{N} l_j$$

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using \texttt{vce(robust)} and \texttt{vce(cluster clustvar)}, respectively. See [P] \texttt{_robust}, particularly \textit{Maximum likelihood estimators} and \textit{Methods and formulas}.

\texttt{cpoisson} also supports estimation with survey data. For details on variance–covariance estimates with survey data, see [SVY] \textit{Variance estimation}.

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

Options for predict

n, the default, calculates the predicted number of events, which is $\exp(x_j \beta)$ if neither `offset()` nor `exposure()` was specified when the model was fit; $\exp(x_j \beta + \text{offset}_j)$ if `offset()` was specified; or $\exp(x_j \beta) \times \text{exposure}_j$ if `exposure()` was specified.

ir calculates the incidence rate $\exp(x_j \beta)$, which is the predicted number of events when exposure is 1. This is equivalent to specifying both the n and the `nooffset` options.

cm calculates the conditional mean,

$$E(y_j \mid \Omega_j) = \frac{E(y_j)}{\Pr(\Omega_j)}$$
where $\Omega_j$ represents $y_j > L_j$ for a left-censored model, $y_j < U_j$ for a right-censored model, and $L_j < y_j < U_j$ for an interval-censored model. $L_j$ is the left-censoring point found in e(llopt), and $U_j$ is the right-censoring point found in e(ulopt).

\(\text{pr}(n)\) calculates the probability $Pr(y_j = n)$, where \(n\) is a nonnegative integer that may be specified as a number or a variable.

\(\text{pr}(a, b)\) calculates the probability $Pr(a \leq y_j \leq b)$, where \(a\) and \(b\) are nonnegative integers that may be specified as numbers or variables;

- \(b\) missing ($b \geq .$) means $+\infty$;
- \(\text{pr}(20, .)\) calculates $Pr(y_j \geq 20)$;
- \(\text{pr}(20, b)\) calculates $Pr(y_j \geq 20)$ in observations for which $b \geq .$ and calculates $Pr(20 \leq y_j \leq b)$ elsewhere.
- \(\text{pr}(., b)\) produces a syntax error. A missing value in an observation of the variable \(a\) causes a missing value in that observation for \(\text{pr}(a, b)\).

\(\text{cpr}(n)\) calculates the conditional probability $Pr(y_j = n | \Omega_j)$, where $\Omega_j$ represents $y_j > L_j$ for a left-censored model, $y_j < U_j$ for a right-censored model, and $L_j < y_j < U_j$ for an interval-censored model. $L_j$ is the left-censoring point found in e(llopt), and $U_j$ is the right-censoring point found in e(ulopt). \(n\) is an integer in the noncensored range.

\(\text{cpr}(a, b)\) calculates the conditional probability $Pr(a \leq y_j \leq b | \Omega_j)$, where $\Omega_j$ represents $y_j > L_j$ for a left-censored model, $y_j < U_j$ for a right-censored model, and $L_j < y_j < U_j$ for an interval-censored model. $L_j$ is the left-censoring point found in e(llopt), and $U_j$ is the right-censoring point found in e(ulopt). \(a\) and \(b\) must fall in the noncensored range if they are not missing. A missing value in an observation of the variable \(a\) causes a missing value in that observation for \(\text{cpr}(a, b)\).

\(\text{xb}\) calculates the linear prediction, which is $x_j \beta$ if neither offset() nor exposure() was specified when the model was fit; $x_j \beta + \text{offset}_j$ if offset() was specified; or $x_j \beta + \ln(\text{exposure}_j)$ if exposure() was specified; see nooffset below.

\(\text{stdp}\) calculates the standard error of the linear prediction.

\(\text{score}\) calculates the equation-level score, $\partial \ln L / \partial (x_j \beta)$.

\(\text{nooffset}\) is relevant only if you specified offset() or exposure() when you fit the model. It modifies the calculations made by predict so that they ignore the offset or exposure variable; the linear prediction is treated as $x_j \beta$ rather than as $x_j \beta + \text{offset}_j$ or $x_j \beta + \ln(\text{exposure}_j)$. Specifying predict ..., nooffset is equivalent to specifying predict ..., ir.
margins

Description for margins

margins estimates margins of response for numbers of events, incidence rates, conditional means, probabilities, and linear predictions.

Menu for margins

Statistics > Postestimation

Syntax for margins

          | or \( Pr(y_j = n \mid L_j < y_j < U_j) \) |
| cpr(a,b)  | conditional probability \( Pr(a \leq y_j \leq b \mid y_j > L_j) \), \( Pr(a \leq y_j \leq b \mid y_j < U_j) \),
          | or \( Pr(a \leq y_j \leq b \mid L_j < y_j < U_j) \) |
| xb        | linear prediction |
| stdp      | not allowed with margins |
| score     | not allowed with margins |

Statistics not allowed with margins are functions of stochastic quantities other than \( e(b) \).
For the full syntax, see [R] margins.

Remarks and examples

Example 1: Obtaining marginal effects

Continuing with example 1 of [R] cpoisson, we estimate the effect of having another child on the uncensored number of trips to amusement parks. We use margins to estimate the average number of trips when each household has its actual number of children and when each household has one additional child. We include the post option so that we can use the results in subsequent commands.

```
. use https://www.stata-press.com/data/r16/trips
   (Visits to the ABC amusement park)
. cpoisson trips income children, ul(3)
   (output omitted)
```
An average of 2.53 trips are taken when each household has its observed number of children. If each household has one additional child, then the average number of trips increases to 2.89.

We now use `contrast` to compute the effect of having an additional child. The Wald test, in this case, is superfluous, so we suppress it with the `nowald` option.

Adding one child to each household increases the average by 0.36 trips.

---

### Methods and formulas

Using the notation under *Methods and formulas* of [R] `cpoisson`, we see that the equation-level scores are given by

\[
\text{score}(x\beta)_j = d_j \{- \exp(\xi_j) + y_j \} \\
+ (1 - d_j) \frac{\Psi_1(L_j|x_j) - \Psi_1(U_j - 1|x_j)}{1 - F(U_j - 1|x_j) + F(L_j|x_j)}
\]

where \( \Psi_1(C) = \sum_{k=0}^{C} f(k|x_j)\{k - \exp(\xi_j)\} \); \( f(y_j|x_j) \) and \( F(y_j|x_j) \) denote the probability mass function and the cumulative distribution function of the Poisson, respectively. \( L_j \) is the left-censoring point found in `e(llopt)`, and \( U_j \) is the right-censoring point found in `e(ulopt)`.

**cumul — Cumulative distribution**

**Description**

cumul creates *newvar*, defined as the empirical cumulative distribution function of *varname*.

**Quick start**

Create new variable *ecd* containing the empirical cumulative distribution of *v*

```
cumul v, gen(ecd)
```

Use frequency as the unit for *v* to generate *ecdf*

```
cumul v, gen(ecdf) freq
```

Give equal values of *v* the same value in generated *ecde*

```
cumul v, gen(ecde) equal
```

Graph the empirical cumulative distribution of *v*

```
line ecd v, sort
```

Graph the distributions of variables *v1* and *v2*

```
cumul v1, gen(ecd1) equal
cumul v2, gen(ecd2) equal
stack ecd1 v1 ecd2 v2, into(ecd v) wide clear
line ecd1 ecd2 v, sort
```

cumul  varname  [  if  ]  [  in  ]  [  weight  ],  \_generate(newvar)  [  options  ]

options  Description

Main
*generate(newvar)  create variable newvar
freq  use frequency units for cumulative
equal  generate equal cumulatives for tied values

*generate(newvar)  is  required.
by  is  allowed;  see  [D]  by.
fweights  and  aweights  are  allowed;  see  [U]  11.1.6 weight.

Options

Remarks and examples

Example 1

cumul  is  most  often  used  with  graph  to  graph  the  empirical  cumulative  distribution.  For  instance, we  have  data  on  the  median  family  income  of  957  U.S.  cities:

.  use  https://www.stata-press.com/data/r16/hsng  
(1980  Census  housing  data)
.  cumul  faminc,  gen(cum)
.  sort  cum
.  line  cum  faminc,  ylab(,  grid)  ytitle("")  xlab(,  grid)
>  title("Cumulative  of  median  family  income")
>  subtitle("1980  Census,  957  U.S.  Cities")
It would have been enough to type `line cum faminc`, but we wanted to make the graph look better; see [G-2] `graph twoway line`.

If we had wanted a weighted cumulative, we would have typed `cumul faminc [w=pop]` at the first step.

### Example 2

To graph two (or more) cumulatives on the same graph, use `cumul` and `stack`; see [D] `stack`. For instance, we have data on the average January and July temperatures of 956 U.S. cities:

```plaintext
use https://www.stata-press.com/data/r16/citytemp, clear
(City Temperature Data)
.cumul tempjan, gen(cjan)
.cumul tempjuly, gen(cjuly)
.stack cjan tempjan cjuly tempjuly, into(c temp) wide clear
.line cjan cjuly temp, sort ylab(, grid) ytitle("") xlab(, grid)
> xtitle("Temperature (F)"
> title("Cumulatives: " "Average January and July Temperatures")
> subtitle("956 U.S. Cities")
```
As before, it would have been enough to type `line cjan cjuly temp, sort`. See `[D] stack` for an explanation of how the `stack` command works.

Technical note

According to Beniger and Robyn (1978), Fourier (1821) published the first graph of a cumulative frequency distribution, which was later given the name “ogive” by Galton (1875).

Jean Baptiste Joseph Fourier (1768–1830) was born in Auxerre in France. As a young man, Fourier became entangled in the complications of the French Revolution. As a result, he was arrested and put into prison, where he feared he might meet his end at the guillotine. When he was not in prison, he was studying, researching, and teaching mathematics. Later, he served Napoleon’s army in Egypt as a scientific adviser. Upon his return to France in 1801, he was appointed Prefect of the Department of Isère. While prefect, Fourier worked on the mathematical basis of the theory of heat, which is based on what are now called Fourier series. This work was published in 1822, despite the skepticism of Lagrange, Laplace, Legendre, and others—who found the work lacking in generality and even rigor—and disagreements of both priority and substance with Biot and Poisson.

Acknowledgment

The `equal` option was added by Nicholas J. Cox of the Department of Geography at Durham University, UK, and coeditor of the `Stata Journal` and author of `Speaking Stata Graphics`.

Description

cusum graphs the cumulative sum (cusum) of a binary (0/1) variable, \( yvar \), against a (usually) continuous variable, \( xvar \).

Quick start

Cusum statistics for binary variable \( y \) and graph of cumulative sum against values of \( x \)

cusum y x

Also generate \( cs \) to store the cumulative sum

cusum y x, generate(cs)

Set the seed first for reproducible results

set seed 87534690

cusum y x, generate(cs)

Cumulative sum of \( y \) against a variable containing fitted values \( yhat \)

cusum y x, yfit(yhat)

Menu

Statistics > Other > Quality control > Cusum plots and tests for binary variables
### Syntax

```
cusum yvar xvar [if] [in] [ , options]
```

</tbody>
</table>

### Options

- **Main**
  - `generate(newvar)` saves the cusum in `newvar`.
  - `yfit(fitvar)` calculates a cusum against `fitvar`, that is, the running sums of the “residuals” `fitvar` minus `yvar`. Typically, `fitvar` is the predicted probability of a positive outcome obtained from a logistic regression analysis.
  - `nograph` suppresses the plot.
  - `nocalc` suppresses calculation of the cusum test statistics.

- **Cusum plot**
  - `connect_options` affect the rendition of the plotted line; see [G-3] `connect_options`.

- **Add plots**
  - `addplot(plot)` provides a way to add other plots to the generated graph. See [G-3] `addplot_option`.

- **Y axis, X axis, Titles, Legend, Overall**
  - `twoway_options` are any of the options documented in [G-3] `twoway_options`, excluding `by()`. These include options for titling the graph (see [G-3] `title_options`) and for saving the graph to disk (see [G-3] `saving_option`).
Remarks and examples

The cusum is the running sum of the proportion of ones in the sample, a constant number, minus \( yvar \),

\[ c_j = \sum_{k=1}^{j} f - yvar(k), \quad 1 \leq j \leq N \]

where \( f = (\sum yvar) / N \) and \( yvar(k) \) refers to the corresponding value of \( yvar \) when \( xvar \) is placed in ascending order: \( xvar(k+1) \geq xvar(k) \). Tied values of \( xvar \) are broken at random. If you want them broken the same way in two runs, you must set the random-number seed to the same value before giving the \texttt{cusum} command; see \texttt{[R] set seed}.

A U-shaped or inverted U-shaped cusum indicates, respectively, a negative or a positive trend of \( yvar \) with \( xvar \). A sinusoidal shape is evidence of a nonmonotonic (for example, quadratic) trend. \texttt{cusum} displays the maximum absolute cusum for monotonic and nonmonotonic trends of \( yvar \) on \( xvar \). These are nonparametric tests of departure from randomness of \( yvar \) with respect to \( xvar \). Approximate values for the tests are given.

\section*{Example 1}

For the automobile dataset, \texttt{auto.dta}, we wish to investigate the relationship between \texttt{foreign} (0 = domestic, 1 = foreign) and car weight as follows:

\begin{verbatim}
. use https://www.stata-press.com/data/r16/auto
(1978 Automobile Data)
. cusum foreign weight

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Pr(1)</th>
<th>CusumL</th>
<th>zL</th>
<th>Pr&gt;zL</th>
<th>CusumQ</th>
<th>zQ</th>
<th>Pr&gt;zQ</th>
</tr>
</thead>
<tbody>
<tr>
<td>foreign</td>
<td>74</td>
<td>0.2973</td>
<td>10.30</td>
<td>3.963</td>
<td>0.000</td>
<td>2.92</td>
<td>0.064</td>
<td>0.475</td>
</tr>
</tbody>
</table>
\end{verbatim}

The resulting plot, which is U-shaped, suggests a negative monotonic relationship. The trend is confirmed by a highly significant linear cusum statistic, labeled \texttt{CusumL} in the output above.

Some 29.73\% of the cars are foreign (coded 1). The proportion of foreign cars diminishes with increasing weight. The domestic cars are crudely heavier than the foreign ones. We could have discovered that by typing \texttt{table foreign, stats(mean weight)}, but such an approach does not
give the full picture of the relationship. The quadratic cusum (CusumQ) is not significant, so we do not suspect any tendency for the very heavy cars to be foreign rather than domestic. A slightly enhanced version of the plot shows the preponderance of domestic (coded 0) cars at the heavy end of the weight axis:

```
. label values foreign
. cusum foreign weight, s(none) recast(scatter) mlabel(foreign) mlabp(0)
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Pr(1)</th>
<th>CusumL</th>
<th>zL</th>
<th>Pr&gt;zL</th>
<th>CusumQ</th>
<th>zQ</th>
<th>Pr&gt;zQ</th>
</tr>
</thead>
<tbody>
<tr>
<td>foreign</td>
<td>74</td>
<td>0.2973</td>
<td>10.30</td>
<td>3.963</td>
<td>0.000</td>
<td>3.32</td>
<td>0.469</td>
<td>0.320</td>
</tr>
</tbody>
</table>

The example is, of course, artificial, because we would not really try to model the probability of a car being foreign given its weight.

Stored results

cusum stores the following in r():

Scalars

- r(N) number of observations
- r(prop1) proportion of positive outcomes
- r(cusuml) cusum
- r(zl) test (linear)
- r(N) number of observations
- r(P_zl) p-value for test (linear)
- r(cusumq) quadratic cusum
- r(zq) test (quadratic)
- r(P_zq) p-value for test (quadratic)

Acknowledgment

cusum was written by Patrick Royston of the MRC Clinical Trials Unit, London, and coauthor of the Stata Press book *Flexible Parametric Survival Analysis Using Stata: Beyond the Cox Model.*

**Title**

**db — Launch dialog**

**Description**

`db` opens the dialog box for the specified command. Programmers who wish to allow the launching of dialogs from a help file, see [P smcl](#) for information on the `dialog` SMCL directive.

`set maxdb` sets the maximum number of dialog boxes whose contents are remembered from one invocation to the next during a session. The default value of `maxdb` is 50.

**Syntax**

*Syntax for db*

```stata
    db commandname
```

*For programmers*

```stata
    db commandname [ , message(string) debug dryrun]
```

*Set system parameter*

```stata
    set maxdb # [ , permanently]
```

where `#` must be between 5 and 1,000.

**Options**

`message(string)` specifies that `string` be passed to the dialog box, where it can be referred to from the `__MESSAGE STRING` property.

`debug` specifies that the underlying dialog box be loaded with debug messaging turned on.

`dryrun` specifies that, rather than launching the dialog, `db` show the commands it would issue to launch the dialog.

`permanently` specifies that, in addition to making the change right now, the `maxdb` setting be remembered and become the default setting when you invoke Stata.

**Remarks and examples**

The usual way to launch a dialog is to open the Data, Graphics, or Statistics menu and to make your selection from there. When you know the name of the command that you want to run, however, `db` provides a way to invoke the dialog from the command line.

`db` follows the same abbreviation rules that Stata's command-line interface follows. So, to launch the dialog for `regress`, you can type

```
    . db regress
```

435
or

    . db reg

Say that you use the dialog box for `regress`, either by selecting

    Statistics > Linear models and related > Linear regression

or by typing

    . db regress

You fit a regression.

Much later during the session, you return to the `regress` dialog box. It will have the contents as you left them if 1) you have not typed `clear all` between the first and second invocations; 2) you have not typed `discard` between the two invocations; and 3) you have not used more than 50 different dialog boxes—regardless of how many times you have used each—between the first and second invocations of `regress`. If you use 51 or more, the contents of the `regress` dialog box will be forgotten.

`set maxdb` determines how many different dialog boxes are remembered. A dialog box takes, on average, about 20 KB of memory, so the 50 default corresponds to allowing dialog boxes to consume about 1 MB of memory.

Description

symplot graphs a symmetry plot of \textit{varname}.
quantile plots the ordered values of \textit{varname} against the quantiles of a uniform distribution.
qqplot plots the quantiles of \textit{varname}_1 against the quantiles of \textit{varname}_2 (Q–Q plot).
qnorm plots the quantiles of \textit{varname} against the quantiles of the normal distribution (Q–Q plot).
pnorm graphs a standardized normal probability plot (P–P plot).
qchi plots the quantiles of \textit{varname} against the quantiles of a $\chi^2$ distribution (Q–Q plot).
pchi graphs a $\chi^2$ probability plot (P–P plot).

See \texttt{[R] regress postestimation diagnostic plots} for regression diagnostic plots and \texttt{[R] logistic postestimation} for logistic regression diagnostic plots.

Quick start

Symmetry plot for \texttt{v1}
\begin{verbatim}
symplot v1
\end{verbatim}
Change marker color and size
\begin{verbatim}
symplot v1, mcolor(red) msize(large)
\end{verbatim}
Plot ordered values of \texttt{v1} against quantiles of the uniform distribution
\begin{verbatim}
quantile v1
\end{verbatim}
As above, but only for observations with \texttt{v2} greater than 5
\begin{verbatim}
quantile v1 if v2 > 5
\end{verbatim}
Plot quantiles of \texttt{v1} against quantiles of \texttt{v2}
\begin{verbatim}
qqplot v1 v2
\end{verbatim}
Change thickness of the reference line
\begin{verbatim}
qqplot v1 v2, rlopts(lwidth(thick))
\end{verbatim}
Plot quantiles of \texttt{v1} against quantiles of the normal distribution
\begin{verbatim}
qnorm v1
\end{verbatim}
Add grid lines
\begin{verbatim}
qnorm v1, grid
\end{verbatim}
Standardized normal probability plot for v1
\[ \text{pnorm} \ v1 \]
Change labels on the x and y axes
\[ \text{pnorm} \ v1, \ xlab(0(0.1)1) \ ylab(0(0.1)1) \]
Plot quantiles of v1 against quantiles of the $\chi^2_1$ distribution
\[ \text{qchi} \ v1 \]
As above, but comparing with quantiles of the $\chi^2_2$ distribution
\[ \text{qchi} \ v1, \ df(2) \]
$\chi^2$ probability plot for v1
\[ \text{pchi} \ v1 \]
Add “$\chi^2(1)$ P-P plot” to graph
\[ \text{pchi} \ v1, \ title("{\&chi}{sup:2}(1) P-P plot") \]

Options for symplot, quantile, and qqplot

Plot
marker_options    affect the rendition of markers drawn at the plotted points, including their shape, size, color, and outline; see [G-3] marker_options.

marker_label_options    specify if and how the markers are to be labeled; see [G-3] marker_label_options.

Reference line
rlopts(cline_options)    affect the rendition of the reference line; see [G-3] cline_options.
Add plots

`addplot(plot)` provides a way to add other plots to the generated graph; see [G-3] `addplot_option`.

Y axis, X axis, Titles, Legend, Overall

twoway_options are any of the options documented in [G-3] `twoway_options`, excluding `by()`. These include options for titling the graph (see [G-3] `title_options`) and for saving the graph to disk (see [G-3] `saving_option`).

Options for qnorm and pnorm

Main

grid adds grid lines at the 0.05, 0.10, 0.25, 0.50, 0.75, 0.90, and 0.95 quantiles when specified with `qnorm`. With `pnorm`, grid is equivalent to `yline(.25,.5,.75) xline(.25,.5,.75)`.

Plot

marker_options affect the rendition of markers drawn at the plotted points, including their shape, size, color, and outline; see [G-3] `marker_options`.

marker_label_options specify if and how the markers are to be labeled; see [G-3] `marker_label_options`.

Reference line

rlopts(cline_options) affect the rendition of the reference line; see [G-3] `cline_options`.

Options for qchi and pchi

Main

g grid adds grid lines at the 0.05, 0.10, 0.25, 0.50, 0.75, 0.90, and .95 quantiles when specified with `qchi`. With `pchi`, grid is equivalent to `yline(.25,.5,.75) xline(.25,.5,.75)`.

df(#) specifies the degrees of freedom of the $\chi^2$ distribution. The default is `df(1)`.

Plot

marker_options affect the rendition of markers drawn at the plotted points, including their shape, size, color, and outline; see [G-3] `marker_options`.

marker_label_options specify if and how the markers are to be labeled; see [G-3] `marker_label_options`. 
Reference line
\texttt{rlopts(cline\_options)} affect the rendition of the reference line; see [G-3] \texttt{cline\_options}.

Add plots
\texttt{addplot(\textit{plot})} provides a way to add other plots to the generated graph; see [G-3] \texttt{addplot\_option}.

\texttt{twoway\_options} are any of the options documented in [G-3] \texttt{twoway\_options}, excluding \texttt{by()}. These include options for titling the graph (see [G-3] \texttt{title\_options}) and for saving the graph to disk (see [G-3] \texttt{saving\_option}).

Remarks and examples

Remarks are presented under the following headings:

\begin{itemize}
  \item \texttt{symplot}
  \item \texttt{quantile}
  \item \texttt{qqplot}
  \item \texttt{qnorm}
  \item \texttt{pnorm}
  \item \texttt{qchi}
  \item \texttt{pchi}
\end{itemize}

\textbf{symplot}

Example 1

We have data on 74 automobiles. To make a symmetry plot of the variable \texttt{price}, we type

\begin{verbatim}
. use https://www.stata-press.com/data/r16/auto
(1978 Automobile Data)
. symplot price
\end{verbatim}
All points would lie along the reference line (defined as $y = x$) if car prices were symmetrically distributed. The points in this plot lie above the reference line, indicating that the distribution of car prices is skewed to the right—the most expensive cars are far more expensive than the least expensive cars are inexpensive.

The logic works as follows: a variable, $z$, is distributed symmetrically if

$$\text{median} - z(i) = z(N+1-i) - \text{median}$$

where $z(i)$ indicates the $i$th-order statistic of $z$. Symplot graphs $y_i = \text{median} - z(i)$ versus $x_i = z(N+1-i) - \text{median}$.

For instance, consider the largest and smallest values of price in the example above. The most expensive car costs $15,906 and the least expensive, $3,291. Let’s compare these two cars with the typical car in the data and see how much more it costs to buy the most expensive car, and compare that with how much less it costs to buy the least expensive car. If the automobile price distribution is symmetric, the price differences would be the same.

Before we can make this comparison, we must agree on a definition for the word “typical”. Let’s agree that “typical” means median. The price of the median car is $5,006.50, so the most expensive car costs $10,899.50 more than the median car, and the least expensive car costs $1,715.50 less than the median car. We now have one piece of evidence that the car price distribution is not symmetric. We can repeat the experiment for the second-most-expensive car and the second-least-expensive car. We find that the second-most-expensive car costs $9,494.50 more than the median car, and the second-least-expensive car costs $1,707.50 less than the median car. We now have more evidence. We can continue doing this with the third most expensive and the third least expensive, and so on.

Once we have all of these numbers, we want to compare each pair and ask how similar, on average, they are. The easiest way to do that is to plot all the pairs.
Quantile

Example 2

We have data on the prices of 74 automobiles. To make a quantile plot of price, we type

```
. use https://www.stata-press.com/data/r16/auto, clear
(1978 Automobile Data)
. quantile price, rlopts(clpattern(dash))
```

We changed the pattern of the reference line by specifying `rlopts(clpattern(dash))`.

In a quantile plot, each value of the variable is plotted against the fraction of the data that have values less than that fraction. The diagonal line is a reference line. If automobile prices were rectangularly distributed, all the data would be plotted along the line. Because all the points are below the reference line, we know that the price distribution is skewed right.

QQplot

Example 3

We have data on the weight and country of manufacture of 74 automobiles. We wish to compare the distributions of weights for domestic and foreign automobiles:

```
. use https://www.stata-press.com/data/r16/auto
(1978 Automobile Data)
. generate weightd=weight if !foreign
(22 missing values generated)
. generate weightf=weight if foreign
(52 missing values generated)
. qqplot weightd weightf
```
qnorm

Example 4

Continuing with our price data on 74 automobiles, we now wish to compare the distribution of price with the normal distribution:

```
. qnorm price, grid ylabel(, angle(horizontal) axis(1))
> ylabel(, angle(horizontal) axis(2))
```

The result shows that the distributions are different.
Technical note

The idea behind qnorm is recommended strongly by Miller (1997): he calls it probit plotting. His recommendations from much practical experience should interest many users. “My recommendation for detecting nonnormality is probit plotting” (Miller 1997, 10). “If a deviation from normality cannot be spotted by eye on probit paper, it is not worth worrying about. I never use the Kolmogorov–Smirnov test (or one of its cousins) or the \( \chi^2 \) test as a preliminary test of normality. They do not tell you how the sample is differing from normality, and I have a feeling they are more likely to detect irregularities in the middle of the distribution than in the tails” (Miller 1997, 13–14).

Example 5

Quantile–normal plots emphasize the tails of the distribution. Normal probability plots put the focus on the center of the distribution:

```
    . pnorm price, grid
```

Example 6

Suppose that we want to examine the distribution of the sum of squares of price and mpg, standardized for their variances.

```
    . egen c1 = std(price)
    . egen c2 = std(mpg)
    . generate ch = c1^2 + c2^2
    . qchi ch, df(2) grid ylabel(, alt axis(2)) xlabel(, alt axis(2))
```
The quadratic form is clearly not $\chi^2$ with 2 degrees of freedom.

Example 7

We can focus on the center of the distribution by doing a probability plot:

```
pchi ch, df(2) grid
```
Methods and formulas

Let \( x_1, x_2, \ldots, x_N \) be the data sorted in ascending order.

If a continuous variable, \( x \), has a cumulative distribution function \( F(x) = P(X \leq x) = p \), the quantiles \( x_{p_i} \) are such that \( F(x_{p_i}) = p_i \). For example, if \( p_i = 0.5 \), then \( x_{0.5} \) is the median. When we plot data, the probabilities, \( p_i \), are often referred to as plotting positions. There are many different conventions for choice of plotting positions, given \( x_1 \leq \cdots \leq x_N \). Most belong to the family \((i - a)/(N - 2a + 1) \). \( a = 0.5 \) (suggested by Hazen) and \( a = 0 \) (suggested by Weibull) are popular choices.

For a wider discussion of the calculation of plotting positions, see Cox (2002).

- **symplot** plots median – \( x_i \) versus \( x_{N+1-i} \) – median.
- **quantile** plots \( x_i \) versus \((i - 0.5)/N \) (the Hazen position).
- **qnorm** plots \( x_i \) against \( q_i \times \hat{\sigma} + \hat{\mu} \), where \( q_i = \Phi^{-1}(p_i) \), \( \Phi \) is the cumulative normal distribution, \( p_i = i/(N + 1) \) (the Weibull position), \( \hat{\sigma} \) is the standard deviation, and \( \hat{\mu} \) is the mean of the data.
- **pnorm** plots \( \Phi\left\{\left( x_i - \hat{\mu}\right)/\hat{\sigma}\right\} \) versus \( p_i = i/(N + 1) \), where \( \hat{\mu} \) is the mean of the data and \( \hat{\sigma} \) is the standard deviation.

- **qchi** and **pchii** are similar to **qnorm** and **pnorm**; the cumulative \( \chi^2 \) distribution is used in place of the cumulative normal distribution.

- **qqplot** is just a two-way scatterplot of one variable against the other after both variables have been sorted into ascending order, and both variables have the same number of nonmissing observations. If the variables have unequal numbers of nonmissing observations, interpolated values of the variable with more data are plotted against the variable with fewer data.

---

**Acknowledgments**

We thank Peter A. Lachenbruch of the Department of Public Health at Oregon State University for writing the original versions of **qchi** and **pchii**, Patrick Royston of the MRC Clinical Trials Unit, London, and coauthor of the Stata Press book *Flexible Parametric Survival Analysis Using Stata: Beyond the Cox Model* also published a similar command in the *Stata Technical Bulletin* (Royston 1996).

Title

**display** — Substitute for a hand calculator

Description
display displays strings and values of scalar expressions.
display really has many more features and a more complex syntax diagram, but the diagram shown above is adequate for interactive use. For a full discussion of display’s capabilities, see [P] display.

Quick start
Perform calculations interactively
```stata
display 100*100
```
As above, but include comma in the result
```stata
display %6.0fc 100*100
```
Verify choice of datetime function
```stata
display %tm monthly("January 1983","MY")
```
View formatted mean after summarize
```stata
display %5.2f r(mean)
```
Add the variance with a different format on its own line
```stata
display "mean = " %5.2f r(mean) _newline "variance = " %10.4f r(Var)
```

Syntax
display exp

Remarks and examples
display can be used as a substitute for a hand calculator.

Example 1
display 2+2 produces the output 4. Stata variables may also appear in the expression, such as in display myvar/2. Because display works only with scalars, the resulting calculation is performed only for the first observation. You could type display myvar[10]/2 to display the calculation for the 10th observation. Here are more examples:
. display sqrt(2)/2
. 0.70710678
. display normal(-1.1)
. 0.13566606
. di (57.2-3)/(12-2)
. 5.42
. display myvar/10
. 7
. display myvar[10]/2
. 3.5

Also see

[P] display — Display strings and values of scalar expressions

[U] 13 Functions and expressions
do — Execute commands from a file

**Description**

do and run cause Stata to execute the commands stored in `filename` just as if they were entered from the keyboard. do echoes the commands as it executes them, whereas run is silent.

**Quick start**

Execute commands stored in `myfile.do`

do myfile

As above, passing `first arg` in local macro 1 and `arg2` in local macro 2 for use by `myfile.do`

do myfile "first arg" arg2

Execute commands stored in `myfile.do`, continuing execution even if an error occurs in one or more commands

do myfile, nostop

Execute commands stored in `myfile.do` silently

run myfile

**Menu**

File > Do...
do — Execute commands from a file

Syntax

\{ do run } filename [ arguments ] [ , nostop ]

filename (called a do-file) can be created using Stata’s Do-file Editor; see [R] doedit. This file will be a standard text file. filename can also be created by using a non-Stata text editor; see [D] shell for a way to invoke your favorite editor from inside Stata. Ensure that you save the file in ASCII or UTF-8 format.

If filename is specified without an extension, .do is assumed.

If the path or filename contains spaces, it should be enclosed in double quotes.

A complete discussion of do-files, including information on arguments, can be found in [U] 16 Do-files.

Option

nostop allows the do-file to continue executing even if an error occurs. Normally, Stata stops executing the do-file when it detects an error (nonzero return code).

Reference

Also see

[R] doedit — Edit do-files and other text files
[P] include — Include commands from file
[GSM] 13 Using the Do-file Editor—automating Stata

[GSW] 13 Using the Do-file Editor—automating Stata
[U] 15 Saving and printing output—log files
[U] 16 Do-files
doedit — Edit do-files and other text files

Description

doedit opens the Do-file Editor. This text editor lets you create and edit do-files, which typically contain a series of Stata commands. If you specify filename, doedit will open a text file, such as a do-file or an ado-file, saved to disk.

Quick start

Open a new untitled do-file in the Do-file Editor

doedit

Open new or existing do-file myfile.do in the Do-file Editor

doedit myfile

Menu

Window > Do-file Editor
Syntax

\texttt{doedit [ filename ]}

Remarks and examples

Clicking on the \textbf{Do-file Editor} button is equivalent to typing \texttt{doedit}.

\texttt{doedit}, typed by itself, invokes the Editor with an empty document. If you specify \texttt{filename}, that file is displayed in the Editor.

You may have more than one Do-file Editor open at once. Each time you submit the \texttt{doedit} command, a new window will be opened.

A tutorial discussion of \texttt{doedit} can be found in the \textit{Getting Started with Stata} manual. Read [U] 16 \textit{Do-files} for an explanation of do-files, and then read [GSW] 13 \textit{Using the Do-file Editor—automating Stata} to learn how to use the Do-file Editor to create and execute do-files.

**Description**

A dotplot is a scatterplot with values grouped together vertically ("binning", as in a histogram) and with plotted points separated horizontally. The aim is to display all the data for several variables or groups in one compact graphic.

**Quick start**

Dotplot of \( v1 \)

```
dotplot v1
```

Columns with separate dotplots of \( v1 \) for each level of categorical variable \( a \)

```
dotplot v1, over(a)
```

As above, but with the dots centered in each column

```
dotplot v1, over(a) center
```

Dotplots for \( v1, v2, \) and \( v3 \) in separate columns

```
dotplot v1 v2 v3
```

Add a horizontal line of pluses at the mean of each variable

```
dotplot v1 v2 v3, mean
```

Add pluses for the medians and dashed lines for the upper and lower quartiles

```
dotplot v1 v2 v3, median bar
```

**Menu**

Graphics > Distributional graphs > Distribution dotplot
## Syntax

**Dotplot of varname, with one column per value of groupvar**

```
dotplot varname [if] [in] [, options]
```

**Dotplot for each variable in varlist, with one column per variable**

```
dotplot varlist [if] [in] [, options]
```

**Y axis, X axis, Titles, Legend, Overall**

```
twoway_options
```

Any options other than `by()` documented in [G-3] `twoway_options`

## Options

`over(groupvar)` identifies the variable for which `dotplot` will display one columnar dotplot for each value of `groupvar`. `over()` may not be specified in the second syntax.

`nx(#)` sets the horizontal dot density. A larger value of `#` will increase the dot density, reducing the horizontal separation between dots. This option will increase the separation between columns if two or more groups or variables are used.

`ny(#)` sets the vertical dot density (number of “bins” on the y axis). A larger value of `#` will result in more bins and a plot that is less spread out horizontally. `#` should be determined in conjunction with `nx()` to give the most pleasing appearance.

`incr(#)` specifies how the x axis is to be labeled. `incr(1)`, the default, labels all groups. `incr(2)` labels every second group.

`[mean|median]` plots a horizontal line of pluses at the mean or median of each group.

`bounded` forces the minimum and maximum of the variable to be used as boundaries of the smallest and largest bins. It should be used with one variable whose support is not the whole of the real line and whose density does not tend to zero at the ends of its support, for example, a uniform random variable or an exponential random variable.
bar plots horizontal dashed lines at the “shoulders” of each group. The shoulders are taken to be the upper and lower quartiles unless mean has been specified; here they will be the mean plus or minus the standard deviation.
	nogroup uses the actual values of yvar rather than grouping them (the default). This option may be useful if yvar takes on only a few values.

center centers the dots for each column on a hidden vertical line.

_plot

marker_options affect the rendition of markers drawn at the plotted points, including their shape, size, color, and outline; see [G-3] marker_options.

marker_label_options specify if and how the markers are to be labeled; see [G-3] marker_label_options.

marker_label_options are not allowed if varlist is specified.

_twoway

twoway_options are any of the options documented in [G-3] twoway_options, excluding by(). These include options for titling the graph (see [G-3] title_options) and for saving the graph to disk (see [G-3] saving_option).

Remarks and examples

dotplot produces a figure that has elements of a boxplot, a histogram, and a scatterplot. Like a boxplot, it is most useful for comparing the distributions of several variables or the distribution of 1 variable in several groups. Like a histogram, the figure provides a crude estimate of the density, and, as with a scatterplot, each symbol (dot) represents 1 observation.

Example 1

dotplot may be used as an alternative to Stata’s histogram graph for displaying the distribution of one variable.
Example 2

The `over()` option lets us use `dotplot` to compare the distribution of one variable within different levels of a grouping variable. The `center`, `median`, and `bar` options create a graph that may be compared with Stata’s `boxplot`; see [G-2] `graph box`. The next graph illustrates this option with Stata’s automobile dataset.

```stata
. use https://www.stata-press.com/data/r16/auto, clear
(1978 Automobile Data)
. dotplot mpg, over(foreign) nx(25) ny(10) center median bar
```
Example 3

The second version of `dotplot` lets us compare the distribution of several variables. In the next graph, all 10 variables contain measurements on tumor volume.

```stata
use https://www.stata-press.com/data/r16/dotgr
dotplot g1r1-g1r10, ytitle("Tumor volume, cu mm")
```

![Tumor volume dotplot](image.png)
Example 4

When using the first form with the `over()` option, we can encode a third dimension in a dotplot by using a different plotting symbol for different groups. The third dimension cannot be encoded with a varlist. The example is of a hypothetical matched case–control study. The next graph shows the exposure of each individual in each matched stratum. Cases are marked by the letter ‘x’, and controls are marked by the letter ‘o’.

```
use https://www.stata-press.com/data/r16/dotdose
label define symbol 0 "o" 1 "x"
label values case symbol
dotplot dose, over(strata) m(none) mlabel(case) mlabp(0) center
```

Example 5

dotplot can also be used with two virtually continuous variables as an alternative to jittering the data to distinguish ties. We must use the `xlabel()` option, because otherwise `dotplot` will attempt to label too many points on the x axis. It is often useful in such instances to use a value of `nx` that is smaller than the default. That was not necessary in this example, partly because of our choice of symbols.

```
use https://www.stata-press.com/data/r16/auto, clear
(1978 Automobile Data)
generate byte hi_price = (price>10000) if price < .
label define symbol 0 "|" 1 "o"
label values hi_price symbol
```
Example 6

The following figure is included mostly for aesthetic reasons. It also demonstrates dotplot’s ability to cope with even very large datasets. The sample size for each variable is 10,000, so it may take a long time to print.

```
clear all
set seed 123456789
set obs 10000
generate norm0 = rnormal()
generate norm1 = rnormal() + 1
generate norm2 = rnormal() + 2
label variable norm0 "N(0,1)"
label variable norm1 "N(1,1)"
label variable norm2 "N(2,1)"
dotplot norm0 norm1 norm2
```
Stored results

dotplot stores the following in r():

Scalars
\[ r(nx) \quad \text{horizontal dot density} \]
\[ r(ny) \quad \text{vertical dot density} \]

Acknowledgments

dotplot was written by Peter Sasieni of the Wolfson Institute of Preventive Medicine, London, and Patrick Royston of the MRC Clinical Trials Unit, London, and coauthor of the Stata Press book *Flexible Parametric Survival Analysis Using Stata: Beyond the Cox Model*.

</tr>
</tbody>
</table>

**Description**

dstdize produces standardized rates, a weighted average of the stratum-specific rates.

istdize produces indirectly standardized rates that are appropriate when the stratum-specific rates for the population being studied are either unavailable or unreliable.

istdize also calculates a point estimate and exact confidence interval for the study population’s standardized mortality ratio (SMR) or the standardized incidence ratio (SIR).

**Quick start**

**Direct standardization**

Use reference population saved in mypop.dta to standardize v1 with stratum identifier svar and stratum size v2 for catvar

```plaintext
dstdize v1 v2 svar, by(catvar) using(mypop)
```

As above, but with reference population in memory where catvar = 1

```plaintext
dstdize v1 v2 svar, by(catvar) base(1)
```

As above, but with reference population in memory where catvar = “nation”

```plaintext
dstdize v1 v2 svar, by(catvar) base("nation")
```

**Indirect standardization**

Use population cases and size saved in cases and pop to standardize study cases v3 and stratum size v4 at each level of svar

```plaintext
istdize v3 v4 svar using mypop.dta, popvars(cases pop)
```

As above, but standardize subpopulations identified by levels of catvar

```plaintext
istdize v3 v4 svar using mypop.dta, popvars(cases pop) by(catvar)
```

As above, but standardize by population stratum-specific and crude rates saved in srate and crate and display summary of standard population

```plaintext
istdize v3 v4 svar using mypop.dta, rate(srate crate) by(catvar) print
```

As above, but indicate that the crude population rate is 0.01

```plaintext
istdize v3 v4 svar using mypop.dta, rate(srate .01) by(catvar) print
```
Menu

dstdize
Statistics > Epidemiology and related > Other > Direct standardization

istdize
Statistics > Epidemiology and related > Other > Indirect standardization

Syntax

Direct standardization

dstdize charvar popvar stratavars [if] [in] , by(groupvars) [dstdize_options]

Indirect standardization

istdize casevar_s popvar_s stratavars [if] [in] using filename,

{ popvars(casevar_p popvar_p) | rate(ratevar_p {# | crudevar_p}) }
[istdize_options]

charvar is the characteristic to be standardized across different subpopulations identified by groupvars.

popvar defines the weights used in standardization.

stratavars defines the strata across which the weights are to be averaged in dstdize. For istdize, stratavars defines the strata for which casevar_s is measured.

casevar_s is the variable name for the study population’s number of cases. If by(groupvars) is specified, casevar_s must be constant or missing within each group defined by combinations of groupvars.

popvar_s identifies the number of subjects in each strata in the study population.

filename must be a Stata dataset and contain popvar and stratavars.
Options for `dstdize`

by(`groupvars`) is required for the `dstdize` command; it specifies the variables identifying the study populations. If `base()` is also specified, there must be only one variable in the by() group. If you do not have a variable for this option, you can generate one by using something like `generate newvar=1` and then use `newvar` as the argument to this option.

`using(filename)` or `base(# | string)` may be used to specify the standard population. You may not specify both options. `using(filename)` supplies the name of a `.dta` file containing the standard population. The standard population must contain the `popvar` and the `stratavars`. If `using()` is not specified, the standard population distribution will be obtained from the data. `base(# | string)` lets you specify one of the values of `groupvar`—either a numeric value or a string—to be used as the standard population. If neither `base()` nor `using()` is specified, the entire dataset is used to determine an estimate of the standard population.

`level(#)` specifies the confidence level, as a percentage, for a confidence interval of the adjusted rate. The default is `level(95)` or as set by `set level`; see [U] 20.8 Specifying the width of confidence intervals.
saving(filename) saves the computed standard population distribution as a Stata dataset that can be used in further analyses.

format(\%fmt) specifies the format in which to display the final summary table. The default is \%10.0g.

print includes a table summary of the standard population before displaying the study population results.

nores suppresses storing results in r(). This option is seldom specified. Some results are stored in matrices. If there are more groups than can fit in a matrix, dstdize will report the “unable to allocate matrix” error message. In this case, you must specify nores. The nores option does not change how results are calculated but specifies that results need not be left behind for use by other programs.

Options for istdize

popvars(casevar, popvar) or rate(ratevar, \{#|crudevar\}) must be specified with istdize. Only one of these two options is allowed. These options are used to describe the standard population’s data.

With popvars(casevar, popvar), casevar records the number of cases (deaths) for each stratum in the standard population, and popvar records the total number of individuals in each stratum (individuals at risk).

With rate(ratevar, \{#|crudevar\}), ratevar contains the stratum-specific rates. #|crudevar specifies the crude case rate either by a variable name or by the crude case rate value. If a crude rate variable is used, it must be the same for all observations, although it could be missing for some.

level(\#) specifies the confidence level, as a percentage, for a confidence interval of the adjusted rate. The default is level(95) or as set by set level; see [U] 20.8 Specifying the width of confidence intervals.

by(groupvars) specifies variables identifying study populations when more than one exists in the data. If this option is not specified, the entire study population is treated as one group.

format(\%fmt) specifies the format in which to display the final summary table. The default is \%10.0g.

print outputs a table summary of the standard population before displaying the study population results.

Remarks and examples

Remarks are presented under the following headings:

Direct standardization
Indirect standardization
In epidemiology and other fields, you will often need to compare rates for some characteristic across different populations. These populations often differ on factors associated with the characteristic under study; thus directly comparing overall rates may be misleading.

**Direct standardization**

The direct method of adjusting for differences among populations involves computing the overall rates that would result if, instead of having different distributions, all populations had the same standard distribution. The standardized rate is defined as a weighted average of the stratum-specific rates, with the weights taken from the standard distribution. Direct standardization may be applied only when the specific rates for a given population are available.

dstdize generates adjusted summary measures of occurrence, which can be used to compare prevalence, incidence, or mortality rates between populations that may differ on certain characteristics (for example, age, gender, race). These underlying differences may affect the crude prevalence, mortality, or incidence rates.

**Example 1**

We have data (Rothman 1986, 42) on mortality rates for Sweden and Panama for 1962, and we wish to compare mortality in these two countries:

. use https://www.stata-press.com/data/r16/mortality
   (1962 Mortality, Sweden & Panama)
. describe

Contains data from https://www.stata-press.com/data/r16/mortality.dta
obs: 6 1962 Mortality, Sweden & Panama
vars: 4 14 Apr 2018 16:18

</tr>
<tr>
<td>Sweden</td>
<td>7496000</td>
<td>73,555</td>
<td>.0098126</td>
</tr>
</tbody>
</table>
```

If we examine the total number of deaths in the two nations, the total crude mortality rate in Sweden is higher than that in Panama. From the original data, we see one possible explanation: Swedes are older than Panamanians, making direct comparison of the mortality rates difficult.

Direct standardization lets us remove the distortion caused by the different age distributions. The adjusted rate is defined as the weighted sum of the crude rates, where the weights are given by the standard distribution. Suppose that we wish to standardize these mortality rates to the following age distribution:

```
. use https://www.stata-press.com/data/r16/1962, clear
(Standard Population Distribution)
. list, abbrev(12) divider

<table>
<thead>
<tr>
<th>age_category</th>
<th>population</th>
</tr>
</thead>
<tbody>
<tr>
<td>0 - 29</td>
<td>.35</td>
</tr>
<tr>
<td>30 - 59</td>
<td>.35</td>
</tr>
<tr>
<td>60+</td>
<td>.3</td>
</tr>
</tbody>
</table>
```

```
. save 1962
file 1962.dta saved
```

If we multiply the above weights for the age strata by the crude rate for the corresponding age category, the sum gives us the standardized rate.

```
. use https://www.stata-press.com/data/r16/mortality
(1962 Mortality, Sweden & Panama)
. generate crude=deaths/pop
. drop pop
. merge m:1 age_cat using 1962
  (note: variable age_category was byte, now float to accommodate using data's values)

Result       # of obs.
-------------------------
not matched 0
matched     6 (_merge==3)
```
Comparing the standardized rates indicates that the Swedes have a slightly lower mortality rate.
To perform the above analysis with `dstdize`, type

```
. use https://www.stata-press.com/data/r16/mortality, clear
(1962 Mortality, Sweden & Panama)
. dstdize deaths pop age_cat, by(nation) using(1962)
```

```

The summary table above lets us make a quick inspection of the results within the study populations, and the detail tables give the behavior among the strata within the study populations.

---

Example 2

We have individual-level data on persons in four cities over several years. Included in the data is a variable indicating whether the person has high blood pressure, together with information on the person’s age, sex, and race. We wish to obtain standardized high blood pressure rates for each city for 1990 and 1992, using, as the standard, the age, sex, and race distribution of the four cities and two years combined.
Our dataset contains

```
. use https://www.stata-press.com/data/r16/hbp
. describe
Contains data from https://www.stata-press.com/data/r16/hbp.dta
    obs:    1,130
   vars:     7  21 Feb 2018 06:42

   storage  display    value
  variable name    type    format   label                  variable label
      id    str10     %10s  Record identification number
      city    byte     %8.0g
      year    int      %8.0g
      sex    byte     %8.0g    sexfmt
   age_group    byte     %8.0g    agefmt
       race    byte     %8.0g    racefmt
       hbp    byte     %8.0g    yn    high blood pressure
```

Sorted by:

The `dstdize` command is designed to work with aggregate data but will work with individual-level data only if we create a variable recording the population represented by each observation. For individual-level data, this is one:

```
. generate pop = 1
```

On the next page, we specify `print` to obtain a listing of the standard population and `level(90)` to request 90% rather than 95% confidence intervals. Typing `if year==1990 | year==1992` restricts the data to the two years for both summary tables and the standard population.
. dstdize hbp pop age race sex if year==1990 | year==1992, by(city year) print > level(90)

Indirect standardization

Standardization of rates can be performed via the indirect method whenever the stratum-specific rates are either unknown or unreliable. If the stratum-specific rates are known, the direct standardization method is preferred.

To apply the indirect method, you must have the following information:

- The observed number of cases in each population to be standardized, \( O \). For example, if death rates in two states are being standardized using the U.S. death rate for the same period, you must know the total number of deaths in each state.
- The distribution across the various strata for the population being studied, \( n_1, \ldots, n_k \). If you are standardizing the death rate in the two states, adjusting for age, you must know the number of individuals in each of the \( k \) age groups.
- The stratum-specific rates for the standard population, \( p_1, \ldots, p_k \). For example, you must have the U.S. death rate for each stratum (age group).
- The crude rate of the standard population, \( C \). For example, you must have the U.S. mortality rate for the year.

The indirect adjusted rate is then

\[
R_{\text{indirect}} = C \frac{O}{E}
\]

where \( E \) is the expected number of cases (deaths) in each population. See *Methods and formulas* for a more detailed description of calculations.

Example 3

This example is borrowed from Kahn and Sempos (1989, 95–105). We want to compare 1970 mortality rates in California and Maine, adjusting for age. Although we have age-specific population counts for the two states, we lack age-specific death rates. Direct standardization is not feasible here. We can use the U.S. population census data for the same year to produce indirectly standardized rates for these two states.

From the U.S. census, the standard population for this example was entered into Stata and saved in popkahn.dta.

```
use https://www.stata-press.com/data/r16/popkahn, clear
list age pop deaths rate, sep(4)
```

<table>
<thead>

</tr>
</tbody>
</table>
The standard population contains for each age stratum the total number of individuals (pop) and both the age-specific mortality rate (rate) and the number of deaths. The standard population need not contain all three. If we have only the age-specific mortality rate, we can use the rate(ratevar) or rate(ratevar, #) option, where crudevar refers to the variable containing the total population’s crude death rate or # is the total population’s crude death rate.

Now let’s look at the states’ data (study population):

```stata
. use https://www.stata-press.com/data/r16/kahn
. list, sep(4)
```

</tbody>
</table>

For each state, the number of individuals in each stratum (age group) is contained in the pop variable. The death variable is the total number of deaths observed in the state during the year. It must have the same value for all observations in the group, as for California, or it could be missing in all but one observation per group, as for Maine.

To match these two datasets, the strata variables must have the same name in both datasets and ideally the same levels. If a level is missing from either dataset, that level will not be included in the standardization.

With kahn.dta in memory, we now execute the command. We will use the print option to obtain the standard population’s summary table, and because we have both the standard population’s age-specific count and deaths, we will specify the popvars(casevar, popvar) option. Or, we could specify the rate(rate 0.00945) option because we know that 0.00945 is the U.S. crude death rate for 1970.

Methods and formulas

The directly standardized rate, $S_R$, is defined by

$$S_R = \frac{\sum_{i=1}^{k} w_i R_i}{\sum_{i=1}^{k} w_i}$$

(Rothman 1986, 44), where $R_i$ is the stratum-specific rate in stratum $i$ and $w_i$ is the weight for stratum $i$ derived from the standard population.

If $n_i$ is the population of stratum $i$, the standard error, $se(S_R)$, in stratified sampling for proportions (ignoring the finite population correction) is

$$se(S_R) = \frac{1}{\sum_{i=1}^{k} w_i} \sqrt{\frac{\sum_{i=1}^{k} w_i^2 R_i (1 - R_i)}{n_i}}$$

(Cochran 1977, 108), from which the confidence intervals are calculated.

For indirect standardization, define $O$ as the observed number of cases in each population to be standardized; $n_1, \ldots, n_k$ as the distribution across the various strata for the population being studied; $R_1, \ldots, R_k$ as the stratum-specific rates for the standard population; and $C$ as the crude rate of the standard population. The expected number of cases (deaths), $E$, in each population is obtained by applying the standard population stratum-specific rates, $R_1, \ldots, R_k$, to the study populations:

$$E = \sum_{i=1}^{k} n_i R_i$$

The indirectly adjusted rate is then

$$R_{\text{indirect}} = \frac{C O}{E}$$

and $O/E$ is the study population’s SMR if death is the event of interest or the SIR for studies of disease (or other) incidence.

The exact confidence interval is calculated for each estimated SMR by assuming a Poisson process as described in Breslow and Day (1987, 69–71). These intervals are obtained by first calculating the upper and lower bounds for the confidence interval of the Poisson-distributed observed events, $O$—say, $L$ and $U$, respectively—and then computing $\text{SMR}_L = L/E$ and $\text{SMR}_U = U/E$.

Acknowledgments

We gratefully acknowledge the collaboration of Dr. Joel A. Harrison, consultant; Dr. José Maria Pacheco of the Departamento de Epidemiologia, Faculdade de Saúde Pública/USP, Sao Paulo, Brazil; and Dr John L. Moran of the Queen Elizabeth Hospital, Woodville, Australia.

**Description**

dydx and integ calculate derivatives and integrals of numeric “functions”.

**Quick start**

For variables $y$ and $x$ corresponding to function $y = f(x)$, compute $dy/dx$ using cubic splines and store result in $dy$

```
dydx y x, generate(dy)
```

Evaluate the integral of $f(x)$ using cubic splines

```
integ y x
```

Evaluate the integral using the trapezoidal rule

```
integ y x, trapezoid
```

As above, and generate variable iy containing integral evaluated for each value of $x$

```
integ y x, trapezoid generate(iy)
```

**Menu**

dydx

integ

Data > Create or change data > Other variable-creation commands > Calculate numeric integrals
Syntax

Derivatives of numeric functions

```plaintext
dydx yvar xvar [if] [in], generate(newvar) [dydx_options]
```

Integrals of numeric functions

```plaintext
integ yvar xvar [if] [in] [, integ_options]
```

### dydx_options

<table>
<thead>
<tr>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><em>generate(newvar)</em> create variable named newvar</td>
</tr>
<tr>
<td><em>replace</em> overwrite the existing variable</td>
</tr>
</tbody>
</table>

*generate(newvar) is required.

### integ_options

<table>
<thead>
<tr>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><em>generate(newvar)</em> create variable named newvar</td>
</tr>
<tr>
<td><em>trapezoid</em> use trapezoidal rule to compute integrals; default is cubic splines</td>
</tr>
<tr>
<td><em>initial(#)</em> initial value of integral; default is initial(0)</td>
</tr>
<tr>
<td><em>replace</em> overwrite the existing variable</td>
</tr>
</tbody>
</table>

by is allowed with dydx and integ; see [D] by.

Options

- `generate(newvar)` specifies the name of the new variable to be created. It must be specified with dydx.
- `trapezoid` requests that the trapezoidal rule \[
\text{the sum of } (x_i - x_{i-1})(y_i + y_{i-1})/2 \]
be used to compute integrals. The default is cubic splines, which give superior results for most smooth functions; for irregular functions, trapezoid may give better results.
- `initial(#)` specifies the initial condition for calculating definite integrals; see Methods and formulas below. The default is initial(0).
- `replace` specifies that if an existing variable is specified for `generate()`, it should be overwritten.

Remarks and examples

- dydx and integ lets you extend Stata’s graphics capabilities beyond data analysis and into mathematics.
Example 1

We graph \( y = e^{-x/6}\sin(x) \) over the interval \([0, 12.56]\):

\[
\begin{align*}
 &. \text{range } x \ 0 \ 12.56 \ 100 \\
 &. \text{number of observations \(_N\) was 0, now 100} \\
 &. \text{generate } y = \exp(-x/6)\sin(x) \\
 &. \text{label variable } y \ "\exp(-x/6)\sin(x)" \\
 &. \text{twoway connected } y \ x, \ connect(i) \ yline(0)
\end{align*}
\]

We estimate the derivative by using \texttt{dydx} and compute the relative difference between this estimate and the true derivative.

\[
\begin{align*}
 &. \text{dydx } y \ x, \ gen(dy) \\
 &. \text{generate dytrue = exp(-x/6)*(cos(x) - sin(x)/6)} \\
 &. \text{generate error = abs(dy - dytrue)/dytrue}
\end{align*}
\]
The error is greatest at the endpoints, as we would expect. The error is approximately 0.5% at each endpoint, but the error quickly falls to less than 0.01%.

. label variable error "Error in derivative estimate"
. twoway line error x, ylabel(0(.002).006)

We now estimate the integral by using integ:

. integ y x, gen(iy)
  number of points = 100
  integral = .85316396
. generate iytrue = (36/37)*(1 - exp(-x/6)*(cos(x) + sin(x)/6))
. display iytrue[_N]
  .85315901
. display abs(r(integral) - iytrue[_N])/iytrue[_N]
  5.799e-06
. generate diff = iy - iytrue

The relative difference between the estimate [stored in r(integral)] and the true value of the integral is about $6 \times 10^{-6}$. A graph of the absolute difference (diff) is shown below. Here error is cumulative. Again most of the error is due to a relatively poorer fit near the endpoints.
. label variable diff "Error in integral estimate"
. twoway line diff x, ylabel(0(5.00e-06).00001)

Stored results

dydx stores the following in r():

Macros
   r(y)  name of yvar

integ stores the following in r():

Scalars
   r(N_points)  number of unique x points
   r(integral)  estimate of the integral

Methods and formulas

Consider a set of data points, \((x_1, y_1), \ldots, (x_n, y_n)\), generated by a function \(y = f(x)\). dydx and integ first fit these points with a cubic spline, which is then analytically differentiated (integrated) to give an approximation for the derivative (integral) of \(f\).
The cubic spline (see, for example, Press et al. [2007]) consists of \( n - 1 \) cubic polynomials \( P_i(x) \), with the \( i \)th one defined on the interval \([x_i, x_{i+1}]\).

\[ P_i(x) = y_i a_i(x) + y_{i+1} b_i(x) + y_i'' c_i(x) + y_{i+1}'' d_i(x) \]

where

\[ a_i(x) = \frac{x_{i+1} - x}{x_{i+1} - x_i} \quad b_i(x) = \frac{x - x_i}{x_{i+1} - x_i} \]

\[ c_i(x) = \frac{1}{6} (x_{i+1} - x_i)^2 a_i(x) \left[\{a_i(x)\}^2 - 1\right] \quad d_i(x) = \frac{1}{6} (x_{i+1} - x_i)^2 b_i(x) \left[\{b_i(x)\}^2 - 1\right] \]

and \( y_i'' \) and \( y_{i+1}'' \) are constants whose values will be determined as described below. The notation for these constants is justified because \( P_i''(x_i) = y_i'' \) and \( P_i''(x_{i+1}) = y_{i+1}'' \).

Because \( a_i(x_i) = 1, a_i(x_{i+1}) = 0, b_i(x_i) = 0, \) and \( b_i(x_{i+1}) = 1 \). Therefore, \( P_i(x_i) = y_i, \) and \( P_i(x_{i+1}) = y_{i+1} \). Thus the \( P_i \) jointly define a function that is continuous at the interval boundaries. The first derivative should be continuous at the interval boundaries; that is,

\[ P_i'(x_{i+1}) = P_{i+1}'(x_{i+1}) \]

The above \( n - 2 \) equations (one equation for each point except the two endpoints) and the values of the first derivative at the endpoints, \( P_1'(x_1) \) and \( P_{n-1}'(x_n) \), determine the \( n \) constants \( y_i'' \).

The value of the first derivative at an endpoint is set to the value of the derivative obtained by fitting a quadratic to the endpoint and the two adjacent points; namely, we use

\[ P_1'(x_1) = \frac{y_1 - y_2}{x_1 - x_2} + \frac{y_1 - y_3}{x_1 - x_3} - \frac{y_2 - y_3}{x_2 - x_3} \]

and a similar formula for the upper endpoint.

dydx approximates \( f'(x_i) \) by using \( P_i'(x_i) \).

integ approximates \( F(x_i) = F(x_1) + \int_{x_1}^{x_i} f(x) \, dx \) by using

\[ I_0 + \sum_{k=1}^{i-1} \int_{x_k}^{x_{k+1}} P_k(x) \, dx \]

where \( I_0 \) (an estimate of \( F(x_1) \)) is the value specified by the initial(#) option. If the trapezoid option is specified, integ approximates the integral by using the trapezoidal rule:

\[ I_0 + \sum_{k=1}^{i-1} \frac{1}{2} (x_{k+1} - x_k)(y_{k+1} + y_k) \]

If there are ties among the \( x_i \), the mean of \( y_i \) is computed at each set of ties and the cubic spline is fit to these values.
Acknowledgment

The present versions of \texttt{dydx} and \texttt{integ} were inspired by the \texttt{dydx2} command written by Patrick Royston of the MRC Clinical Trials Unit, London, and coauthor of the Stata Press book \textit{Flexible Parametric Survival Analysis Using Stata: Beyond the Cox Model}.

Maria Gaetana Agnesi (1718–1799) was an Italian mathematician and philosopher. Born in Milan into a wealthy family, she was recognized as a child prodigy. At age nine, she published a detailed argument in Latin on the importance of education for women. At age 15, her father, a mathematics professor at the University of Bologna, presented her talents in language and philosophical reasoning to Bologna’s intellectual elite. Uncomfortable with public life, she educated her twenty siblings and published on mathematics. After her father’s death in 1752, she studied theology and devoted the rest of her life to helping the poor, homeless, and sick.

Agnesi’s best known work, \textit{Instituzioni analitiche ad uso della gioventù italiana} (\textit{Analytical Institutions for the Use of Italian Youth}), written in 1748, helped develop the analysis of finite quantities and infinitesimals. At the time, it was hailed as the best introduction to calculus. The work also discussed an asymptotic curve that, because of mistranslation, would come to be known as the “Witch of Agnesi”. In 1750, Pope Benedict XIV appointed her to the chair of mathematics and natural philosophy at Bologna, though she never served.

In addition to being recognized as an important mathematician, Agnesi is revered in the Basilica of San Nazaro in Milan. At her death, she was mourned by radical authors as a proponent for women’s rights and by the Catholic faithful as a symbol of personal piety.

Description

An `eform_option` causes the coefficient table to be displayed in exponentiated form: for each coefficient, $e^b$ rather than $b$ is displayed. Standard errors and confidence intervals (CIs) are also transformed.

An `eform_option` is one of the following:

<table>
<thead>
<tr>
<th><code>eform_option</code></th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>eform(string)</code></td>
<td>use <code>string</code> for the column title</td>
</tr>
<tr>
<td><code>eform</code></td>
<td>exponentiated coefficient, <code>string</code> is $\exp(b)$</td>
</tr>
<tr>
<td><code>hr</code></td>
<td>hazard ratio, <code>string</code> is Haz. Ratio</td>
</tr>
<tr>
<td><code>shr</code></td>
<td>subhazard ratio, <code>string</code> is SHR</td>
</tr>
<tr>
<td><code>irr</code></td>
<td>incidence-rate ratio, <code>string</code> is IRR</td>
</tr>
<tr>
<td><code>or</code></td>
<td>odds ratio, <code>string</code> is Odds Ratio</td>
</tr>
<tr>
<td><code>rrr</code></td>
<td>relative-risk ratio, <code>string</code> is RRR</td>
</tr>
</tbody>
</table>

Remarks and examples

▷ Example 1

Here is a simple example of the `or` option with `svy: logit`. The CI for the odds ratio is computed by transforming (by exponentiating) the endpoints of the CI for the corresponding coefficient.

```
. use https://www.stata-press.com/data/r16/nhanes2d
. svy, or: logit highbp female black
(running `logit` on estimation sample)
(output omitted)
```

```
<table>
<thead>
<tr>
<th>highbp</th>
<th></th>
<th>Linearized</th>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Odds Ratio</td>
<td>Std. Err.</td>
<td>t</td>
<td>P&gt;</td>
<td>t</td>
</tr>
<tr>
<td>female</td>
<td>.6107011</td>
<td>.0326159</td>
<td>-9.23</td>
<td>0.000</td>
<td>.5476753</td>
</tr>
<tr>
<td>black</td>
<td>1.384865</td>
<td>.1336054</td>
<td>3.37</td>
<td>0.002</td>
<td>1.137507</td>
</tr>
<tr>
<td>_cons</td>
<td>.7249332</td>
<td>.0551062</td>
<td>-4.23</td>
<td>0.000</td>
<td>.6208222</td>
</tr>
</tbody>
</table>
```

Note: _cons estimates baseline odds.

We also could have specified the following command and received the same results as above:

```
. svy: logit highbp female black, or
```

**Description**

eivreg fits errors-in-variables regression models when one or more of the independent variables are measured with error. To use eivreg, you must have an estimate of each independent variable’s reliability or assume it is measured without error.

**Quick start**

Regression of y on x1, x2, and x3 adjusted for x1 measured with 90% reliability

eivreg y x1 x2 x3, reliab(x1 .9)

As above, but also specify 80% reliability for x2

eivreg y x1 x2 x3, reliab(x1 .9 x2 .8)

**Menu**

Statistics > Linear models and related > Errors-in-variables regression
## Syntax

```
eivreg depvar [ indepvars ] [ if ] [ in ] [ weight ] [ , options ]
```

</table>

`indepvars` may contain factor variables; see [U] 11.4.3 Factor variables.

bootstrap, by, jackknife, rolling, and statsby are allowed; see [U] 11.10 Prefix commands.

Weights are not allowed with the bootstrap prefix; see [R] bootstrap.

aweights are not allowed with the jackknife prefix; see [R] jackknife.

aweights and fweights are allowed; see [U] 11.6 weight.

`coeflegend` does not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

## Options

### Model

```
reliab(`indepvar # [ indepvar # [... ] ]`) specifies the measurement reliability for each independent variable measured with error. Reliabilities are specified as pairs consisting of an independent variable name (a name that appears in `indepvars`) and the corresponding reliability \( r, 0 < r \leq 1 \). Independent variables for which no reliability is specified are assumed to have reliability 1. If the option is not specified, all variables are assumed to have reliability 1, and the result is thus the same as that produced by `regress` (the ordinary least-squares results).
```

### Reporting

```
level(#); see [R] Estimation options.

display_options: noci, nopvalues, noomitted, vsquish, noemptycells, baselevels, allbaselevels, noflabel, fwrap(#), fwrapon(style), cformat(`%fmt`), pformat(`%fmt`), sformat(`%fmt`), and nolstretch; see [R] Estimation options.
```

The following option is available with eivreg but is not shown in the dialog box:

`coeflegend`; see [R] Estimation options.
Remarks and examples

Errors-in-variables regression models are useful when one or more of the independent variables are measured with additive noise. Standard regression (as performed by `regress`) would underestimate the effect of the variable, and the other coefficients in the model can be biased to the extent that they are correlated with the poorly measured variable. You can adjust for the biases if you know the reliability:

\[ r = 1 - \frac{\text{noise variance}}{\text{total variance}} \]

That is, given the model \( y = X\beta + u \), for some variable \( x_i \) in \( X \), the \( x_i \) is observed with error, \( x_i = x_i^* + e \), and the noise variance is the variance of \( e \). The total variance is the variance of \( x_i \).

> Example 1

Say that in our automobile data, the weight of cars was measured with error, and the reliability of our measured weight is 0.85. The result of this would be to underestimate the effect of weight in a regression of, say, `price` on `weight` and `foreign`, and it would also bias the estimate of the coefficient on `foreign` (because being of foreign manufacture is correlated with the weight of cars). We would ignore all of this if we fit the model with `regress`:

```
. use https://www.stata-press.com/data/r16/auto
(1978 Automobile Data)
. regress price weight foreign
```

```
Number of obs = 74
F(2, 71) = 35.35
Prob > F = 0.0000
R-squared = 0.4989
Adj R-squared = 0.4848
Root MSE = 2117

price       Coef.  Std. Err.   t    P>|t|     [95% Conf. Interval]
-------------------------------------------------------------------------
weight       3.320737   .3958784   8.39    0.000     2.531378   4.110096
foreign        3637.001   668.583    5.44    0.000     2303.885   4970.118
    _cons    -4942.844   1345.591   -3.67    0.000    -7625.876   -2259.812
```

With `eivreg`, we can account for our measurement error:

```
. eivreg price weight foreign, reliab(weight .85)
```

<table>
<thead>
<tr>
<th>assumed variable</th>
<th>reliability</th>
</tr>
</thead>
<tbody>
<tr>
<td>weight</td>
<td>0.8500</td>
</tr>
<tr>
<td>*</td>
<td>1.0000</td>
</tr>
</tbody>
</table>

Errors-in-variables regression

```
Number of obs    =     74  
F(  2,   71)    =   18.46  
Prob > F         =  0.0000  
R-squared        =   0.6483  
Root MSE         =   1773.54
```

|            | Coef.  | Std. Err. |     t  | P>|t| |  [95% Conf. Interval] |
|------------|--------|-----------|--------|-----|----------------------|
| weight     | 4.31985 | .7134251  | 6.06   | 0.000 | 2.89732 – 5.742379   |
| foreign    | 4637.32 | 849.0221  | 5.46   | 0.000 | 2944.418 – 6330.222  |
| _cons      | -8257.017 | 2390.337 | -3.45  | 0.001 | -13023.21 – -3490.821|

The effect of weight is increased—as we knew it would be—and here the effect of foreign manufacture is also increased. A priori, we knew only that the estimate of `foreign` might be biased; we did not know the direction.

Technical note

Swept under the rug in our example is how we would determine the reliability, \( r \). We can easily see that a variable is measured with error, but we may not know the reliability because the ingredients for calculating \( r \) depend on the unobserved noise.

For our example, we made up a value for \( r \), and in fact we do not believe that weight is measured with error at all, so the reported `eivreg` results have no validity. The `regress` results were the statistically correct results here.

But let’s say that we do suspect that weight is measured with error and that we do not know \( r \). We could then experiment with various values of \( r \) to describe the sensitivity of our estimates to possible error levels. We may not know \( r \), but \( r \) does have a simple interpretation, and we could probably produce a sensible range for \( r \) by thinking about how the data were collected.

If the reliability, \( r \), is less than the \( R^2 \) from a regression of the poorly measured variable on all the other variables, including the dependent variable, the information might as well not have been collected; no adjustment to the final results is possible. For our automobile data, running a regression of weight on foreign and price would result in an \( R^2 \) of 0.6743. Thus the reliability must be at least 0.6743 here. If we specify a reliability that is too small, `eivreg` will inform us and refuse to fit the model:

```
. eivreg price weight foreign, reliab(weight .6742)
reliability r() too small
r(399);
```

Returning to our problem of how to estimate \( r \), too small or not, if the measurements are summaries of scaled items, the reliability may be estimated using the `alpha` command; see `[MV] alpha`. If the score is computed from factor analysis and the data are scored using `predict`'s default options (see `[MV] factor postestimation`), the square of the standard deviation of the score is an estimate of the reliability.
Example 2

Consider a model with more than one variable measured with error. For instance, say that our model is that price is a function of weight, foreign, and mpg and that both weight and mpg are measured with error.

```
.eivreg price weight foreign mpg, reliab(weight .85 mpg .95)
```

Stored results

`eivreg` stores the following in `e()`:  

Scalars:
- `e(N)` number of observations
- `e(df_m)` model degrees of freedom
- `e(df_r)` residual degrees of freedom
- `e(r2)` $R^2$
- `e(F)` F statistic
- `e(rmse)` root mean squared error
- `e(rank)` rank of `e(V)`

Macros:
- `e(cmd)` `eivreg`
- `e(cmdline)` command as typed
- `e(depvar)` name of dependent variable
- `e(rellist)` `indepvars` and associated reliabilities
- `e(wtype)` weight type
- `e(wexp)` weight expression
- `e(properties)` `b V`
- `e(predict)` program used to implement `predict`
- `e(marginsok)` predictions allowed by `margins`
- `e(asbalanced)` factor variables `fvset` as `asbalanced`
- `e(asobserved)` factor variables `fvset` as `asobserved`

Matrices:
- `e(b)` coefficient vector
- `e(V)` variance–covariance matrix of the estimators

Functions:
- `e(sample)` marks estimation sample
Methods and formulas

Let the model to be fit be

\[ y = X^* \beta + \epsilon \]
\[ X = X^* + U \]

where \( X^* \) are the true values and \( X \) are the observed values. \( \epsilon \) and \( U \) are assumed to be independent and have zero means and finite fourth moments. \( \text{Var}(U) \) is assumed to be diagonal.

Let \( W \) be the user-specified weights. If no weights are specified, \( W = I \). If weights are specified, let \( v \) be the specified weights. If \( fweight \) frequency weights are specified, then \( W = \text{diag}(v/(1'v)(1')) \), meaning that the weights are normalized to sum to the number of observations.

The estimates \( b \) of \( \beta \) are obtained as \( A^{-1}X'Wy \), where \( A = X'WX - S \). \( S \) is a diagonal matrix with elements \((1 - r_j)s_j^2\). Here \( r_j \) is the user-specified reliability coefficient for the \( j \)th explanatory variable (or 1 if not specified), and \( s_j^2 \) is the (appropriately weighted) sample variance of the variable.

The root mean squared error is \( \sqrt{(y'Wy - bAb')/(n - p)} \), where \( n \) is the number of observations and \( p \) is the number of estimated parameters. The variance–covariance matrix of the estimators is obtained based on the formulas provided in Stefanski and Boos (2002), Buonaccorsi (2010), and Fuller (1987). For each \( i = 1, 2, \ldots, n \), let residual \( e_i = y_i - x_i b \), where \( x_i \) is the \( i \)th row of \( X \). Consider matrix \( H \), where the \( i \)th row of \( H, h_i, \) is

\[
h_i' = \begin{pmatrix}
e_i x_{i1} + (x_{i1} - \bar{x}_1)^2(1 - r_1)b_1 \\
e_i x_{i2} + (x_{i2} - \bar{x}_2)^2(1 - r_2)b_2 \\
\vdots \\
e_i x_{ip} + (x_{ip} - \bar{x}_p)^2(1 - r_p)b_p
\end{pmatrix}
\]

where \( \bar{x}_j \) is the weighted mean of the \( j \)th variable.

If analytic weights, \( aweights \), are specified, the variance–covariance matrix is \( A^{-1}H'WWHA^{-1} \); otherwise, it is \( A^{-1}H'WH \)

predict

Description for predict

predict creates a new variable containing the linear prediction assuming that values of the covariates used for the prediction were measured without error.

Menu for predict

Statistics  >  Postestimation

Syntax for predict

```
predict [type] newvar [if] [in]
```

Available both in and out of sample; type predict ... if e(sample) ... if wanted only for the estimation sample.
margins

Description for margins

margins estimates margins of response for linear predictions.

Menu for margins

Statistics > Postestimation

Syntax for margins

margins [ marginlist ] [ , options ]

Remarks and examples

Example 1

We return to example 1 from [R] eivreg:

. use https://www.stata-press.com/data/r16/auto
  (1978 Automobile Data)
. eivreg price weight foreign, reliab(weight .85)
  assumed Errors-in-variables regression

We wish to predict the price of a foreign car that weighs 2,300 pounds. We can use predict because 2,300 pounds is the true weight, not the result of an error-prone measurement.

To make this prediction, first we add the new observation to the dataset.

. set obs 75
  number of observations (_N) was 74, now 75
. replace foreign = 1 in 75
  (1 real change made)
. replace weight = 2300 in 75
  (1 real change made)
Now, we use `predict` to predict the price of the car.

```
. predict newprice in 75
(option xb assumed; fitted values)
(74 missing values generated)
(predictions assume covariates measured without error)
. list weight foreign newprice in 75
```

```
<table>
<thead>
<tr>
<th>weight</th>
<th>foreign</th>
<th>newprice</th>
</tr>
</thead>
<tbody>
<tr>
<td>75.</td>
<td>2,300</td>
<td>6315.957</td>
</tr>
</tbody>
</table>
```

`predict` issued a note reminding us that the computed predictions assume that the covariates used for prediction are measured without error. In general, you should avoid using `predict` to obtain in-sample predictions unless you first replace the measurement-error covariates with values that are error free.

---

**Also see**

[R] eivreg — Errors-in-variables regression

[U] 20 Estimation and postestimation commands
**Description**

- **ir** is used with incidence-rate (incidence-density or person-time) data. It calculates point estimates and confidence intervals for the incidence-rate ratio and difference, along with attributable or prevented fractions for the exposed and total population. **iri** is the immediate form of **ir**; see [U] 19 Immediate commands. Also see [R] poisson and [ST] stcox for related commands.

- **cs** is used with cohort study data with equal follow-up time per subject and sometimes with cross-sectional data. Risk is then the proportion of subjects who become cases. It calculates point estimates and confidence intervals for the risk difference, risk ratio, and (optionally) the odds ratio, along with attributable or prevented fractions for the exposed and total population. **csi** is the immediate form of **cs**; see [U] 19 Immediate commands. Also see [R] logistic for related commands.

- **cc** is used with case–control and cross-sectional data. It calculates point estimates and confidence intervals for the odds ratio, along with attributable or prevented fractions for the exposed and total population. **cci** is the immediate form of **cc**; see [U] 19 Immediate commands. Also see [R] logistic for related commands.

- **tabodds** is used with case–control and cross-sectional data. It tabulates the odds of failure against a categorical explanatory variable **expvar**. If **expvar** is specified, **tabodds** performs an approximate $\chi^2$ test of homogeneity of odds and a test for linear trend of the log odds against the numerical code used for the categories of **expvar**. Both tests are based on the score statistic and its variance; see Methods and formulas. When **expvar** is absent, the overall odds are reported. The variable **var_case** is coded 0/1 for individual and simple frequency records and equals the number of cases for binomial frequency records. Optionally, **tabodds** tabulates adjusted or unadjusted odds ratios, using either the lowest levels of **expvar** or a user-defined level as the reference group. If **adjust(varlist)** is specified, it produces odds ratios adjusted for the variables in **varlist** along with a (score) test for trend.

- **mhodds** is used with case–control and cross-sectional data. It estimates the ratio of the odds of failure for two categories of **expvar**, controlled for specified confounding variables, **vars_adjust**, and tests whether this odds ratio is equal to one. When **expvar** has more than two categories but none are specified with the **compare()** option, **mhodds** assumes that **expvar** is a quantitative variable and calculates a 1-degree-of-freedom test for trend. It also calculates an approximate estimate of the log odds-ratio for a one-unit increase in **expvar**. This is a one-step Newton–Raphson approximation to the maximum likelihood estimate calculated as the ratio of the score statistic, $U$, to its variance, $V$ (Clayton and Hills 1993, 103).

- **mcc** is used with matched case–control data. It calculates McNemar’s chi-squared; point estimates and confidence intervals for the difference, ratio, and relative difference of the proportion with the factor; and the odds ratio and its confidence interval. **mcci** is the immediate form of **mcc**; see [U] 19 Immediate commands. Also see [R] clogit and [R] symmetry for related commands.
Quick start

*Cohort studies*

IRR and difference for the number of cases stored in cases for binary indicator exposed given time exposed time

\[ \text{ir cases exposed time} \]

Crude and Mantel–Haenszel combined IRRs with test of homogeneity for strata defined by svar

\[ \text{ir cases exposed time, by(svar)} \]

As above, and standardize the IRR by weighting variable wvar1

\[ \text{ir cases exposed time, by(svar) standard(wvar1)} \]

As above, but use person-time of the unexposed group as weights

\[ \text{ir cases exposed time, by(svar) estandard} \]

IRR and difference for 10 cases over 50 person-years in the exposed group and 15 cases over 100 person-years in the unexposed group

\[ \text{iri 10 15 50 100} \]

Risk difference and ratio with binary indicators case and exposed using cumulative incidence data

\[ \text{cs case exposed \{fweight=wvar2\}} \]

Add odds ratios and calculate Fisher's exact \( p \)

\[ \text{cs case exposed \{fweight=wvar2\}, or exact} \]

Internally standardized risk ratio for strata defined by svar

\[ \text{cs case exposed \{fweight=wvar2\}, by(svar) istandard} \]

Risk difference and ratio for 12 cases and 55 noncases among exposed subjects and 16 cases and 125 noncases among unexposed subjects

\[ \text{csi 12 16 55 125} \]

*Case–control studies*

Odds ratios from summary data with binary indicators case and exposed and frequency weight wvar3

\[ \text{cc case exposed \{fweight=wvar3\}} \]

As above, but stratify analysis by svar and perform Breslow–Day and Tarone’s homogeneity tests

\[ \text{cc case exposed \{fweight=wvar3\}, by(svar) bd tarone} \]

Odds ratios for 37 exposed cases, 148 unexposed cases, 7 exposed controls, and 137 unexposed controls

\[ \text{cci 37 148 7 137} \]

Odds of binary event against catvar using summary data with frequency weight wvar4

\[ \text{tabodds event catvar \{fweight=wvar4\}} \]

As above, but report odds ratios with the fourth level of catvar as the reference

\[ \text{tabodds event catvar \{fweight=wvar4\}, or base(4)} \]
As above, but tabulate Mantel–Haenszel adjusted odds ratios adjusting for values of categorical variable \( a \)

\[ \texttt{tabodds event catvar [fweight=wvar4], base(4) adjust(a)} \]

Graph odds and confidence intervals against categories of \( \text{catvar} \)

\[ \texttt{tabodds event catvar [fweight=wvar4], ciplot} \]

Odds ratios for the effect of \( \text{catvar} \) on \( \text{event} \) controlling for categorical variable \( a \) using summary data with frequency weight \( \text{wvar5} \)

\[ \texttt{mhodds event catvar a [fweight=wvar5]} \]

As above, but calculate odds ratios for each level of \( s\text{var} \)

\[ \texttt{mhodds event catvar a [fweight=wvar5], by(svar)} \]

Maximum likelihood estimate of odds ratio for a equal to 4 compared with a equal to 1

\[ \texttt{mhodds event a [fweight=wvar5], compare(4,1)} \]

Statistics on the difference in the proportion with the factor for exposed cases indicated in \( \text{expcase} \) and exposed controls indicated in \( \text{expcontrol} \) using summary data with frequency weight \( \text{wvar6} \)

\[ \texttt{mcc expcase expcontrol [fweight=wvar6]} \]

As above, but indicate that there are 4 pairs where both cases and controls were exposed, 9 pairs where the case was exposed but the control was not, 3 pairs where the control was exposed but the case was not, and 14 pairs where neither subject was exposed

\[ \texttt{mcci 4 9 3 14} \]

Fweights are allowed; see [U] 11.1.6 weight.
Options

Options are listed in the order that they appear in the syntax tables above. The commands for which the option is valid are indicated in parentheses immediately after the option name.

by(varname[, missing]) (ir, cs, cc, and mhodds) specifies that the tables be stratified on varname. Missing categories in varname are omitted from the stratified analysis, unless option missing is specified within by(). Within-stratum statistics are shown and then combined with Mantel–Haenszel weights. If estandard, istandard, or standard() is also specified (see below), the weights specified are used in place of Mantel–Haenszel weights.
estandard, istandard, and standard(varname) (ir, cs, and cc) request that within-stratum statistics be combined with external, internal, or user-specified weights to produce a standardized estimate. These options are mutually exclusive and can be used only when by() is also specified. (When by() is specified without one of these options, Mantel–Haenszel weights are used.)
estandard external weights are the person-time for the unexposed (ir), the total number of unexposed (cs), or the number of unexposed controls (cc).
istandard internal weights are the person-time for the exposed (ir), the total number of exposed (cs), or the number of exposed controls (cc). istandard can be used to produce, among other things, standardized mortality ratios (SMRs).
standard(varname) allows user-specified weights. varname must contain a constant within stratum and be nonnegative. The scale of varname is irrelevant.
pool (ir, cs, and cc) specifies that, in a stratified analysis, the directly pooled estimate also be displayed. The pooled estimate is a weighted average of the stratum-specific estimates using inverse-variance weights, which are the inverse of the variance of the stratum-specific estimate. pool is relevant only if by() is also specified.
nocrude (ir, cs, and cc) specifies that in a stratified analysis the crude estimate—an estimate obtained without regard to strata—not be displayed. nocrude is relevant only if by() is also specified.
nohom (ir, cs, and cc) specifies that a $\chi^2$ test of homogeneity not be included in the output of a stratified analysis. This tests whether the exposure effect is the same across strata and can be performed for any pooled estimate—directly pooled or Mantel–Haenszel. nohom is relevant only if by() is also specified.
ird (ir) may be used only with estandard, istandard, or standard(). It requests that ir calculate the standardized incidence-rate difference rather than the default incidence-rate ratio.
rd (cs) may be used only with estandard, istandard, or standard(). It requests that cs calculate the standardized risk difference rather than the default risk ratio.
bd (cc) specifies that Breslow and Day’s $\chi^2$ test of homogeneity be included in the output of a stratified analysis. This tests whether the exposure effect is the same across strata. bd is relevant only if by() is also specified.
tarone (cc) specifies that Tarone’s $\chi^2$ test of homogeneity, which is a correction to the Breslow–Day test, be included in the output of a stratified analysis. This tests whether the exposure effect is the same across strata. tarone is relevant only if by() is also specified.
binomial(varname) (cs, cc, tabodds, and mhodds) supplies the number of subjects (cases plus controls) for binomial frequency records. For individual and simple frequency records, this option is not used.

or (cs, csi, and tabodds), for cs and csi, reports the calculation of the odds ratio in addition to the risk ratio if by() is not specified. With by(), or specifies that a Mantel–Haenszel estimate of the combined odds ratio be made rather than the Mantel–Haenszel estimate of the risk ratio. In either case, this is the same calculation that would be made by cc and cci. Typically, cc, cci, or tabodds is preferred for calculating odds ratios. For tabodds, or specifies that odds ratios be produced; see base() for details about selecting a reference category. By default, tabodds will calculate odds.

adjust(varlist) (tabodds) specifies that odds ratios adjusted for the variables in varlist be calculated.

base(#) (tabodds) specifies that the #th category of expvar be used as the reference group for calculating odds ratios. If base() is not specified, the first category, corresponding to the minimum value of expvar, is used as the reference group.

cornfield (cc, cci, and tabodds) requests that the Cornfield (1956) approximation be used to calculate the confidence interval of the odds ratio. By default, cc and cci report an exact interval and tabodds reports a standard-error–based interval, with the standard error coming from the square root of the variance of the score statistic.

woolf (cs, csi, cc, cci, and tabodds) requests that the Woolf (1955) approximation, also known as the Taylor expansion, be used for calculating the standard error and confidence interval for the odds ratio. By default, cs and csi with the or option report the Cornfield (1956) interval; cc and cci report an exact interval; and tabodds reports a standard-error–based interval, with the standard error coming from the square root of the variance of the score statistic.

exact (cs, csi, cc, and cci) requests that Fisher’s exact p be calculated rather than the $\chi^2$ and its significance level. We recommend specifying exact whenever samples are small. When the least-frequent cell contains 1,000 cases or more, there will be no appreciable difference between the exact significance level and the significance level based on the $\chi^2$, but the exact significance level will take considerably longer to calculate. exact does not affect whether exact confidence intervals are calculated. Commands always calculate exact confidence intervals where they can, unless cornfield or woolf is specified.

compare($v_1$, $v_2$) (mhodds) indicates the categories of expvar to be compared; $v_1$ defines the numerator and $v_2$, the denominator. When compare() is not specified and there are only two categories, the second is compared to the first; when there are more than two categories, an approximate estimate of the odds ratio for a unit increase in expvar, controlled for specified confounding variables, is given.

level(#) (ir, iri, cs, csi, cc, cci, tabodds, mhodds, mcc, and mcci) specifies the confidence level, as a percentage, for confidence intervals. The default is level(95) or as set by set level; see [R] level.
The following options are for use only with \texttt{tabodds}.

---

\textbf{Main graph} (\texttt{tabodds}) produces a graph of the odds against the numerical code used for the categories of \textit{expvar}. All graph options except \texttt{connect()} are allowed. This option is not allowed with the \texttt{or} option or the \texttt{adjust()} option.

\textbf{ciplot} (\texttt{tabodds}) produces the same plot as the \texttt{graph} option, except that it also includes the confidence intervals. This option may not be used with either the \texttt{or} option or the \texttt{adjust()} option.

---

\textbf{CI plot} \texttt{ciplot(rcap options)} (\texttt{tabodds}) is allowed only with the \texttt{ciplot} option. It affects the rendition of the confidence bands; see [G-3] \texttt{rcap options}.

---

\textbf{Plot} \texttt{marker\_options} (\texttt{tabodds}) affect the rendition of markers drawn at the plotted points, including their shape, size, color, and outline; see [G-3] \texttt{marker\_options}.

\texttt{marker\_label\_options} (\texttt{tabodds}) specify if and how the markers are to be labeled; see [G-3] \texttt{marker\_label\_options}.

\texttt{cline\_options} (\texttt{tabodds}) affect whether lines connect the plotted points and the rendition of those lines; see [G-3] \texttt{cline\_options}.

---

\textbf{Add plots} \texttt{addplot(plot)} (\texttt{tabodds}) provides a way to add other plots to the generated graph; see [G-3] \texttt{addplot\_option}.

---

\textbf{Y axis, X axis, Titles, Legend, Overall} \texttt{twoway\_options} (\texttt{tabodds}) are any of the options documented in [G-3] \texttt{twoway\_options}, excluding \texttt{by()}. These include options for titling the graph (see [G-3] \texttt{title\_options}) and options for saving the graph to disk (see [G-3] \texttt{saving\_option}).

---

\textbf{Remarks and examples}

Remarks are presented under the following headings:

- Incidence-rate data
- Stratified incidence-rate data
- Standardized estimates with stratified incidence-rate data
- Cumulative incidence data
- Stratified cumulative incidence data
- Standardized estimates with stratified cumulative incidence data
- Case–control data
- Stratified case–control data
- Case–control data with multiple levels of exposure
- Case–control data with confounders and possibly multiple levels of exposure
- Standardized estimates with stratified case–control data
- Matched case–control data
- Video examples
- Glossary
To calculate appropriate statistics and suppress inappropriate statistics, the \texttt{ir}, \texttt{cs}, \texttt{cc}, \texttt{tabodds}, \texttt{mhodds}, and \texttt{mcc} commands, along with their immediate counterparts, are organized in the way epidemiologists conceptualize data. \texttt{ir} processes incidence-rate data from prospective studies; \texttt{cs}, cohort study data with equal follow-up time (cumulative incidence); \texttt{cc}, \texttt{tabodds}, and \texttt{mhodds}, case–control or cross-sectional (prevalence) data; and \texttt{mcc}, matched case–control data. With the exception of \texttt{mcc}, these commands work with both simple and stratified tables.

Epidemiological data are often summarized in a contingency table from which various statistics are calculated. The rows of the table reflect cases and noncases or cases and person-time, and the columns reflect exposure to a risk factor. To an epidemiologist, cases and noncases refer to the outcomes of the process being studied. For instance, a case might be a person with cancer and a noncase might be a person without cancer.

A factor is something that might affect the chances of being ultimately designated a case or a noncase. Thus a case might be a cancer patient and the factor, smoking behavior. A person is said to be exposed or unexposed to the factor. Exposure can be classified as a dichotomy, smokes or does not smoke, or as multiple levels, such as number of cigarettes smoked per week.

For an introduction to epidemiological methods, see Walker (1991). For an intermediate treatment, see Clayton and Hills (1993) and Lilienfeld and Stolley (1994). For other advanced discussions, see Kleinbaum, Kupper, and Morgenstern (1982) and Rothman, Greenland, and Lash (2008). For an analysis of incidence rates, see, for instance, Cummings (2019). For an anthology of writings on epidemiology since World War II, see Greenland (1987). See Jewell (2004) for a text aimed at graduate students in the medical professions that uses Stata for much of the analysis. See Dohoo, Martin, and Stryhn (2010) for a graduate-level text on the principles and methods of veterinary epidemiologic research; Stata datasets and do-files are available. Also see Dohoo, Martin, and Stryhn (2012) for a text that is a revision of their veterinary epidemiology text, but examples from human epidemiology are used.

\textbf{Incidence-rate data}

In incidence-rate data from a prospective study, you observe the transformation of noncases into cases. Starting with a group of noncase subjects, you monitor them to determine whether they become cases (for example, stricken with cancer). You monitor two populations: those exposed and those unexposed to the factor (for example, multiple X-rays). A summary of the data is

\begin{center}
\begin{tabular}{lrr}
 & Exposed & Unexposed \\
\hline
Cases & $a$ & $b$ \\
Person-time & $N_1$ & $N_0$ \\
\hline
& $a + b$ & $N_1 + N_0$
\end{tabular}
\end{center}

\textbf{Example 1: iri}

It will be easiest to understand these commands if we start with the immediate forms. Remember, in the immediate form, we specify the data on the command line rather than specifying names of variables containing the data; see \textbf{[U] 19 Immediate commands}. We have data (Boice and Monson [1977]; reported in Rothman, Greenland, and Lash [2008, 244]) on breast cancer cases and person-years of observation for women with tuberculosis repeatedly exposed to multiple X-ray fluoroscopies, and those not so exposed:

\begin{center}
\begin{tabular}{lrr}
 & X-ray fluoroscopy \\
Exposed & Unexposed \\
\hline
Breast cancer cases & 41 & 15 \\
Person-years & 28,010 & 19,017
\end{tabular}
\end{center}
Using \textit{iri}, the immediate form of \textit{ir}, we specify the values in the table following the command:

\begin{verbatim}
. iri 41 15 28010 19017
\end{verbatim}

<table>
<thead>
<tr>
<th></th>
<th>Exposed</th>
<th>Unexposed</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>Cases</td>
<td>41</td>
<td>15</td>
<td>56</td>
</tr>
<tr>
<td>Person-time</td>
<td>28010</td>
<td>19017</td>
<td>47027</td>
</tr>
<tr>
<td>Incidence rate</td>
<td>.0014638</td>
<td>.0007888</td>
<td>.0011908</td>
</tr>
<tr>
<td>Point estimate</td>
<td>[95% Conf. Interval]</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Inc. rate diff.</td>
<td>.000675</td>
<td>.0000749</td>
<td>.0012751</td>
</tr>
<tr>
<td>Inc. rate ratio</td>
<td>1.855759</td>
<td>1.005684</td>
<td>3.6093 (exact)</td>
</tr>
<tr>
<td>Attr. frac. ex.</td>
<td>.4611368</td>
<td>.0056519</td>
<td>.722938 (exact)</td>
</tr>
<tr>
<td>Attr. frac. pop</td>
<td>.337618</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

(\textit{midp}) \Pr(k\geq41) = 0.0177 (exact)
(\textit{midp}) 2\times\Pr(k\geq41) = 0.0355 (exact)

\textit{iri} shows the table, reports the incidence rates for the exposed and unexposed populations, and then shows the point estimates of the difference and ratio of the two incidence rates along with their confidence intervals. The incidence rate is simply the frequency with which noncases are transformed into cases.

Next \textit{iri} reports the attributable fraction among the exposed population, an estimate of the proportion of exposed cases attributable to exposure. We estimate that 46.1\% of the 41 breast cancer cases among the exposed were due to exposure. (Had the incidence-rate ratio been less than 1, \textit{iri} would have reported the prevented fraction in the exposed population, an estimate of the net proportion of all potential cases in the exposed population that was prevented by exposure; see the following technical note.)

After that, the table shows the attributable fraction in the total population, which is the net proportion of all cases attributable to exposure. This number, of course, depends on the proportion of cases that are exposed in the base population, which here is taken to be 41/56 and may not be relevant in all situations. We estimate that 33.8\% of the 56 cases were due to exposure. We estimate that 18.9 cases were caused by exposure; that is, \(0.338 \times 56 = 0.461 \times 41 = 18.9\).

At the bottom of the table, \textit{iri} reports both one- and two-sided exact significance tests. For the one-sided test, the probability that the number of exposed cases is 41 or greater is 0.0177. This is a “\textit{midp}” calculation; see \textit{Methods and formulas} below. The two-sided test is \(2 \times 0.0177 = 0.0354\).

\begin{itemize}
  \item \textbf{Technical note}
\end{itemize}

When the incidence-rate ratio is less than 1, \textit{iri} (and \textit{ir}, \textit{cs}, \textit{csi}, \textit{cc}, and \textit{cci}) substitutes the prevented fraction for the attributable fraction. Let’s reverse the roles of exposure in the above data, treating as exposed a person who did not receive the X-ray fluoroscopy. You can think of this as a new treatment for preventing breast cancer—the suggested treatment being not to use fluoroscopy.
### Example 2: ir

`ir` works like `iri`, except that it obtains the entries in the tables by summing data. You specify three variables: the first represents the number of cases represented by this observation, the second indicates whether the observation is for subjects exposed to the factor, and the third records the total time the subjects in this observation were observed. An observation may reflect one subject or a group of subjects.

For instance, here is a 2-observation dataset for the table in the previous example:

```stata
.use https://www.stata-press.com/data/r16/irxmpl
.list
cases exposed time
1. 41 0 28010
2. 15 1 19017
```

If we typed `ir cases exposed time`, we would obtain the same output that we obtained above. Another way the data might be recorded is...
Here the first 2 observations will be automatically summed by `ir` because both are exposed. Finally, the data might be individual-level data:

```
. use https://www.stata-press.com/data/r16/irxmpl3
. list in 1/5
```

<table>
<thead>
<tr>
<th>cases</th>
<th>exposed</th>
<th>time</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>1</td>
<td>10</td>
</tr>
<tr>
<td>2</td>
<td>0</td>
<td>8</td>
</tr>
<tr>
<td>3</td>
<td>0</td>
<td>9</td>
</tr>
<tr>
<td>4</td>
<td>1</td>
<td>2</td>
</tr>
<tr>
<td>5</td>
<td>0</td>
<td>1</td>
</tr>
</tbody>
</table>

The first observation represents a woman who got cancer, was exposed, and was observed for 10 years. The second is a woman who did not get cancer, was exposed, and was observed for 8 years, and so on.

---

**Technical note**

`ir` (and all the other commands) assumes that a subject was exposed if the exposed variable is nonzero and not missing, assumes the subject was not exposed if the variable is zero, and ignores the observation if the variable is missing. For `ir`, the case variable and the time variable are restricted to nonnegative integers and are summed within the exposed and unexposed groups to obtain the entries in the table.
Stratified incidence-rate data

Example 3: ir with stratified data

`ir` can work with stratified tables, as well as with single tables. For instance, Rothman (1986, 185) discusses data from Rothman and Monson (1973) on mortality by sex and age for patients with trigeminal neuralgia:

```
<table>
<thead>
<tr>
<th>Age through 64</th>
<th>Age 65+</th>
</tr>
</thead>
<tbody>
<tr>
<td>Males</td>
<td>Females</td>
</tr>
<tr>
<td>Deaths</td>
<td>14</td>
</tr>
<tr>
<td>Person-years</td>
<td>1516</td>
</tr>
</tbody>
</table>
```

Entering the data into Stata, we have the following dataset:

```
. use https://www.stata-press.com/data/r16/rm
(Rothman and Monson 1973 data)
. list

<table>
<thead>
<tr>
<th>age</th>
<th>male</th>
<th>deaths</th>
<th>pyears</th>
</tr>
</thead>
<tbody>
<tr>
<td>&lt;65</td>
<td>1</td>
<td>14</td>
<td>1516</td>
</tr>
<tr>
<td>&lt;65</td>
<td>0</td>
<td>10</td>
<td>1701</td>
</tr>
<tr>
<td>65+</td>
<td>1</td>
<td>76</td>
<td>949</td>
</tr>
<tr>
<td>65+</td>
<td>0</td>
<td>121</td>
<td>2245</td>
</tr>
</tbody>
</table>
```

The stratified analysis of the incidence-rate ratio is

```
. ir deaths male pyears, by(age)
```

<table>
<thead>
<tr>
<th>Age category</th>
<th>IRR</th>
<th>[95% Conf. Interval]</th>
<th>M-H Weight</th>
</tr>
</thead>
<tbody>
<tr>
<td>&lt;65</td>
<td>1.570844</td>
<td>0.6489373 3.952809</td>
<td>4.712465 (exact)</td>
</tr>
<tr>
<td>65+</td>
<td>1.485862</td>
<td>1.100305 1.99584</td>
<td>35.95147 (exact)</td>
</tr>
<tr>
<td>Crude</td>
<td>1.099794</td>
<td>0.831437 1.449306</td>
<td>(exact)</td>
</tr>
<tr>
<td>M-H combined</td>
<td>1.49571</td>
<td>1.141183 1.960377</td>
<td></td>
</tr>
</tbody>
</table>

Test of homogeneity (M-H) chi2(1) = 0.02 Pr>chi2 = 0.8992

The row labeled M-H combined reflects the combined Mantel–Haenszel estimates.

As with the previous example, it is not important that each entry in the table correspond to 1 observation in the data—`ir` sums the time (`pyears`) and case (`deaths`) variables within the exposure (`male`) category.

The difference between the unadjusted crude estimate and the Mantel–Haenszel estimate suggests confounding by age: women in the study are older, and older patients are more likely to die. But we should not use the Mantel–Haenszel estimate without checking its homogeneity assumption. The chi-squared test of homogeneity gives a p-value of 0.8992, so we have no evidence that the exposure effect (the effect of being male) differs across age categories. We are justified in using the Mantel–Haenszel estimate.
Stratification is one way to deal with confounding; that is, perhaps sex affects the incidence of trigeminal neuralgia and so does age, so the table was stratified by age in an attempt to uncover the sex effect. (We are concerned that age may confound the true association between sex and the incidence of trigeminal neuralgia because the age distributions are so different for males and females. If age affects incidence, the difference in the age distributions would induce different incidences for males and females and thus confound the true effect of sex.)

We do not, however, have to use tables to uncover effects; the estimation alternative when we have aggregate data is Poisson regression, and we can use the same data on which we ran `ir` with `poisson`. Poisson regression also works with individual-level data.

(Although age in the previous example appears to be a string, it is actually a numeric variable taking on values 1 and 2. We attached a value label to produce the labels <65 and 65+ to make `ir`'s output look better; see [U] 12.6.3 Value labels. Stata’s estimation commands will ignore this labeling.)

```
. poisson deaths male age, exposure(pyears) irr
Iteration 0: log likelihood = -10.836732
Iteration 1: log likelihood = -10.734087
Iteration 2: log likelihood = -10.733944
Iteration 3: log likelihood = -10.733944
Poisson regression Number of obs = 4
LR chi2(2) = 164.01
Prob > chi2 = 0.0000
Log likelihood = -10.733944 Pseudo R2 = 0.8843

                deaths | IRR   Std. Err.      z    P>|z|     [95% Conf. Interval]
-------------|------------------|------------------|------|--------|-----------------------------
     male     | 1.495096   .2060997  2.92  0.004    1.141118    1.958888
     age      | 8.888775   1.934943  10.04  0.000    5.801616    13.61867
   _cons     | 0.0006805  .0002908 -17.07  0.000    0.0002945   0.0015724
ln(pyears)  | 1 (exposure)                                      
```

Note: _cons estimates baseline incidence rate.

Compare these results with the Mantel–Haenszel estimates produced by `ir`:

```
          Source |    IR Ratio |  95% Conf. Int.
-------------|-------------|-----------------
 Mantel–Haenszel (ir) | 1.50 | 1.14 1.96
     poisson   | 1.50 | 1.14 1.96
```

The results from `poisson` agree with the Mantel–Haenszel estimates to two decimal places. But `poisson` also estimates an incidence-rate ratio for age. Here the estimate is not of much interest, because the outcome variable is total mortality and we already knew that older people have a higher mortality rate. In other contexts, however, the estimate might be of greater interest.

See [R] poisson for an explanation of the `poisson` command.
. poisson deaths male age male#c.age, exposure(pyears) irr

Note: _cons estimates baseline incidence rate.

The significance level of the male#c.age effect is 0.899, the same as previously reported by ir.

Here forming the male-times-age interaction effect was easy because there were only two age groups. Had there been more groups, the test would have been slightly more difficult—see the following technical note.

ʔTechnical note

A word of caution is in order when applying poisson (or any estimation technique) to more than two age categories. Say that in our data, we had three age categories, which we will call categories 0, 1, and 2, and that they are stored in the variable agecat. We might think of the categories as corresponding to age less than 35, 35–64, and 65 and above.

With such data, we might type `ir deaths male pyears, by(agecat)` but we would not type `poisson deaths male agecat, exposure(pyears)` to obtain the equivalent Poisson-regression estimated results. Such a model might be reasonable, but it is not equivalent because we would be constraining the age effect in category 2 to be (multiplicatively) twice the effect in category 1.

To poisson (and all of Stata’s estimation commands other than anova), agecat is simply one variable, and only one estimated coefficient is associated with it. Thus the model is

\[
P = \beta_0 + \beta_1 \text{male} + \beta_2 \text{agecat}
\]

The expected number of deaths is then \( e^P \), and the incidence-rate ratio associated with a variable is \( e^\beta \); see [R] poisson. Thus the value of the Poisson index when `male==0` and `agecat==1` is \( \beta_0 + \beta_2 \), and the possibilities are

<table>
<thead>
<tr>
<th></th>
<th>male==0</th>
<th>male==1</th>
</tr>
</thead>
<tbody>
<tr>
<td>agecat==0</td>
<td>( \beta_0 )</td>
<td>( \beta_0 + \beta_1 )</td>
</tr>
<tr>
<td>agecat==1</td>
<td>( \beta_0 + \beta_2 )</td>
<td>( \beta_0 + \beta_2 + \beta_1 )</td>
</tr>
<tr>
<td>agecat==2</td>
<td>( \beta_0 + 2\beta_2 )</td>
<td>( \beta_0 + 2\beta_2 + \beta_1 )</td>
</tr>
</tbody>
</table>
The age effect for \texttt{agecat==2} is constrained to be twice the age effect for \texttt{agecat==1}—the only difference between lines 3 and 2 of the table is that $\beta_2$ is replaced with $2\beta_2$. Under certain circumstances, such a constraint might be reasonable, but it does not correspond to the assumptions made in generating the Mantel–Haenszel combined results.

To obtain results equivalent to the Mantel–Haenszel result, we must estimate a separate effect for each age group, meaning that we must replace $2\beta_2$, the constrained effect, with $\beta_3$, a new coefficient that is free to take on any value. We can achieve this by creating two new variables and using them in place of \texttt{agecat}. \texttt{agecat1} will take on the value 1 when \texttt{agecat} is 1 and 0 otherwise; \texttt{agecat2} will take on the value 1 when \texttt{agecat} is 2 and 0 otherwise:

\begin{verbatim}
    . generate agecat1 = (agecat==1)
    . generate agecat2 = (agecat==2)
    . poisson deaths male agecat1 agecat2 [freq=pop], exposure(pyears) irr
\end{verbatim}

In Stata, we do not have to generate these variables for ourselves. We could use factor variables:

\begin{verbatim}
    . poisson deaths male i.agecat [freq=pop], exposure(pyears) irr
\end{verbatim}

See [U] 11.4.3 Factor variables.

To reproduce the homogeneity test with multiple age categories, we could type

\begin{verbatim}
    . poisson deaths agecat##male [freq=pop], exp(pyears) irr
    . testparm agecat#male
\end{verbatim}

Poisson regression combined with factor variables generalizes to multiway tables. Suppose that there are three exposure categories. Assume exposure variable \texttt{burn} takes on the values 1, 2, and 3 for first-, second-, and third-degree burns. The table itself is estimated by typing

\begin{verbatim}
    . poisson deaths i.burn i.agecat [freq=pop], exp(pyears) irr
\end{verbatim}

and the test of homogeneity is estimated by typing

\begin{verbatim}
    . poisson deaths burn##agecat [freq=pop], exp(pyears) irr
    . testparm burn#agecat
\end{verbatim}

\section*{Standardized estimates with stratified incidence-rate data}

The by() option specifies that the data are stratified and, by default, will produce a Mantel–Haenszel combined estimate of the incidence-rate ratio. With the estandard, istandard, or standard(varname) options, you can specify your own weights and obtain standardized estimates of the incidence-rate ratio or difference.

\begin{example}

\textbf{Example 4: ir with stratified data, using standardized estimates}

\begin{table}[h]
\begin{tabular}{llll}
\hline
Age & Smokers & Non-smokers \\
   & Deaths & Person-years & Deaths & Person-years \\
35–44 & 32 & 52,407 & 2 & 18,790 \\
45–54 & 104 & 43,248 & 12 & 10,673 \\
55–64 & 206 & 28,612 & 28 & 5,710 \\
65–74 & 186 & 12,663 & 28 & 2,585 \\
75–84 & 102 & 5,317 & 31 & 1,462 \\
\hline
\end{tabular}
\end{table}
\end{example}
We have entered these data into Stata:

```
. use https://www.stata-press.com/data/r16/dollhill3
  (Doll and Hill (1966))
. list
```

<table>
<thead>
<tr>
<th>agecat</th>

Note the presence of heterogeneity revealed by the test; the effect of smoking is not the same across age categories. Moreover, the listed stratum-specific estimates show an effect that appears to be declining with age. (Even if the test of homogeneity is not significant, you should always examine estimates carefully when stratum-specific effects occur on both sides of 1 for ratios and 0 for differences.)

Rothman, Greenland, and Lash (2008, 269) obtain the standardized incidence-rate ratio and 90% confidence intervals, weighting each age category by the population of the exposed group, thus producing the standardized mortality ratio (SMR). This calculation can be reproduced by specifying by(age) to indicate that the table is stratified and istandard to specify that we want the internally standardized rate. We may also specify that we would like to see the pooled estimate (weighted average where the weights are based on the variance of the strata calculations):
We obtained the simple pooled results because we specified the `pool` option. Note the significance of the homogeneity test; it provides the motivation for standardizing the rate ratios.

If we wanted the externally standardized ratio (weights proportional to the population of the unexposed group), we would substitute `estandard` for `istandard` in the above command.

We are not limited to incidence-rate ratios; `ir` can also estimate incidence-rate differences. Differences may be standardized internally or externally. We will obtain the internally weighted difference (Rothman, Greenland, and Lash 2008, 266–267):

In addition to calculating results by using internal or external weights, `ir` (and `cs` and `cc`) can calculate results for arbitrary weights. If we wanted to obtain the incidence-rate ratio weighting each age category equally, we would type:

```
. generate conswgt=1
. ir deaths smokes pyears, by(age) standard(conswgt)
```
Technical note

`estandard` and `istandard` are convenience features; they do nothing different from what you could accomplish by creating the appropriate weights and using the `standard()` option. For instance, we could duplicate the previously shown results of `istandard` (example before last) by typing

```
sort age smokes
by age: generate wgt=pyears[_N]
list in 1/4
```

```
agecat smokes deaths pyears conswgt wgt
1. 35-44 0 2 18,790 1 52407
2. 35-44 1 32 52,407 1 52407
3. 45-54 0 12 10,673 1 43248
4. 45-54 1 104 43,248 1 43248
```

```
sort age smokes
by age: gen wgt=pyears[_N]
```

Cumulative incidence data

Cumulative incidence data are “follow-up data with denominators consisting of persons rather than person-time” (Rothman 1986, 172). A group of noncases is monitored for some time, during which some become cases. Each subject is also known to be exposed or unexposed. A summary of the data is

<table>
<thead>
<tr>
<th></th>
<th>Exposed</th>
<th>Unexposed</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>Cases</td>
<td>a</td>
<td>b</td>
<td>a + b</td>
</tr>
<tr>
<td>Noncases</td>
<td>c</td>
<td>d</td>
<td>c + d</td>
</tr>
<tr>
<td>Total</td>
<td>a + c</td>
<td>b + d</td>
<td>a + b + c + d</td>
</tr>
</tbody>
</table>

Data of this type are generally summarized using the risk ratio, \( \frac{a}{a+c} / \frac{b}{b+d} \). A ratio of 2 means that an exposed subject is twice as likely to become a case than is an unexposed subject, a ratio of one-half means half as likely, and so on. The “null” value—the number corresponding to no effect—is a ratio of 1. If cross-sectional data are analyzed in this format, the risk ratio becomes a prevalence ratio.

Example 6: csi

We have data on diarrhea during a 10-day follow-up period among 30 breast-fed infants colonized with *Vibrio cholerae* 01 according to antilipopolysaccharide antibody titers in the mother’s breast milk (Glass et al. [1983]; reported in Rothman, Greenland, and Lash [2008, 248]):

<table>
<thead>
<tr>
<th>Antibody level</th>
<th>High</th>
<th>Low</th>
</tr>
</thead>
<tbody>
<tr>
<td>Diarrhea</td>
<td>7</td>
<td>12</td>
</tr>
<tr>
<td>No diarrhea</td>
<td>9</td>
<td>2</td>
</tr>
</tbody>
</table>
The `csi` command works much like the `iri` command. Our sample is small, so we will specify the `exact` option.

\[. csi 7 12 9 2, \text{exact}\]

<table>
<thead>
<tr>
<th></th>
<th>Exposed</th>
<th>Unexposed</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>Cases</td>
<td>7</td>
<td>12</td>
<td>19</td>
</tr>
<tr>
<td>Noncases</td>
<td>9</td>
<td>2</td>
<td>11</td>
</tr>
<tr>
<td>Total</td>
<td>16</td>
<td>14</td>
<td>30</td>
</tr>
</tbody>
</table>

Risk

<table>
<thead>
<tr>
<th>risk difference</th>
<th>Point estimate [95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>-.4196429</td>
<td>-.7240828 - .1152029</td>
</tr>
<tr>
<td>Risk ratio</td>
<td>.5104167 .2814332 .9257086</td>
</tr>
<tr>
<td>Prev. frac. ex.</td>
<td>.4895833 .0742914 .7185668</td>
</tr>
<tr>
<td>Prev. frac. pop</td>
<td>.2611111</td>
</tr>
</tbody>
</table>

1-sided Fisher’s exact \(P = 0.0212\)
2-sided Fisher’s exact \(P = 0.0259\)

We find that high antibody levels reduce the risk of diarrhea (the risk falls from 0.86 to 0.44). The difference is just significant at the 2.59% two-sided level. (Had we not specified the `exact` option, a \(\chi^2\) value and its significance level would have been reported in place of Fisher’s exact \(p\). The calculated \(\chi^2\) two-sided significance level would have been 0.0173, but this calculation is inferior for small samples.)

---

## Technical note

By default, `cs` and `csi` do not report the odds ratio, but they will if you specify the `or` option. If you want odds ratios, however, use the `cc` or `cci` commands—the commands appropriate for case–control data—because `cs` and `csi` calculate the attributable (prevented) fraction with the risk ratio, even if you specify `or`:

\[. csi 7 12 9 2, \text{or exact}\]

<table>
<thead>
<tr>
<th></th>
<th>Exposed</th>
<th>Unexposed</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>Cases</td>
<td>7</td>
<td>12</td>
<td>19</td>
</tr>
<tr>
<td>Noncases</td>
<td>9</td>
<td>2</td>
<td>11</td>
</tr>
<tr>
<td>Total</td>
<td>16</td>
<td>14</td>
<td>30</td>
</tr>
</tbody>
</table>

Risk

<table>
<thead>
<tr>
<th>risk difference</th>
<th>Point estimate [95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>-.4196429</td>
<td>-.7240828 - .1152029</td>
</tr>
<tr>
<td>Risk ratio</td>
<td>.5104167 .2814332 .9257086</td>
</tr>
<tr>
<td>Prev. frac. ex.</td>
<td>.4895833 .0742914 .7185668</td>
</tr>
<tr>
<td>Prev. frac. pop</td>
<td>.2611111</td>
</tr>
<tr>
<td>Odds ratio</td>
<td>.1296296 .0246233 .7180882 (Cornfield)</td>
</tr>
</tbody>
</table>

1-sided Fisher’s exact \(P = 0.0212\)
2-sided Fisher’s exact \(P = 0.0259\)
Technical note

As with iri and ir, csi and cs report either the attributable or the prevented fraction for the exposed and total populations; see the discussion under Incidence-rate data above. In example 6, we estimated that 49% of potential cases in the exposed population were prevented by exposure. We also estimated that exposure accounted for a 26% reduction in cases over the entire population, but that is based on the exposure distribution of the (small) population (16/30) and probably is of little interest.

Fleiss, Levin, and Paik (2003, 128) report infant mortality by birthweight for 72,730 live white births in 1974 in New York City:

<table>
<thead>
<tr>
<th></th>
<th>Exposed</th>
<th>Unexposed</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>Cases</td>
<td>618</td>
<td>422</td>
<td>1040</td>
</tr>
<tr>
<td>Noncases</td>
<td>4597</td>
<td>67093</td>
<td>71690</td>
</tr>
<tr>
<td>Total</td>
<td>5215</td>
<td>76515</td>
<td>72730</td>
</tr>
</tbody>
</table>

| Risk     | .1185043 | .0062505 | .0142995 |
| Point estimate | [95% Conf. Interval] |
| Risk difference | .1122539 | .1034617 | .121046 |
| Risk ratio  | 18.95929 | 16.80661 | 21.38769 |
| Attr. frac. ex. | .9472554 | .9404996 | .9532441 |
| Attr. frac. pop | .5628883 |          |        |

\[ \chi^2(1) = 4327.92 \quad \text{Pr}>\chi^2 = 0.0000 \]

In these data, exposed means a premature baby (birthweight \(\leq 2,500\) g), and a case is a baby who is dead at the end of one year. We find that being premature accounts for 94.7% of deaths among the premature population. We also estimate, paraphrasing from Fleiss, Levin, and Paik (2003, 128), that 56.3% of all white infant deaths in New York City in 1974 could have been prevented if prematurity had been eliminated. (Moreover, Fleiss, Levin, and Paik put a standard error on the attributable fraction for the population. The formula is given in Methods and formulas but is appropriate only for the population on which the estimates are based because other populations may have different probabilities of exposure.)

Example 7: cs

cs works like csi, except that it obtains its information from the data. The data equivalent to typing `csi 7 12 9 2` are

```
  . use https://www.stata-press.com/data/r16/csxmpl, clear
  . list
```

<table>
<thead>
<tr>
<th>case</th>
<th>exp</th>
<th>pop</th>
</tr>
</thead>
<tbody>
<tr>
<td>1.</td>
<td>1</td>
<td>1</td>
</tr>
<tr>
<td>2.</td>
<td>1</td>
<td>0</td>
</tr>
<tr>
<td>3.</td>
<td>0</td>
<td>1</td>
</tr>
<tr>
<td>4.</td>
<td>0</td>
<td>0</td>
</tr>
</tbody>
</table>

We could then type `cs case exp [freq=pop]`. If we had individual-level data, so that each observation reflected a patient and we had 30 observations, we would type `cs case exp`. 

Example 8: cs with stratified data

Rothman, Greenland, and Lash (2008, 260) reprint the following age-specific information for deaths from all causes for tolbutamide and placebo treatment groups (University Group Diabetes Program 1970):

<table>
<thead>
<tr>
<th>Age through 54</th>
<th>Age 55 and above</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Tolbutamide</td>
</tr>
<tr>
<td>Dead</td>
<td>8</td>
</tr>
<tr>
<td>Surviving</td>
<td>98</td>
</tr>
</tbody>
</table>

The data corresponding to these results are

```
. use https://www.stata-press.com/data/r16/ugdp
. list
```

```
<table>
<thead>
<tr>
<th>age</th>
<th>case</th>
<th>exposed</th>
<th>pop</th>
</tr>
</thead>
<tbody>
<tr>
<td>&lt;55</td>
<td>0</td>
<td>0</td>
<td>115</td>
</tr>
<tr>
<td>&lt;55</td>
<td>0</td>
<td>1</td>
<td>98</td>
</tr>
<tr>
<td>&lt;55</td>
<td>1</td>
<td>0</td>
<td>5</td>
</tr>
<tr>
<td>&lt;55</td>
<td>1</td>
<td>1</td>
<td>8</td>
</tr>
<tr>
<td>55+</td>
<td>0</td>
<td>0</td>
<td>69</td>
</tr>
<tr>
<td>55+</td>
<td>0</td>
<td>1</td>
<td>76</td>
</tr>
<tr>
<td>55+</td>
<td>1</td>
<td>0</td>
<td>16</td>
</tr>
<tr>
<td>55+</td>
<td>1</td>
<td>1</td>
<td>22</td>
</tr>
</tbody>
</table>
```

The order of the observations is unimportant. If we were now to type `cs case exposed [freq=pop]`, we would obtain a summary for all the data, ignoring the stratification by age. To incorporate the stratification, we type

```
. cs case exposed [freq=pop], by(age)
```

<table>
<thead>
<tr>
<th>Age category</th>
<th>RR</th>
<th>[95% Conf. Interval]</th>
<th>M-H Weight</th>
</tr>
</thead>
<tbody>
<tr>
<td>&lt;55</td>
<td>1.811321</td>
<td>0.6112044</td>
<td>5.367898</td>
</tr>
<tr>
<td>55+</td>
<td>1.192602</td>
<td>0.6712664</td>
<td>2.11883</td>
</tr>
<tr>
<td>Crude</td>
<td>1.435574</td>
<td>0.8510221</td>
<td>2.421645</td>
</tr>
<tr>
<td>M-H combined</td>
<td>1.325555</td>
<td>0.797907</td>
<td>2.202132</td>
</tr>
</tbody>
</table>

Test of homogeneity (M-H)  
chi2(1) = 0.447  Pr>chi2 = 0.5037

Mantel–Haenszel weights are appropriate when the risks may differ according to the strata but the risk ratio is believed to be the same (homogeneous across strata). Under these assumptions, Mantel–Haenszel weights are designed to use the information efficiently. They are not intended to measure a composite risk ratio when the within-stratum risk ratios differ. Then we want a standardized ratio (see below).

The risk ratios above appear to differ markedly, but the confidence intervals are also broad because of the small sample sizes. The test of homogeneity shows that the differences can be attributed to chance; the use of the Mantel–Haenszel combined test is sensible.
Technical note

Stratified cumulative incidence tables are not the only way to control for confounding. Another way is logistic regression. However, logistic regression measures effects with odds ratios, not with risk ratios. So before we fit a logistic model, let’s use `cs` to estimate the Mantel–Haenszel odds ratio:

```
. cs case exposed [freq=pop], by(age) or
```

<table>
<thead>
<tr>
<th>Age category</th>
<th>OR [95% Conf. Interval]</th>
<th>M-H Weight</th>
</tr>
</thead>
<tbody>
<tr>
<td>&lt;55</td>
<td>1.877551 .6238165 5.637046</td>
<td>2.168142 (Cornfield)</td>
</tr>
<tr>
<td>55+</td>
<td>1.248355 .6112772 2.547411</td>
<td>6.644809 (Cornfield)</td>
</tr>
</tbody>
</table>

Crude

| OR [95% Conf. Interval] | |
|-------------------------|
| 1.510673 .8381198 2.722012 |

M-H combined

| OR [95% Conf. Interval] | |
|-------------------------|
| 1.403149 .7625152 2.582015 |

Test of homogeneity (M-H) chi2(1) = 0.347 Pr>chi2 = 0.5556

Test that combined OR = 1:
Mantel-Haenszel chi2(1) = 1.19
Pr>chi2 = 0.2750

The Mantel–Haenszel odds ratio is 1.40. It measures the association between death and treatment while adjusting for age. A more general way to adjust for age is logistic regression; the outcome variable is `case`, and it is explained by `age` and `exposed`. (As in the incidence-rate example, `age` may appear to be a string variable in our data—we listed the data in the previous example—but it is actually a numeric variable taking on values 0 and 1 with value labels disguising that fact; see [U] 12.6.3 Value labels.)

```
. logistic case exposed age [freq=pop]
```

Logistic regression

<table>
<thead>
<tr>
<th>Number of obs = 409</th>
</tr>
</thead>
<tbody>
<tr>
<td>LR chi2(2) = 22.47</td>
</tr>
<tr>
<td>Prob &gt; chi2 = 0.0000</td>
</tr>
<tr>
<td>Log likelihood = -142.6212</td>
</tr>
<tr>
<td>Pseudo R2 = 0.0730</td>
</tr>
</tbody>
</table>

| case | Odds Ratio | Std. Err. | z | P>|z| | [95% Conf. Interval] |
|------|------------|-----------|---|-----|---------------------|
| exposed | 1.404674 | .4374454 | 1.09 | 0.275 | .7629451 2.586175 |
| age | 4.216299 | 1.431519 | 4.24 | 0.000 | 2.167361 8.202223 |
| _cons | .0513818 | .0170762 | -8.93 | 0.000 | .0267868 .0985593 |

Note: _cons estimates baseline odds.

Compare these results with the Mantel–Haenszel estimates obtained with `cs`:

<table>
<thead>
<tr>
<th>Source</th>
<th>Odds Ratio</th>
<th>95% Conf. Int.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Mantel–Haenszel (cs)</td>
<td>1.40</td>
<td>0.76 2.58</td>
</tr>
<tr>
<td>logistic</td>
<td>1.40</td>
<td>0.76 2.59</td>
</tr>
</tbody>
</table>

They are virtually identical.

Logistic regression has advantages over the stratified-table approach. First, we obtained an estimate of the age effect: being 55 years or over significantly increases the odds of death. In addition to the point estimate, 4.22, we have a confidence interval for the effect: 2.17 to 8.20.

A discrete effect at age 55 is not a plausible model of aging. It would be more reasonable to assume that a 54-year-old patient has a higher probability of death, due merely to age, than does a 53-year-old patient; a 53-year-old, a higher probability than a 52-year-old patient; and so on. If we had the underlying data, where each patient’s age is presumably known, we could include the actual age in the model and so better control for the age effect. This would improve our estimate of the effect of being exposed to tolbutamide.
See [R] `logistic` for an explanation of the `logistic` command. Also see the technical note in *Stratified incidence-rate data* concerning categorical variables, which applies to logistic regression as well as Poisson regression.

### Standardized estimates with stratified cumulative incidence data

As with `ir`, `cs` can produce standardized estimates, and the method is basically the same, although the options for which estimates are to be combined or standardized make it confusing. We showed above that `cs` can produce Mantel–Haenszel weighted estimates of the risk ratio (the default) or the odds ratio (obtained by specifying `or`). `cs` can also produce standardized estimates of the risk ratio (the default) or the risk difference (obtained by specifying `rd`).

#### Example 9: `cs` with stratified data, using standardized estimates

To produce an estimate of the internally standardized risk ratio by using our age-specific data on deaths from all causes for tolbutamide and placebo treatment groups (example above), we type

```stata
.cs case exposed [freq=pop], by(age) istandard
```

<table>
<thead>
<tr>
<th>Age category</th>
<th>RR</th>
<th>[95% Conf. Interval]</th>
<th>Weight</th>
</tr>
</thead>
<tbody>
<tr>
<td>&lt;55</td>
<td>1.811321</td>
<td>.6112044</td>
<td>5.367898</td>
</tr>
<tr>
<td>55+</td>
<td>1.192602</td>
<td>.6712664</td>
<td>2.11883</td>
</tr>
</tbody>
</table>

#### Standardized estimates

We could obtain externally standardized estimates by substituting `estandard` for `istandard`.

To produce an estimate of the risk ratio weighting each age category equally, we could type

```stata
generate wgt=1
.cs case exposed [freq=pop], by(age) standard(wgt)
```

<table>
<thead>
<tr>
<th>Age category</th>
<th>RR</th>
<th>[95% Conf. Interval]</th>
<th>Weight</th>
</tr>
</thead>
<tbody>
<tr>
<td>&lt;55</td>
<td>1.811321</td>
<td>.6112044</td>
<td>5.367898</td>
</tr>
<tr>
<td>55+</td>
<td>1.192602</td>
<td>.6712664</td>
<td>2.11883</td>
</tr>
</tbody>
</table>

If we instead wanted the risk difference, we would type

```stata
.cs case exposed [freq=pop], by(age) standard(wgt) rd
```

<table>
<thead>
<tr>
<th>Age category</th>
<th>RD</th>
<th>[95% Conf. Interval]</th>
<th>Weight</th>
</tr>
</thead>
<tbody>
<tr>
<td>&lt;55</td>
<td>.033805</td>
<td>-.0278954</td>
<td>.0955055</td>
</tr>
<tr>
<td>55+</td>
<td>.0362545</td>
<td>-.0809204</td>
<td>.1534294</td>
</tr>
</tbody>
</table>

If we wanted to weight the less-than-55 age group five times as heavily as the 55-and-over group, we would create `wgt` to contain 5 for the first age group and 1 for the second (or 10 for the first group and 2 for the second—the scale of the weights does not matter).
Case–control data

In case–control data, you select a sample on the basis of the outcome under study; that is, cases and noncases are sampled at different rates. If you were examining the link between coffee consumption and heart attacks, for instance, you could select a sample of subjects with and without the heart problem and then examine their coffee-drinking behavior. A subject who has suffered a heart attack is called a case just as with cohort study data. A subject who has never suffered a heart attack, however, is called a control rather than merely a noncase, emphasizing that the sampling was performed with respect to the outcome.

In case–control data, all hope of identifying the risk (that is, incidence) of the outcome (heart attacks) associated with the factor (coffee drinking) vanishes, at least without information on the underlying sampling fractions, but you can examine the proportion of coffee drinkers among the two populations and reason that, if there is a difference, coffee drinking may be associated with the risk of heart attacks. Remarkably, even without the underlying sampling fractions, you can also measure the ratio of the odds of heart attacks if a subject drinks coffee to the odds if a subject does not—the so-called odds ratio.

What is lost is the ability to compare absolute rates, which is not always the same as comparing relative rates; see Fleiss, Levin, and Paik (2003, 123).

Example 10: cci

cci calculates the odds ratio and the attributable risk associated with a $2 \times 2$ table. Rothman et al. (1979; reprinted in Rothman [1986, 161], and Rothman, Greenland, and Lash [2008, 251]) present case–control data on the history of chlordiazopoxide use in early pregnancy for mothers of children born with and without congenital heart defects:

<table>
<thead>
<tr>
<th>Chlordiazopoxide use</th>
<th>Yes</th>
<th>No</th>
</tr>
</thead>
<tbody>
<tr>
<td>Case mothers</td>
<td>4</td>
<td>386</td>
</tr>
<tr>
<td>Control mothers</td>
<td>4</td>
<td>1250</td>
</tr>
</tbody>
</table>

\[ cci \ 4 \ 386 \ 4 \ 1250, \ level(90) \]

<table>
<thead>
<tr>
<th></th>
<th>Exposed</th>
<th>Unexposed</th>
<th>Total</th>
<th>Exposed</th>
</tr>
</thead>
<tbody>
<tr>
<td>Cases</td>
<td>4</td>
<td>386</td>
<td>390</td>
<td>0.0103</td>
</tr>
<tr>
<td>Controls</td>
<td>4</td>
<td>1250</td>
<td>1254</td>
<td>0.0032</td>
</tr>
<tr>
<td>Total</td>
<td>8</td>
<td>1636</td>
<td>1644</td>
<td>0.0049</td>
</tr>
</tbody>
</table>

Point estimate

<table>
<thead>
<tr>
<th></th>
<th>[90% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>Odds ratio</td>
<td>3.238342 \ (exact)</td>
</tr>
<tr>
<td>Attr. frac. ex.</td>
<td>.6912 \ (-.2989599, .9264524) (exact)</td>
</tr>
<tr>
<td>Attr. frac. pop</td>
<td>.0070892</td>
</tr>
</tbody>
</table>

\[ \chi^2(1) = 3.07 \quad Pr>\chi^2 = 0.0799 \]

We obtain a point estimate of the odds ratio as 3.24 and a $\chi^2$ value, which is a test that the odds ratio is 1, significant at the 10% level.
The epitab commands can calculate three different confidence intervals for the odds ratio: the exact, Woolf, and Cornfield intervals. The exact interval, illustrated in example 10, is the default. The interval is “exact” because it uses an exact sampling distribution—a distribution with no unknown parameters under the null hypothesis. An exact interval does not use a normal or chi-squared approximation. “Exact” does not describe the coverage probability; the coverage probability of a 90% exact interval is not exactly 90%. The coverage probability is actually bounded below by 90% (Agresti 2013, 606), so a 90% exact interval will always cover the odds ratio with probability at least 90% (if the model is correct).

The Woolf and Cornfield intervals, on the other hand, are approximate. They approximate the exact sampling distribution with a normal model and are not guaranteed to maintain their nominal coverage: the coverage probability of a 90% approximate interval fluctuates above and below 90%. The coverage approaches 90% only in the limit as the sample size increases. Exact intervals are conservative; approximate intervals can be conservative or anticonservative (Agresti 2013, 607).

If you wish to maintain nominal coverage, then you should use the exact interval. But you will pay a price for the coverage: the exact interval will usually be wider than the approximate intervals. Example 10 is no exception:

<table>
<thead>
<tr>
<th>Method</th>
<th>90% Conf. Int.</th>
<th>Command</th>
</tr>
</thead>
<tbody>
<tr>
<td>exact</td>
<td>0.77 13.60</td>
<td>cci</td>
</tr>
<tr>
<td>Woolf</td>
<td>1.01 10.40</td>
<td>cci, woolf</td>
</tr>
<tr>
<td>Cornfield</td>
<td>1.07 9.83</td>
<td>cci, cornfield</td>
</tr>
</tbody>
</table>

The exact interval is the widest of the three—so wide that it includes the null value of one—even though the chi-squared $p$-value of 0.0799 was significant at the 10% level. The exact interval and chi-squared test come from different models, so we should not expect them to always agree on sharp conclusions such as statistical significance.

The odds-ratio intervals are all frequentist methods, so we cannot compare them rigorously with one example. See Brown (1981), Gart and Thomas (1982), and Agresti (1999) for more rigorous comparisons. Agresti (1999) found that the Woolf interval performed well, even for small samples.

Jerome Cornfield (1912–1979) was born in New York City. He majored in history at New York University and took courses in statistics at the U.S. Department of Agriculture Graduate School but otherwise had little formal training. Cornfield held positions at the Bureau of Labor Statistics, the National Cancer Institute, the National Institutes of Health, Johns Hopkins University, the University of Pittsburgh, and George Washington University. He worked on many problems in biomedical statistics, including the analysis of clinical trials, epidemiology (especially case–control studies), and Bayesian approaches.

Barnet Woolf (1902–1983) was born in London. His parents were immigrants from Lithuania. Woolf was educated at Cambridge, where he studied physiology and biochemistry, and proposed methods for linearizing plots in enzyme chemistry that were later rediscovered by others (see Haldane [1957]). His later career in London, Birmingham, Rothamsted, and Edinburgh included lasting contributions to nutrition, epidemiology, public health, genetics, and statistics. He was also active in left-wing causes and penned humorous poems, songs, and revues.
Technical note

By default, cc and cci report exact confidence intervals but an approximate significance test. You can replace the approximate test with Fisher’s exact test by specifying the exact option. We recommend specifying exact whenever any cell count is less than 1,000.

```
ci 4 386 4 1250, exact level(90)
```

<table>
<thead>
<tr>

<td>1644</td>
<td>0.0049</td>
</tr>
</tbody>
</table>

Point estimate | [90% Conf. Interval]
--- | ---
Odds ratio | 3.238342
Attr. frac. ex. | .6912
Attr. frac. pop | .0070892

1-sided Fisher’s exact P = 0.0964
2-sided Fisher’s exact P = 0.0964

In this table, the one- and two-sided significance values are equal. This is not a mistake, but it does not happen often. Exact significance values are calculated by summing the probabilities for tables that have the same marginals (row and column sums) but that are less likely (given an odds ratio of 1) than the observed table. When considering each possible table, we might ask if the table is in the same or opposite tail as the observed table. If it is in the same tail, we would count the table under consideration in the one-sided test and, either way, we would count it in the two-sided test. Here all the tables more extreme than this table are in the same tail, so the one- and two-sided tests are the same.

The p-value of 0.0964 is significant at the 10% level, but the exact confidence interval is not (it includes the null odds ratio of one). It was not surprising that the exact interval disagreed with the chi-squared test; after all, they come from different models. Now the exact interval and Fisher’s exact test also disagree, even though they come from the same model!

The test and interval disagree because the exact sampling distribution is asymmetric, and the test and interval handle the asymmetry differently. The two-sided test, as we have seen, sums the probabilities of all tables at least as unlikely as the observed table, and in example 10, all the unlikely tables fall in the same tail of the distribution. The other tail does not contribute to the p-value. The exact interval, on the other hand, must always use both tails of the distribution, because the interval inverts two one-sided tests, not one two-sided test (Breslow and Day 1980, 128–129).

Technical note

The reported value of the attributable or prevented fraction among the exposed is calculated using the odds ratio as a proxy for the risk ratio. This can be justified only if the outcome is rare in the population. The extrapolation to the attributable or prevented fraction for the population assumes that the control group is a random sample of the corresponding group in the underlying population.
Example 11: cc equivalent to cci

Equivalent to typing `cci 4 386 4 1250` would be typing `cc case exposed [freq=pop]` with the following data:

```
use https://www.stata-press.com/data/r16/ccxmpl, clear
list

<table>
<thead>
<tr>
<th>case</th>
<th>exposed</th>
<th>pop</th>
</tr>
</thead>
<tbody>
<tr>

</tr>
<tr>
<td>3</td>
<td>0</td>
<td>1</td>
</tr>
<tr>
<td>4</td>
<td>0</td>
<td>1250</td>
</tr>
</tbody>
</table>
```

Stratified case–control data

Example 12: cc with stratified data

`cc` can work with stratified tables. Rothman, Greenland, and Lash (2008, 276) reprint and discuss data from a case–control study on infants with congenital heart disease and Down syndrome and healthy controls, according to maternal spermicide use before conception and maternal age at delivery (Rothman 1982):

```
<table>
<thead>
<tr>
<th>Maternal age to 34</th>
<th>Maternal age 35+</th>
</tr>
</thead>
<tbody>
<tr>
<td>Spermicide used</td>
<td>Spermicide used</td>
</tr>
<tr>
<td>Down syndrome</td>
<td>3 9</td>
</tr>
<tr>
<td>Controls</td>
<td>104 1059</td>
</tr>
</tbody>
</table>
```

The data corresponding to these tables are

```
use https://www.stata-press.com/data/r16/downs
list

<table>
<thead>
<tr>
<th>case</th>
<th>exposed</th>
<th>pop</th>
<th>age</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>1</td>

<td>1.18734 12.04142</td>
<td></td>
</tr>
</tbody>
</table>

Test of homogeneity (M-H)  \( \text{chi}^2(1) = 0.14 \)  \( \text{Pr}>\text{chi}^2 = 0.7105 \)

Test that combined OR = 1:

Mantel-Haenszel  \( \text{chi}^2(1) = 5.81 \)  \( \text{Pr}>\text{chi}^2 = 0.0159 \)

For no particular reason, we also specified the `woolf` option to obtain Woolf approximations to the within-stratum confidence intervals rather than the default. Had we wanted Tarone’s test of homogeneity, we would have used

```
. cc case exposed [freq=pop], by(age) tarone
```

<table>
<thead>
<tr>
<th>Maternal age</th>
<th>OR</th>
<th>[95% Conf. Interval]</th>
<th>M-H Weight</th>
</tr>
</thead>
<tbody>
<tr>
<td>&lt;35</td>
<td>3.394231</td>
<td>.5812415 13.87412</td>
<td>.7965957 (exact)</td>
</tr>
<tr>
<td>35+</td>
<td>5.733333</td>
<td>.0911619 85.89602</td>
<td>.1578947 (exact)</td>
</tr>
<tr>
<td>Crude</td>
<td>3.501529</td>
<td>.8080857 11.78958</td>
<td></td>
</tr>
<tr>
<td>M-H combined</td>
<td>3.781172</td>
<td>1.18734 12.04142</td>
<td></td>
</tr>
</tbody>
</table>

Test of homogeneity (M-H)  \( \text{chi}^2(1) = 0.14 \)  \( \text{Pr}>\text{chi}^2 = 0.7105 \)

Test of homogeneity (Tarone)  \( \text{chi}^2(1) = 0.14 \)  \( \text{Pr}>\text{chi}^2 = 0.7092 \)

Test that combined OR = 1:

Mantel-Haenszel  \( \text{chi}^2(1) = 5.81 \)  \( \text{Pr}>\text{chi}^2 = 0.0159 \)

Whatever method you choose for calculating confidence intervals, Stata will report a test of homogeneity, which here is \( \chi^2(1) = 0.14 \) and not significant. That is, the odds of Down syndrome might vary with maternal age, but we cannot reject the hypothesis that the association between Down syndrome and spermicide is the same in the two maternal age strata. This is thus a test to reject the appropriateness of the single, Mantel–Haenszel combined odds ratio—a rejection not justified by these data.

---

**Technical note**

The `cc` command includes four tests of homogeneity: Mantel–Haenszel (the default); directly pooled, also known as the Woolf test (available with the `pool` option); Tarone (available with the `tarone` option); and Breslow–Day (available with the `bd` option). The preferred test is Tarone’s (Tarone 1985, 94), which corrected an error in the Breslow–Day test; see Breslow (1996, 17–18) for details of the error and Tarone’s correction.

The other two homogeneity tests, the Mantel–Haenszel and directly pooled, are less useful: they use the logs of the stratum-specific odds ratios, so they are undefined when any stratum has a zero cell. The epitab commands deal with the problem differently: `cs` omits the offending strata, while `cc` substitutes the Tarone test. The Tarone test does not use the stratum-specific odds ratios, so it can still be calculated when there are zero cells.
None of the tests are appropriate for finely stratified (many strata with only a few observations each) studies (Rothman, Greenland, and Lash 2008, 280). If you have fine stratification, one alternative is multilevel logistic regression; see \[\text{ME}\] \texttt{melogit}.

### Technical note

As with cohort study data, an alternative to stratified tables for uncovering effects is logistic regression. From the logistic point of view, case–control data are no different from cohort study data—you must merely ignore the estimated intercept. The intercept is meaningless in case–control data because it reflects the baseline prevalence of the outcome, which you controlled by sampling.

The data we used with \texttt{cc} can be used directly by \texttt{logistic}. (The \texttt{age} variable, which appears to be a string, is really numeric with an associated value label; see \[\text{U}\] 12.6.3 Value labels. \texttt{age} takes on the value 0 for the age-less-than-35 group and 1 for the 35+ group.)

```
. logistic case exposed age [freq=pop]
Logistic regression

Number of obs = 1,270
LR chi2(2) = 8.74
Prob > chi2 = 0.0127

Log likelihood = -81.517532 Pseudo R2 = 0.0509

| Case  | Odds Ratio | Std. Err. | z   | P>|z|   | [95% Conf. Interval] |
|-------|------------|-----------|-----|-------|----------------------|
| exposed | 3.787779 | 2.241922 | 2.25 | 0.024 | 1.187334 | 12.0836 |
| age | 4.582857 | 2.717352 | 2.57 | 0.010 | 1.433594 | 14.65029 |
| _cons | .0082631 | .0027325 | -14.50 | 0.000 | .0043218 | .0157988 |
```

Note: \_cons estimates baseline odds.

We compare the results with those presented by \texttt{cc} in the previous example:

<table>
<thead>
<tr>
<th>Source</th>
<th>Odds ratio</th>
<th>95% CI</th>
</tr>
</thead>
<tbody>
<tr>
<td>Mantel–Haenszel (cc)</td>
<td>3.78</td>
<td>1.19</td>
</tr>
<tr>
<td>logistic</td>
<td>3.79</td>
<td>1.19</td>
</tr>
</tbody>
</table>

As with the cohort study data in example 8, results are virtually identical, and all the same comments we made previously apply once again.

To demonstrate an advantage of logistic regression, let’s now ask a question that would be difficult to answer on the basis of a stratified table analysis. We now know that spermicide use appears to increase the risk of having a baby with Down syndrome, and we know that the mother’s age also increases the risk. Is the effect of spermicide use statistically different for mothers in the two age groups?
. logistic case exposed age c.age#exposed [freq=pop]

Logistic regression
Number of obs = 1,270
LR chi2(3) = 8.87
Prob > chi2 = 0.0311
Log likelihood = -81.451332 Pseudo R2 = 0.0516

| case     | Odds Ratio | Std. Err. | z    | P>|z| | [95% Conf. Interval] |
|---------|------------|-----------|------|------|----------------------|
| exposed | 3.394231   | 2.289544  | 1.81 | 0.070| .9048403 12.73242   |
| age     | 4.104651   | 2.774868  | 2.09 | 0.037| 1.091034 15.44237   |
| exposed#c.age 1 | 1.689141 | 2.388785  | 0.37 | 0.711| .1056563 27.0045    |
| _cons   | .0084986   | .0028449  | -14.24 | 0.000| .0044097 0.0163789  |

Note: _cons estimates baseline odds.

The answer is no. The odds ratio and confidence interval reported for exposed now measure the spermicide effect for an age==0 (age < 35) mother. The odds ratio and confidence interval reported for c.age#exposed are the (multiplicative) difference in the spermicide odds ratio for an age==1 (age 35+) mother relative to a young mother. The point estimate is that the effect is larger for older mothers, suggesting grounds for future research, but the difference is not significant.

See [R] logistic for an explanation of the logistic command. Also see the technical note under Incidence-rate data above concerning Poisson regression, which applies equally to logistic regression.

---

**Case–control data with multiple levels of exposure**

In a case–control study, subjects with the disease of interest (cases) are compared to disease-free individuals (controls) to assess the relationship between exposure to one or more risk factors and disease incidence. Often exposure is measured qualitatively at several discrete levels or measured on a continuous scale and then grouped into three or more levels. The data can be summarized as

<table>
<thead>
<tr>
<th>Exposure level</th>
<th>1</th>
<th>2</th>
<th>...</th>
<th>k</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>Cases</td>
<td>a1</td>
<td>a2</td>
<td>...</td>
<td>ak</td>
<td>M1</td>
</tr>
<tr>
<td>Controls</td>
<td>c1</td>
<td>c2</td>
<td>...</td>
<td>ck</td>
<td>M0</td>
</tr>
<tr>
<td>Total</td>
<td>N1</td>
<td>N2</td>
<td>...</td>
<td>Nk</td>
<td>T</td>
</tr>
</tbody>
</table>

An advantage afforded by having multiple levels of exposure is the ability to examine dose–response relationships. If the association between a risk factor and a disease or outcome is real, we expect the strength of that association to increase with the level and duration of exposure. A dose–response relationship provides strong support for a direct or even causal relationship between the risk factor and the outcome. On the other hand, the lack of a dose–response is usually seen as an argument against causality.

We can use the tabodds command to tabulate the odds of failure or odds ratios against a categorical exposure variable. The test for trend calculated by tabodds can serve as a test for dose–response if the exposure variable is at least ordinal. If the exposure variable has no natural ordering, the trend test is meaningless and should be ignored. See the technical note at the end of this section for more information regarding the test for trend.
Before looking at an example, consider three possible data arrangements for case–control and prevalence studies. The most common data arrangement is individual records, where each subject in the study has his or her own record. Closely related are frequency records where identical individual records are included only once, but with a variable giving the frequency with which the record occurs. The \texttt{fweight} weight option is used for these data to specify the frequency variable. Data can also be arranged as binomial frequency records where each record contains a variable, \( D \), the number of cases; another variable, \( N \), the number of total subjects (cases plus controls); and other variables. An advantage of binomial frequency records is that large datasets can be entered succinctly into a Stata database.

\section*{Example 13: \texttt{tabodds}}

Consider the following data from the Ille-et-Vilaine study of esophageal cancer, discussed in Breslow and Day (1980, chap. 4 and app. 1), corresponding to subjects age 55–64 who use from 0 to 9 g of tobacco per day:

<table>
<thead>
<tr>
<th>Alcohol consumption (g/day)</th>
<th>0–39</th>
<th>40–79</th>
<th>80–119</th>
<th>120+</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>Cases</td>
<td>2</td>
<td>9</td>
<td>9</td>
<td>5</td>
<td>25</td>
</tr>
<tr>
<td>Controls</td>
<td>47</td>
<td>31</td>
<td>9</td>
<td>5</td>
<td>92</td>
</tr>
<tr>
<td>Total</td>
<td>49</td>
<td>40</td>
<td>18</td>
<td>10</td>
<td>117</td>
</tr>
</tbody>
</table>

The study included 24 such tables, each representing one of four levels of tobacco use and one of six age categories. We can create a binomial frequency-record dataset by typing

```
. input alcohol D N agegrp tobacco
   alcohol  D  N  agegrp  tobacco
1. 1 2 49 4 1
2. 2 9 40 4 1
3. 3 9 18 4 1
4. 4 5 10 4 1
5. end
```

where \( D \) is the number of esophageal cancer cases and \( N \) is the number of total subjects (cases plus controls) for each combination of six age groups (\texttt{agegrp}), four levels of alcohol consumption in g/day (\texttt{alcohol}), and four levels of tobacco use in g/day (\texttt{tobacco}).

Both the \texttt{tabodds} and \texttt{mhodds} commands can correctly handle all three data arrangements. Binomial frequency records require that the number of total subjects (cases plus controls) represented by each record \( N \) be specified with the \texttt{binomial()} option.

We could also enter the data as frequency-weighted data:

```
. input alcohol case freq agegrp tobacco
   alcohol  case  freq  agegrp  tobacco
1. 1 1 2 4 1
2. 1 0 47 4 1
3. 2 1 9 4 1
4. 2 0 31 4 1
5. 3 1 9 4 1
6. 3 0 9 4 1
7. 4 1 5 4 1
8. 4 0 5 4 1
9. end
```
If you are planning on using any of the other estimation commands, such as `poisson` or `logistic`, we recommend that you enter your data either as individual records or as frequency-weighted records and not as binomial frequency records, because the estimation commands currently do not recognize the `binomial()` option.

We have entered all the esophageal cancer data into Stata as a frequency-weighted record dataset as previously described. In our data, `case` indicates the esophageal cancer cases and controls, and `freq` is the number of subjects represented by each record (the weight).

We added value labels to the `agegrp`, `alcohol`, and `tobacco` variables in our dataset to ease interpretation in outputs, but these variables are numeric.

We are interested in the association between alcohol consumption and esophageal cancer. We first use `tabodds` to tabulate the odds of esophageal cancer against alcohol consumption:

```
. use https://www.stata-press.com/data/r16/bdesop, clear
. tabodds case alcohol [fweight=freq]
```

<table>
<thead>
<tr>
<th>alcohol</th>
<th>cases</th>
<th>controls</th>
<th>odds</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>0-39</td>
<td>29</td>
<td>386</td>
<td>0.07513</td>
<td>0.05151 0.10957</td>
</tr>
<tr>
<td>40-79</td>
<td>75</td>
<td>280</td>
<td>0.26786</td>
<td>0.20760 0.34560</td>
</tr>
<tr>
<td>80-119</td>
<td>51</td>
<td>87</td>
<td>0.58621</td>
<td>0.41489 0.82826</td>
</tr>
<tr>
<td>120+</td>
<td>45</td>
<td>22</td>
<td>2.04545</td>
<td>1.22843 3.40587</td>
</tr>
</tbody>
</table>

Test of homogeneity (equal odds): chi2(3) = 158.79  
Pr>chi2 = 0.0000

Score test for trend of odds: chi2(1) = 152.97  
Pr>chi2 = 0.0000

The test of homogeneity clearly indicates that the odds of esophageal cancer differ by level of alcohol consumption, and the test for trend indicates a significant increase in odds with increasing alcohol use. This suggests a strong dose–response relation. The `graph` option can be used to study the shape of the relationship of the odds with alcohol consumption. Most of the heterogeneity in these data can be “explained” by the linear increase in risk of esophageal cancer with increased dosage (alcohol consumption).

We also could have requested that the odds ratios at each level of alcohol consumption be calculated by specifying the `or` option. For example, `tabodds case alcohol [fweight=freq], or` would produce odds ratios using the minimum value of alcohol—that is, `alcohol = 1 (0–39)—as the reference group, and the command `tabodds case alcohol [fweight=freq], base(2)` would use `alcohol = 2 (40–79)` as the reference group.

Although our results appear to provide strong evidence supporting an association between alcohol consumption and esophageal cancer, we need to be concerned with the possible existence of confounders, specifically age and tobacco use, in our data. We can again use `tabodds` to tabulate the odds of esophageal cancer against age and against tobacco use, independently:
We can see that there is evidence to support our concern that both age and tobacco use are potentially important confounders. Clearly, before we can make any statements regarding the association between esophageal cancer and alcohol use, we must examine and, if necessary, adjust for the effect of any confounder. We will return to this example in the following section.

### Technical note

The score test for trend performs a test for linear trend of the log odds against the numerical code used for the exposure variable. The test depends not only on the relationship between dose level and the outcome but also on the numeric values assigned to each level or, to be more accurate, to the distance between the numeric values assigned. For example, the trend test on a dataset with four exposure levels coded 1, 2, 3, and 4 gives the same results as coding the levels 10, 20, 30, and 40 because the distance between the levels in each case is constant. In the first case, the distance is one unit, and in the second case, it is 10 units. However, if we code the exposure levels as 1, 10, 100, and 1,000, we would obtain different results because the distance between exposure levels is not constant. Thus be careful when assigning values to exposure levels. You must determine whether equally spaced numbers make sense for your data or if other more meaningful values should be used.

Remember that we are testing whether a log-linear relationship exists between the odds and the exposure variable. For your particular problem, this relationship may not be correct or even make sense, so you must be careful in interpreting the output of this trend test.
Case–control data with confounders and possibly multiple levels of exposure

In the esophageal cancer data example introduced earlier, we determined that the apparent association between alcohol consumption and esophageal cancer could be confounded by age and tobacco use. You can adjust for the effect of possible confounding factors by stratifying on these factors. This is the method used by both `tabodds` and `mhodds` to adjust for other variables in the dataset. We will compare and contrast these two commands in the following example.

Example 14: `tabodds`, adjusting for confounding factors

We begin by using `tabodds` to tabulate unadjusted odds ratios.

```
. tabodds case alcohol [fweight=freq], or

<table>
<thead>
<tr>
<th></th>
<th>Odds Ratio</th>
<th>chi2</th>
<th>P&gt;</th>
<th>chi2</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>0–39</td>
<td>1.000000</td>
<td>.</td>
<td>.</td>
<td>.</td>
<td>.</td>
</tr>
<tr>
<td>40–79</td>
<td>3.565271</td>
<td>32.70</td>
<td>0.0000</td>
<td>2.237981  5.679744</td>
<td></td>
</tr>
<tr>
<td>80–119</td>
<td>7.802616</td>
<td>75.03</td>
<td>0.0000</td>
<td>4.497054  13.537932</td>
<td></td>
</tr>
<tr>
<td>120+</td>
<td>27.225705</td>
<td>160.41</td>
<td>0.0000</td>
<td>12.507808 59.262107</td>
<td></td>
</tr>
</tbody>
</table>
```

Test of homogeneity (equal odds): `chi2(3) = 158.79  Pr>chi2 = 0.0000`
Score test for trend of odds: `chi2(1) = 152.97  Pr>chi2 = 0.0000`

The `alcohol = 1` group (0–39) was used by `tabodds` as the reference category for calculating the odds ratios. We could have selected a different group by specifying the `base()` option; however, because the lowest dosage level is most often the appropriate reference group, as it is in these data, the `base()` option is seldom used.

We use `tabodds` with the `adjust()` option to tabulate Mantel–Haenszel age-adjusted odds ratios:

```
. tabodds case alcohol [fweight=freq], adjust(age)

<table>
<thead>
<tr>
<th></th>
<th>Odds Ratio</th>
<th>chi2</th>
<th>P&gt;</th>
<th>chi2</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>0–39</td>
<td>1.000000</td>
<td>.</td>
<td>.</td>
<td>.</td>
<td>.</td>
</tr>
<tr>
<td>40–79</td>
<td>4.268155</td>
<td>37.36</td>
<td>0.0000</td>
<td>2.570025  7.088314</td>
<td></td>
</tr>
<tr>
<td>80–119</td>
<td>8.018305</td>
<td>59.30</td>
<td>0.0000</td>
<td>4.266893  15.067922</td>
<td></td>
</tr>
<tr>
<td>120+</td>
<td>28.570426</td>
<td>139.70</td>
<td>0.0000</td>
<td>12.146409 67.202514</td>
<td></td>
</tr>
</tbody>
</table>
```

Score test for trend of odds: `chi2(1) = 135.09  Pr>chi2 = 0.0000`

We observe that the age-adjusted odds ratios are just slightly higher than the unadjusted ones, so it appears that age is not as strong a confounder as it first appeared. Even after adjusting for age, the dose–response relationship, as measured by the trend test, remains strong.
We now perform the same analysis but this time adjust for tobacco use instead of age.

```
. tabodds case alcohol [fweight=freq], adjust(tobacco)
```

Mantel-Haenszel odds ratios adjusted for tobacco

<table>
<thead>
<tr>
<th>alcohol</th>
<th>Odds Ratio</th>
<th>chi2</th>
<th>P&gt;chi2</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>0-39</td>
<td>1.000000</td>
<td>.</td>
<td>.</td>
<td>2.059764</td>
</tr>
<tr>
<td>40-79</td>
<td>3.261178</td>
<td>28.53</td>
<td>0.0000</td>
<td>2.059764</td>
</tr>
<tr>
<td>80-119</td>
<td>6.771638</td>
<td>62.54</td>
<td>0.0000</td>
<td>3.908113</td>
</tr>
<tr>
<td>120+</td>
<td>19.919526</td>
<td>123.93</td>
<td>0.0000</td>
<td>9.443830</td>
</tr>
</tbody>
</table>

Score test for trend of odds: chi2(1) = 135.04
Pr>chi2 = 0.0000

Again we observe a significant dose–response relationship and not much difference between the adjusted and unadjusted odds ratios. We could also adjust for the joint effect of both age and tobacco use by specifying `adjust(tobacco age)`, but we will not bother here.

A different approach to analyzing these data is to use the `mhodds` command. This command estimates the ratio of the odds of failure for two categories of an exposure variable, controlling for any specified confounding variables, and it tests whether this odds ratio is equal to one. For multiple exposures, if two exposure levels are not specified with `compare()`, then `mhodds` assumes that exposure is quantitative and calculates a 1-degree-of-freedom test for trend. This test for trend is the same one that `tabodds` reports.

> **Example 15: mhodds, controlling for confounding factors**

We first use `mhodds` to estimate the effect of alcohol controlled for age:

```
. mhodds case alcohol agegrp [fweight=freq]
```

```
Score test for trend of odds with alcohol controlling for agegrp
(The Odds Ratio estimate is an approximation to the odds ratio for a one unit increase in alcohol)
```

<table>
<thead>
<tr>
<th>Odds Ratio</th>
<th>chi2(1)</th>
<th>P&gt;chi2</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>2.845895</td>
<td>135.09</td>
<td>0.0000</td>
<td>2.385749</td>
</tr>
</tbody>
</table>

Because `alcohol` has more than two levels, `mhodds` estimates and reports an approximate age-adjusted odds ratio for a one-unit increase in alcohol consumption. The \( \chi^2 \) value reported is identical to that reported by `tabodds` for the score test for trend on the previous page.
We now use `mhodds` to estimate the effect of alcohol controlled for age, and while we are at it, we do this by levels of tobacco consumption:

\[
\text{. mhodds case alcohol agegrp [fweight=freq], by(tobacco)}
\]

Score test for trend of odds with alcohol controlling for agegrp by tobacco

**note:** only 19 of the 24 strata formed in this analysis contribute information about the effect of the explanatory variable

(The Odds Ratio estimate is an approximation to the odds ratio for a one unit increase in alcohol)

</tr>
</tbody>
</table>

Test of homogeneity of ORs (approx): chi2(3) = 5.46

\[Pr>\text{chi2} = 0.1409\]

The first table reports estimates of the effect of alcohol for each level of tobacco use, controlling for age.

From the second table, we find that the effect of alcohol is about \( \times 2.8 \) when we control for both age and tobacco use. Again, because *alcohol* has more than two levels, *mhodds* estimates and reports an approximate Mantel–Haenszel age and tobacco-use adjusted odds ratio for a one-unit increase in alcohol consumption.

The \( \chi^2 \) test for trend reported with the Mantel–Haenszel estimate is again the same one that *tabodds* produces if *adjust(agegrp tobacco)* is specified.
To instead estimate the effect of tobacco use for each level of alcohol consumption, controlling for age, we type

```
.mhodds case tobacco agegrp [fweight=freq], by(alcohol)
```

Score test for trend of odds with tobacco controlling for agegrp by alcohol

*note:* only 18 of the 24 strata formed in this analysis contribute information about the effect of the explanatory variable

(The Odds Ratio estimate is an approximation to the odds ratio for a one unit increase in tobacco)

</tr>
</tbody>
</table>

Test of homogeneity of ORs (approx): \(\chi^2(3) = 5.26\)

\[\text{Pr}\geq \chi^2 = 0.1540\]

From the second table, we find that the effect of tobacco, controlled for both age and alcohol consumption is about \(\times 1.6\).

Comparisons between particular levels of alcohol and tobacco consumption can be made by generating a new variable with levels corresponding to all combinations of alcohol and tobacco, as in

```
. egen alctob = group(alcohol tobacco)
. mhodds case alctob [fweight=freq], compare(16,1)
```

Maximum likelihood estimate of the odds ratio
Comparing \(\text{alctob}==16\) vs. \(\text{alctob}==1\)

<table>
<thead>
<tr>

<td>103.21</td>
<td>0.0000</td>
<td>14.766136 589.938431</td>
</tr>
</tbody>
</table>

which yields an odds ratio of 93 between subjects with the highest levels of alcohol and tobacco and those with the lowest levels. Similar results can be obtained simultaneously for all levels of \(\text{alctob}\) using \(\text{alctob} = 1\) as the comparison group by specifying `tabodds D alctob, bin(N)` or.
Standardized estimates with stratified case–control data

Example 16: cc with stratified data, using standardized estimates

You obtain standardized estimates (here for the odds ratio) by using `cc` just as you obtain standardized estimates by using `ir` or `cs`. Along with the `by()` option, you specify one of `estandard`, `istandard`, or `standard(varname)`. Case–control studies can provide standardized rate-ratio estimates when density sampling is used, or when the disease is rare (Rothman, Greenland, and Lash 2008, 269). Rothman, Greenland, and Lash (2008, 276) report the SMR for the case–control study on infants with congenital heart disease and Down syndrome. We can reproduce their estimates along with the pooled estimates by typing

```
. use https://www.stata-press.com/data/r16/downs, clear
. cc case exposed [freq=pop], by(age) istandard pool
```

<table>
<thead>
<tr>
<th>Maternal age</th>
<th>OR</th>
<th>[95% Conf. Interval]</th>
<th>Weight</th>
</tr>
</thead>
<tbody>
<tr>
<td>&lt;35</td>
<td>3.394231</td>
<td>.5812415</td>
<td>13.87412</td>
</tr>
<tr>
<td>35+</td>
<td>5.733333</td>
<td>.0911619</td>
<td>85.89602</td>
</tr>
<tr>
<td>Crude</td>
<td>3.501529</td>
<td>.8080857</td>
<td>11.78958</td>
</tr>
<tr>
<td>Pooled (direct)</td>
<td>3.824166</td>
<td>1.196437</td>
<td>12.22316</td>
</tr>
<tr>
<td>I. Standardized</td>
<td>3.779749</td>
<td>1.180566</td>
<td>12.10141</td>
</tr>
</tbody>
</table>

Test of homogeneity (direct) chi2(1) = 0.14 Pr>chi2 = 0.7109

Using the distribution of the nonexposed subjects in the source population as the standard, we can obtain an estimate of the standardized rate ratio (SRR):

```
. cc case exposed [freq=pop], by(age) estandard
```

<table>
<thead>
<tr>
<th>Maternal age</th>
<th>OR</th>
<th>[95% Conf. Interval]</th>
<th>Weight</th>
</tr>
</thead>
<tbody>
<tr>
<td>&lt;35</td>
<td>3.394231</td>
<td>.5812415</td>
<td>13.87412</td>
</tr>
<tr>
<td>35+</td>
<td>5.733333</td>
<td>.0911619</td>
<td>85.89602</td>
</tr>
<tr>
<td>Crude</td>
<td>3.501529</td>
<td>.8080857</td>
<td>11.78958</td>
</tr>
<tr>
<td>E. Standardized</td>
<td>3.979006</td>
<td>1.176096</td>
<td>13.46191</td>
</tr>
</tbody>
</table>

Finally, if we wanted to weight the two age groups equally, we could type

```
. generate wgt=1
. cc case exposed [freq=pop], by(age) standard(wgt)
```

<table>
<thead>
<tr>
<th>Maternal age</th>
<th>OR</th>
<th>[95% Conf. Interval]</th>
<th>Weight</th>
</tr>
</thead>
<tbody>
<tr>
<td>&lt;35</td>
<td>3.394231</td>
<td>.5812415</td>
<td>13.87412</td>
</tr>
<tr>
<td>35+</td>
<td>5.733333</td>
<td>.0911619</td>
<td>85.89602</td>
</tr>
<tr>
<td>Crude</td>
<td>3.501529</td>
<td>.8080857</td>
<td>11.78958</td>
</tr>
<tr>
<td>Standardized</td>
<td>5.275104</td>
<td>.6233794</td>
<td>44.6385</td>
</tr>
</tbody>
</table>

Matched case–control data

Matched case–control studies are performed to gain sample-size efficiency and to control for important confounding factors. In a matched case–control design, each case is matched with a control on the basis of demographic characteristics, clinical characteristics, etc. Thus their difference with respect to the outcome must be due to something other than the matching variables. If the only difference between them was exposure to the factor, we could attribute any difference in outcome to the factor.
A summary of the data is

<table>
<thead>
<tr>
<th>Controls</th>
<th>Cases</th>
<th>Exposed</th>
<th>Unexposed</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>Exposed</td>
<td>a</td>
<td>b</td>
<td></td>
<td>$M_1$</td>
</tr>
<tr>
<td>Unexposed</td>
<td>c</td>
<td>d</td>
<td></td>
<td>$M_0$</td>
</tr>
<tr>
<td>Total</td>
<td>$N_1$</td>
<td>$N_0$</td>
<td></td>
<td>$T = a + b + c + d$</td>
</tr>
</tbody>
</table>

Each entry in the table represents the number of case–control pairs. For instance, in $a$ of the pairs, both members were exposed; in $b$ of the pairs, the case was exposed but the control was not; and so on. In total, $T$ pairs were observed.

**Example 17: mcci**

Rothman (1986, 257) discusses data from Jick et al. (1973) on a matched case–control study of myocardial infarction and drinking six or more cups of coffee per day (persons drinking from one to five cups per day were excluded):

<table>
<thead>
<tr>
<th>Controls</th>
<th>Cases</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>6+ cups</td>
</tr>
<tr>
<td></td>
<td>0 cups</td>
</tr>
<tr>
<td>6+ cups</td>
<td>8</td>
</tr>
<tr>
<td>0 cups</td>
<td>3</td>
</tr>
</tbody>
</table>

mcci analyzes matched case–control data:

```
. mcci 8 8 3 8
```

<table>
<thead>
<tr>
<th>Cases</th>
<th>Controls</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Exposed</td>
</tr>
<tr>
<td></td>
<td>Unexposed</td>
</tr>
<tr>
<td>Exposed</td>
<td>8</td>
</tr>
<tr>
<td></td>
<td>8</td>
</tr>
<tr>
<td>Unexposed</td>
<td>3</td>
</tr>
<tr>
<td></td>
<td>8</td>
</tr>
<tr>
<td>Total</td>
<td>11</td>
</tr>
<tr>
<td></td>
<td>16</td>
</tr>
</tbody>
</table>

McNemar’s chi2(1) = 2.27 Prob > chi2 = 0.1317
Exact McNemar significance probability = 0.2266

Proportion with factor

<table>
<thead>
<tr>
<th>Cases</th>
<th>Controls</th>
<th>.5925926</th>
<th>.4074074</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>difference</td>
<td>.1851852</td>
<td>-.0822542</td>
<td>.4526246</td>
<td></td>
</tr>
<tr>
<td>ratio</td>
<td>1.454545</td>
<td>.891101</td>
<td>2.374257</td>
<td></td>
</tr>
<tr>
<td>rel. diff.</td>
<td>.3125</td>
<td>-.0243688</td>
<td>.6493688</td>
<td></td>
</tr>
<tr>
<td>odds ratio</td>
<td>2.666667</td>
<td>.6400364</td>
<td>15.6064 (exact)</td>
<td></td>
</tr>
</tbody>
</table>

The point estimate states that the odds of drinking 6 or more cups of coffee per day is 2.67 times greater among the myocardial infarction patients. The confidence interval is wide, however, and the $p$-value of 0.1317 from McNemar’s test is not statistically significant.

mcci works like the other nonimmediate commands but does not handle stratified data. If you have stratified matched case–control data, you can use conditional logistic regression to estimate odds ratios; see [R] clogit.
Matched case–control studies can also be analyzed using `mhodds` by controlling on the variable used to identify the matched sets. For example, if the variable `set` is used to identify the matched set for each subject,

```
   . mhodds fail xvar set
```

will do the job. Any attempt to control for further variables will restrict the analysis to the comparison of cases and matched controls that share the same values of these variables. In general, this would lead to the omission of many records from the analysis. Similar considerations usually apply when investigating effect modification by using the `by()` option. An important exception to this rule is that a variable used in matching cases to controls may appear in the `by()` option without loss of data.

> **Example 18: mhodds with matched case–control data**

Let’s use `mhodds` to analyze matched case–control studies using the study of endometrial cancer and exposure to estrogen described in Breslow and Day (1980, chap. 5). In this study, there are four controls matched to each case. Cases and controls are matched on age, marital status, and time living in the community. The data collected include information on the daily dose of conjugated estrogen therapy. Breslow and Day created four levels of the dose variable and began by analyzing the 1:1 study formed by using the first control in each set. We examine the effect of exposure to estrogen:

```
   . use https://www.stata-press.com/data/r16/bdendo11, clear
   . describe
   Contains data from https://www.stata-press.com/data/r16/bdendo11.dta
   obs: 126

<td>21.12</td>
<td>0.0000</td>
<td>2.944702 31.733072</td>
</tr>
</tbody>
</table>

For the 1:1 matched study, the Mantel–Haenszel methods are equivalent to conditional likelihood methods. The maximum conditional likelihood estimate of the odds ratio is given by the ratio of
the off-diagonal frequencies in the two-way (case–control) table below. The data must be in the 1-observation-per-group format; that is, the matched case and control must appear in 1 observation (the same format as required by the `mcc` command; see also `R` `clogit`).

```
. keep fail est set
. reshape wide est, i(set) j(fail)
    (note: j = 0 1)
Data long -> wide
Number of obs. 126 -> 63
Number of variables 3 -> 3
j variable (2 values) fail -> (dropped)
xij variables: est -> est0 est1
```

```
. rename est1 case
. rename est0 control
. label variable case case
. label variable control control
. tabulate case control
```

<table>
<thead>
<tr>
<th>case</th>
<th>control</th>
<th></th>
<th></th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>4</td>
<td>3</td>
<td></td>
<td>7</td>
</tr>
<tr>
<td>1</td>
<td>29</td>
<td>27</td>
<td></td>
<td>56</td>
</tr>
</tbody>
</table>

| Total | 33    | 30 |   |  63   |

The odds ratio is $29/3 = 9.67$, which agrees with the value obtained from `mhodds`. In the more general $1:m$ matched study, however, the Mantel–Haenszel methods are no longer equivalent to maximum conditional likelihood, although they are usually close.
To illustrate the use of the by() option in matched case–control studies, we look at the effect of exposure to estrogen, stratified by age3, which codes the sets into three age groups (55–64, 65–74, and 75+) as follows:

```stata
use https://www.stata-press.com/data/r16/bdendo11, clear
generate age3 = agegrp
code age3 1/2=1 3/4=2 5/6=3
mhodds fail est set, by(age3)
```

Mantel-Haenszel estimate of the odds ratio
Comparing est==1 vs. est==0, controlling for set by age3

Note: only 32 of the 63 strata formed in this analysis contribute information about the effect of the explanatory variable

<table>
<thead>
<tr>
<th>age3</th>

<table>
<thead>
<tr>
<th>Odds Ratio</th>
<th>chi2(1)</th>
<th>P&gt;chi2</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>9.666667</td>
<td>21.12</td>
<td>0.0000</td>
<td>2.944702 31.733072</td>
</tr>
</tbody>
</table>

Test of homogeneity of ORs (approx): chi2(2) = 0.41
Pr>chi2 = 0.8128

There is no further loss of information when we stratify by age3 because age was one of the matching variables.

The full set of matched controls can be used in the same way. For example, the effect of exposure to estrogen is obtained (using the full dataset) with

```stata
use https://www.stata-press.com/data/r16/bdendo, clear
mhodds fail est set
```

Mantel-Haenszel estimate of the odds ratio
Comparing est==1 vs. est==0, controlling for set

Note: only 58 of the 63 strata formed in this analysis contribute information about the effect of the explanatory variable

<table>
<thead>
<tr>
<th>Odds Ratio</th>
<th>chi2(1)</th>
<th>P&gt;chi2</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>

\section*{Glossary}

\textbf{attributable fraction.} An attributable fraction is the reduction in the risk of a disease or other condition of interest when a particular risk factor is removed.

\textbf{case–control studies.} In case–control studies, cases meeting a fixed criterion are matched to noncases \textit{ex post} to study differences in possible covariates. Relative sample sizes are usually fixed at 1:1 or 1:2 but sometimes vary once the survey is complete. In any case, sample sizes do not reflect the distribution in the underlying population.

\textbf{cohort studies.} In cohort studies, a group that is well defined is monitored over time to track the transition of noncases to cases. Cohort studies differ from incidence studies in that they can be retrospective as well as prospective.
confounding. In the analysis of contingency tables, factor or interaction effects are said to be confounded when the effect of one factor is combined with that of another. For example, the effect of alcohol consumption on esophageal cancer may be confounded with the effects of age, smoking, or both. In the presence of confounding, it is often useful to stratify on the confounded factors that are not of primary interest, in the above example, age and smoking.

cross-sectional or prevalence studies. Cross-sectional studies sample distributions of healthy and diseased subjects in the population at one point in time.

crude estimate. A crude estimate has not been adjusted for the effects of other variables. Disregarding a stratification variable, for example, yields a crude estimate.

incidence and incidence rate. Incidence is the number of new failures (for example, number of new cases of a disease) that occur during a specified period in a population at risk (for example, of the disease).

Incidence rate is incidence divided by the sum of the length of time each individual was exposed to the risk.

Do not confuse incidence with prevalence. Prevalence is the fraction of a population that has the disease. Incidence refers to the rate at which people contract a disease, whereas prevalence is the total number actually sick at a given time.

incidence studies, longitudinal studies, and follow-up studies. Whichever word is used, these studies monitor a population for a time to track the transition of noncases into cases. Incidence studies are prospective. Also see cohort studies.

matched case–control study. Also known as a retrospective study, a matched case–control study is a study in which persons with positive outcomes are each matched with one or more persons with negative outcomes but with similar characteristics.

odds and odds ratio. The odds in favor of an event are \( o = p/(1 - p) \), where \( p \) is the probability of the event. Thus if \( p = 0.2 \), the odds are 0.25, and if \( p = 0.8 \), the odds are 4.

The log of the odds is \( \ln(o) = \text{logit}(p) = \ln\{p/(1 - p)\} \), and logistic-regression models, for instance, fit \( \ln(o) \) as a linear function of the covariates.

The odds ratio is a ratio of two odds: \( o_1/o_0 \). The individual odds that appear in the ratio are usually for an experimental group and a control group, or two different demographic groups.

prevented fraction. A prevented fraction is the reduction in the risk of a disease or other condition of interest caused by including a protective risk factor or public-health intervention.

prospective study. Also known as a prospective longitudinal study, a prospective study is a study based on observations over the same subjects for a given period.

risk factor. This is a variable associated with an increased or decreased risk of failure.

risk ratio. In a log-linear model, this is the ratio of probability of survival associated with a one-unit increase in a risk factor relative to that calculated without such an increase, that is, \( R(x + 1)/R(x) \). Given the exponential form of the model, \( R(x + 1)/R(x) \) is constant and is given by the exponentiated coefficient.

SMR. See standardized mortality (morbidity) ratio.

standardized mortality (morbidity) ratio. Standardized mortality (morbidity) ratio (SMR) is the observed number of deaths divided by the expected number of deaths. It is calculated using indirect standardization: you take the population of the group of interest—say, by age, sex, and other factors—and calculate the expected number of deaths in each cell (expected being defined as the number of deaths that would have been observed if those in the cell had the same mortality
as some other population). You then take the ratio to compare the observed with the expected number of deaths. For instance,

\[
\frac{\text{Observed deaths}}{\text{Expected deaths}} = \frac{92}{100.9} = 1.08
\]

A stratified test is performed separately for each stratum. The stratum-specific results are then combined into an overall test statistic.

If the tables are stratified, all quantities are indexed by $i$, the stratum number.

We will refer to Fleiss, Levin, and Paik (2003); Kleinbaum, Kupper, and Morgenstern (1982); and Rothman (1986) so often that we will adopt the notation $F$-23 to mean Fleiss, Levin, and Paik (2003) page 23; KKM-52 to mean Kleinbaum, Kupper, and Morgenstern (1982) page 52; and R-164 to mean Rothman (1986) page 164.

We usually avoid making the continuity corrections to $\chi^2$ statistics, following the advice of KKM-292: “... the use of a continuity correction has been the subject of considerable debate in the statistical literature ... On the basis of our evaluation of this debate and other evidence, we do not recommend the use of the continuity correction.” Breslow and Day (1980, 133), on the other hand, argue for inclusion of the correction, but not strongly. Their summary is that for small datasets, one should use exact statistics. In practice, we believe that the adjustment makes little difference for reasonably sized datasets.

Methods and formulas are presented under the following headings:

- Unstratified incidence-rate data (ir and iri)
- Unstratified cumulative incidence data (cs and csi)
- Unstratified case–control data (cc and cci)
- Unstratified matched case–control data (mcc and mcc)
- Stratified incidence-rate data (ir with the by() option)
- Stratified cumulative incidence data (cs with the by() option)
- Stratified case–control data (cc with by() option, mhodds, tabodds)

### Unstratified incidence-rate data (ir and iri)

The incidence-rate difference is defined as $I_d = a/N_1 - b/N_0$ (R-164). The standard error of the difference is $s_{I_d} \approx \sqrt{a/N_1^2 + b/N_0^2}$ (R-170), from which confidence intervals are calculated.

The incidence-rate ratio is defined as $I_r = (a/N_1)/(b/N_0)$ (R-164). Let $p_l$ and $p_u$ be the exact confidence interval of the binomial probability for observing $a$ successes in $M_1$ trials (obtained from cii proportions; see [R] ci). The exact confidence interval for the incidence ratio is then $(p_l N_0)/(1 - p_l) N_1$ to $(p_u N_0)/(1 - p_u) N_1$ (R-166).

The attributable fraction among the exposed is defined as $AFE = (I_r - 1)/I_r$ for $I_r \geq 1$ (KKM-164; R-38); the confidence interval is obtained by similarly transforming the interval values of $I_r$. The attributable fraction for the population is $AF = AFE \cdot a/M_1$ (KKM-161); no confidence interval is reported. For $I_r < 1$, the prevented fraction among the exposed is defined as $PFE = 1 - I_r$ (KKM-166; R-39); the confidence interval is obtained by similarly transforming the interval values of $I_r$. The prevented fraction for the population is $PF = PFE \cdot N_1/T$ (KKM-165); no confidence interval is reported.

The “midp” one-sided exact significance (R-155) is calculated as the binomial probability (with $n = M_1$ and $p = N_1/T$) $Pr(k = a)/2 + Pr(k > a)$ if $I_r \geq 1$ and $Pr(k = a)/2 + Pr(k < a)$ otherwise. The two-sided significance is twice the one-sided significance (R-155). If preferred, you can obtain nonmidp exact probabilities (and, to some ways of thinking, a more reasonable definition of two-sided significance) using bitest; see [R] bitest.
Unstratified cumulative incidence data (cs and csi)

The risk difference is defined as

\[ R_d = a/N_1 - b/N_0 \]  

(R-164). Its standard error is

\[ s_{R_d} \approx \left\{ \frac{ac}{N_1^3} + \frac{bd}{N_0^3} \right\}^{1/2} \]  

(R-172), from which confidence intervals are calculated.

The risk ratio is defined as

\[ R_r = \frac{(a/N_1)}{(b/N_0)} \]  

(R-165). The standard error of \( \ln R_r \) is

\[ s_{\ln R_r} \approx \left( \frac{c}{aN_1} + \frac{d}{bN_0} \right)^{1/2} \]  

(R-173), from which confidence intervals are calculated.

For \( R_r \geq 1 \), the attributable fraction among the exposed is calculated as

\[ AFE = \frac{(R_r - 1)}{R_r} \]  

(KKM-164; R-38); the confidence interval is obtained by similarly transforming the interval values for \( R_r \). The attributable fraction for the population is calculated as

\[ AF = AFE \cdot \frac{a}{M_1} \]  

(KKM-161); no confidence interval is reported, but F-128 provides

\[ \left\{ \frac{c + (a + d)AF}{bT} \right\}^{1/2} \]  

as the approximate standard error of \( \ln(1 - AF) \).

For \( R_r < 1 \), the prevented fraction among the exposed is calculated as

\[ PFE = 1 - R_r \]  

(KKM-166; R-39); the confidence interval is obtained by similarly transforming the interval values for \( R_r \). The prevented fraction for the population is calculated as

\[ PF = PFE \cdot \frac{N_1}{T} \]  

no confidence interval is reported.

The odds ratio, available with the \texttt{or} option, is defined as \( \psi = (ad)/(bc) \) (R-165). Several confidence intervals are available. The default interval for cs and csi is the Cornfield (1956) approximate interval. If we let \( z_\alpha \) be the index from a normal distribution for an \( \alpha \) significance level, the Cornfield interval \((\psi_l, \psi_u)\) is calculated from

\[ \psi_l = a_l(M_0 - N_1 + a_l) / \left\{ (N_1 - a_l)(M_1 - a_l) \right\} \]  

\[ \psi_u = a_u(M_0 - N_1 + a_u) / \left\{ (N_1 - a_u)(M_1 - a_u) \right\} \]  

where \( a_u \) and \( a_l \) are determined iteratively from

\[ a_{i+1} = a \pm z_\alpha \left( \frac{1}{a_i} + \frac{1}{N_1 - a_i} + \frac{1}{M_1 - a_i} + \frac{1}{M_0 - N_1 + a_i} \right)^{-1/2} \]  

(Newman 2001, sec. 4.4). \( a_{i+1} \) converges to \( a_u \) using the plus sign and \( a_l \) using the minus sign. \( a_0 \) is taken as \( a \). With small numbers, the iterative technique may fail. It is then restarted by decrementing \( a_l \) or incrementing \( a_u \) \( a_0 \). If that fails, \( a_0 \) is again decremented or incremented and iterations restarted, and so on, until a terminal condition is met \((a_0 < 0 \text{ or } a_0 > M_1)\), at which point the value is not calculated.
The Woolf odds-ratio confidence intervals are available with `cs` and `csi`. The Woolf method (Woolf 1955; R-173; Schlesselman 1982, 176), available with the `woolf` option, estimates the standard error of $\ln \psi$ by

$$s \ln \psi = \left( \frac{1}{a} + \frac{1}{b} + \frac{1}{c} + \frac{1}{d} \right)^{1/2}$$

from which confidence intervals are calculated. The Woolf interval cannot be calculated when there exists a zero cell. Sometimes the Woolf interval is called the “logit interval” (Breslow and Day 1980, 134).

The $\chi^2$ statistic, reported by default, can be calculated as

$$\chi^2 = \frac{(ad - bc)^2 T}{M_1 M_0 N_1 N_0}$$

(Schlesselman 1982, 179).

Fisher’s exact test, available with the `exact` option, is calculated as described in [R] tabulate `twoway`.

Unstratified case–control data (cc and cci)

cc and cci report by default the same odds ratio, $\psi$, that is available with the `or` option in `cs` and `csi`. But cc and cci calculate the confidence interval differently: they default to the exact odds-ratio interval, not the Cornfield interval, but you can request the Cornfield interval with the `cornfield` option. The $1 - \alpha$ exact interval $(\underline{R}, \overline{R})$ is calculated from

$$\frac{\alpha}{2} = \frac{\sum_{k=a}^{\min(N_1, M_1)} (N_1 k) (N_0 M_1 - k) \underline{R}^k}{\sum_{k=\max(0, M_1 - N_0)}^{\min(N_1, M_1)} (N_1 k) (N_0 M_1 - k) \overline{R}^k}$$

and

$$1 - \frac{\alpha}{2} = \frac{\sum_{k=a+1}^{\min(N_1, M_1)} (N_1 k) (N_0 M_1 - k) \overline{R}^k}{\sum_{k=\max(0, M_1 - N_0)}^{\min(N_1, M_1)} (N_1 k) (N_0 M_1 - k) \underline{R}^k}$$

(R-169). The equations invert two one-sided Fisher exact tests.

cc and cci also report the same tests of significance as cs and csi: the $\chi^2$ statistic is the default, and Fisher’s exact test is obtained with the `exact` option. The odds ratio, $\psi$, is used as an estimate of the risk ratio in calculating attributable or prevented fractions. For $\psi \geq 1$, the attributable fraction among the exposed is calculated as $AFE = (\psi - 1)/\psi$ (KKM-164); the confidence interval is obtained by similarly transforming the interval values for $\psi$. The attributable fraction for the population is calculated as $AF = AFE \cdot a/M_1$ (KKM-161). No confidence interval is reported; however, F-152 provides

$$\left( \frac{a}{M_1 b} + \frac{c}{M_0 d} \right)^{1/2}$$

as the standard error of $\ln(1 - AF)$.

For $\psi < 1$, the prevented fraction among the exposed is calculated as $PFE = 1 - \psi$ (KKM-166); the confidence interval is obtained by similarly transforming the interval values for $\psi$. The prevented fraction for the population is calculated as $PF = \left\{ (a/M_1)PFE \right\} / \left\{ (a/M_1)PFE + \psi \right\}$ (KKM-165); no confidence interval is reported.
Unstratified matched case–control data (mcc and mcci)

Referring to the table at the beginning of Matched case–control data under Remarks and examples above, the columns of the table indicate controls; the rows are cases. Each entry in the table reflects a pair of a matched case and control.

McNemar’s (1947) $\chi^2$ is defined as

$$\chi^2 = \frac{(b - c)^2}{b + c}$$

(KKM-389).

The proportion of controls with the factor is $p_1 = N_1/T$, and the proportion of cases with the factor is $p_2 = M_1/T$.

The difference in the proportions is $P_d = p_2 - p_1$. An estimate of its standard error when the two underlying proportions are not hypothesized to be equal is

$$s_{P_d} \approx \left\{\frac{(a + d)(b + c) + 4bc}{T^{3/2}}\right\}$$

(R-378), from which confidence intervals are calculated. The confidence interval uses a continuity correction (R-378, eq. 13.15).

The ratio of the proportions is $P_r = p_2/p_1$ (R-276, R-278). The standard error of $\ln P_r$ is

$$s_{\ln P_r} \approx \left\{\frac{b + c}{M_1N_1}\right\}^{1/2}$$

(R-276), from which confidence intervals are calculated.

The relative difference in the proportions is $P_e = (b - c)/(b + d)$ (R-379). Its standard error is

$$s_{P_e} \approx (b + d)^{-2} \left\{((b + c + d)(bc + bd + cd) - bcd)^{1/2}ight\}$$

(R-379), from which confidence intervals are calculated.

The odds ratio is $\psi = b/c$ (R-376), and the exact Fisher confidence interval is obtained by transforming into odds ratios the exact binomial confidence interval for the binomial parameter from observing $b$ successes in $b + c$ trials (R-264). Binomial confidence limits are obtained from cii proportions (see [R] ci) and are transformed by $p/(1 - p)$.

The exact McNemar significance probability is a two-tailed exact test of $H_0: \psi = 1$. The $p$-value, calculated from the binomial distribution, is

$$\min \left\{1, 2 \sum_{k=0}^{\min(b,c)} \binom{b + c}{k} \left(\frac{1}{2}\right)^{b+c}\right\}$$

(Agresti 2013, 416).

Quinn McNemar (1900–1986) was born in West Virginia and attended college there and in Pennsylvania. After a brief spell of high school teaching, he began graduate study of psychology at Stanford and then joined the faculty. McNemar’s text Psychological Statistics, first published in 1949, was widely influential, and he made many substantive and methodological contributions to the application of statistics in psychology.
Stratified incidence-rate data (ir with the by() option)

Statistics presented for each stratum are calculated independently according to the formulas in Unstratified incidence-rate data (ir and iri) above. Within strata, the Mantel–Haenszel style weight is $W_i = b_i N_{1i}/T_i$, and the Mantel–Haenszel combined incidence-rate ratio (Rothman and Boice 1982) is

$$I_{mh} = \frac{\sum_i a_i N_{0i}/T_i}{\sum_i W_i}$$

(R-196). The standard error for the log of the incidence-rate ratio was derived by Greenland and Robins (1985, 63) and appears in R-213:

$$s \ln I_{mh} \approx \left\{ \frac{\sum_i M_{1i} N_{1i} N_{0i}/T_i^2}{(\sum_i a_i N_{0i}/T_i)(\sum_i b_i N_{1i}/T_i)} \right\}^{1/2}$$

The confidence interval is calculated first on the log scale and then is transformed.

For standardized rates, let $w_i$ be the user-specified weight within stratum $i$. The standardized rate difference (the ird option) and rate ratio are defined as

$$SRD = \frac{\sum_i w_i (R_{1i} - R_{0i})}{\sum_i w_i}$$

$$SRR = \frac{\sum_i w_i R_{1i}}{\sum_i w_i R_{0i}}$$

(R-229). The standard error of SRD is

$$s_{SRD} \approx \left\{ \frac{1}{(\sum_i w_i)^2} \sum_i w_i^2 \left( \frac{a_i}{N_{1i}^2} + \frac{b_i}{N_{0i}^2} \right) \right\}^{1/2}$$

(R-231), from which confidence intervals are calculated. The standard error of $\ln(SRR)$ is

$$s \ln(SRR) \approx \left\{ \frac{\sum_i w_i^2 a_i/N_{1i}^2}{(\sum_i w_i R_{1i})^2} + \frac{\sum_i w_i^2 b_i/N_{0i}^2}{(\sum_i w_i R_{0i})^2} \right\}^{1/2}$$

(R-231), from which confidence intervals are calculated.

Internally and externally standardized measures are calculated using $w_i = N_{1i}$ and $w_i = N_{0i}$, respectively, and are obtained with the istandard and estandard options, respectively.

Directly pooled estimates are available with the pool option. The directly pooled estimate is a weighted average of stratum-specific estimates; each weight, $w_i$, is inversely proportional to the variance of the estimate for stratum $i$. The variances for rate differences come from the formulas in Unstratified incidence-rate data (ir and iri), while the variances of log rate-ratios are estimated by $(1/a_i + 1/b_i)$ (R-184). Ratios are averaged in the log scale before being exponentiated. The standard error of the directly pooled estimate is calculated as $1/\sqrt{\sum w_i}$, from which confidence intervals are calculated (R-183–185); the calculation for ratios again uses the log scale.

For rate differences, the $\chi^2$ test of homogeneity is calculated as $\sum (R_{di} - \hat{R}_d)^2/\text{var}(R_{di})$, where $R_{di}$ are the stratum-specific rate differences and $\hat{R}_d$ is the directly pooled estimate. The number of degrees of freedom is one less than the number of strata (R-222).

For rate ratios, the same calculation is made, except that it is made on a logarithmic scale using $\ln(R_{ri})$ (R-222), and $\ln(\hat{R}_d)$ may be the log of either the directly pooled estimate or the Mantel–Haenszel estimate.
Stratified cumulative incidence data (cs with the by() option)

Statistics presented for each stratum are calculated independently according to the formulas in Unstratified cumulative incidence data (cs and csi) above. The Mantel–Haenszel $\chi^2$ test (Mantel and Haenszel 1959) is

$$\chi^2_{\text{mh}} = \frac{\left\{ \sum_i (a_i - N_{1i}M_{1i}/T_i) \right\}^2}{\sum_i (N_{1i}N_{0i}M_{1i}M_{0i})/\left\{ T_i^2(T_i - 1) \right\}}$$

(R-206).

For the odds ratio (available with the or option), the Mantel–Haenszel weight is $W_i = b_i c_i / T_i$, and the combined odds ratio (Mantel and Haenszel 1959) is

$$\psi_{\text{mh}} = \frac{\sum_i a_i d_i / T_i}{\sum_i W_i}$$

(R-195). The standard error (Robins, Breslow, and Greenland 1986) is

$$s \ln \psi_{\text{mh}} \approx \left\{ \frac{\sum_i P_i R_i}{2(\sum_i R_i)^2} + \frac{\sum_i P_i S_i + Q_i R_i}{2 \sum_i R_i \sum_i S_i} + \frac{\sum_i Q_i S_i}{2(\sum_i S_i)^2} \right\}^{1/2}$$

where

$$P_i = (a_i + d_i) / T_i$$

$$Q_i = (b_i + c_i) / T_i$$

$$R_i = a_i d_i / T_i$$

$$S_i = b_i c_i / T_i$$

(R-220).

For the risk ratio (the default), the Mantel–Haenszel-style weight is $W_i = b_i N_{1i} / T_i$, and the combined risk ratio (Rothman and Boice 1982) is

$$R_{\text{mh}} = \frac{\sum_i a_i N_{0i} / T_i}{\sum_i W_i}$$

(R-196). The standard error (Greenland and Robins 1985) is

$$s \ln R_{\text{mh}} \approx \left\{ \frac{\sum_i (M_{1i}N_{1i}N_{0i} - a_i b_i T_i)}{(\sum_i a_i N_{0i} / T_i)(\sum_i b_i N_{1i} / T_i)} \right\}^{1/2}$$

(R-216), from which confidence intervals are calculated.

For standardized rates, let $w_i$ be the user-specified weight within stratum $i$. The standardized rate difference (SRD, the rd option) and rate ratios (SRR, the default) are defined as in Stratified incidence-rate data (ir with the by() option), where the individual risks are defined $R_{1i} = a_i / N_{1i}$ and $R_{0i} = b_i / N_{0i}$. The standard error of SRD is

$$s_{\text{SRD}} \approx \left[ \frac{1}{(\sum_i w_i)^2} \sum_i w_i^2 \left\{ \frac{a_i (N_{1i} - a_i)}{N_{1i}^3} + \frac{b_i (N_{0i} - b_i)}{N_{0i}^3} \right\} \right]^{1/2}$$
(R-231), from which confidence intervals are calculated. The standard error of $\ln(SRR)$ is

$$s\ln(SRR) \approx \left\{ \frac{\sum_i w_i^2 a_i (N_{1i} - a_i)}{(\sum_i w_i R_{1i})^2} + \frac{\sum_i w_i^2 b_i (N_{0i} - b_i)}{(\sum_i w_i R_{0i})^2} \right\}^{1/2}$$

(R-231), from which confidence intervals are calculated.

Internally and externally standardized measures are calculated using $w_i = N_{1i}$ and $w_i = N_{0i}$, respectively, and are obtained with the `istandard` and `estandard` options, respectively.

Directly pooled estimates of the odds ratio are available when you specify both the `pool` and `or` options. The directly pooled estimate is a weighted average of stratum-specific log odds-ratios; each weight, $w_i$, is inversely proportional to the variance of the log odds-ratio for stratum $i$. The variances of the log odds-ratios are estimated by Woolf’s method, described under *Unstratified cumulative incidence data (cs and csi)*. The standard error of the directly pooled log odds-ratio is calculated as $1/\sqrt{\sum w_i}$, from which confidence intervals are calculated and then exponentiated (Kahn and Sempos 1989, 113–115).

Direct pooling is also available for risk ratios and risk differences; the variance formulas may be found in *Unstratified cumulative incidence data (cs and csi)*. The directly pooled risk ratio is provided when the `pool` option is specified. The directly pooled risk difference is provided only when you specify the `pool` and `rd` options, and one of the `estandard`, `istandard`, and `standard()` options.

For risk differences, the $\chi^2$ test of homogeneity is calculated as $\sum (R_{di} - \hat{R}_d)^2 / \text{var}(R_{di})$, where $R_{di}$ are the stratum-specific risk differences and $\hat{R}_d$ is the directly pooled estimate. The number of degrees of freedom is one less than the number of strata (R-222).

For risk and odds ratios, the same calculation is made, except that it is made in the log scale using $\ln(R_{ri})$ or $\ln(\psi_i)$ (R-222), and $\ln(\hat{R}_d)$ may be the log of either the directly pooled estimate or the Mantel–Haenszel estimate.

**Stratified case–control data (cc with by() option, mhodds, tabodds)**

Statistics presented for each stratum are calculated independently according to the formulas in *Unstratified cumulative incidence data (cs and csi)* above. The combined odds ratio, $\psi_{mh}$, and the test that $\psi_{mh} = 1$ ($\chi^2_{mh}$) are calculated as described in *Stratified cumulative incidence data (cs with the by() option)* above.

For standardized weights, let $w_i$ be the user-specified weight within stratum $i$. The standardized odds ratio (the `standard()` option) is calculated as

$$\text{SOR} = \frac{\sum_i w_i a_i / c_i}{\sum_i w_i b_i / d_i}$$

(Greenland 1986, 473). The standard error of $\ln(SOR)$ is

$$s\ln(SOR) = \left\{ \frac{\sum_i (w_i a_i / c_i)^2 (1/a_i + 1/b_i + 1/c_i + 1/d_i)}{(\sum_i w_i a_i / c_i)^2} \right\}^{1/2}$$

from which confidence intervals are calculated. The internally and externally standardized odds ratios are calculated using $w_i = c_i$ and $w_i = d_i$, respectively.
The directly pooled estimate of the odds ratio (the pool option) is calculated as described in *Stratified cumulative incidence data (cs with the by() option)* above.

The directly pooled and Mantel–Haenszel $\chi^2$ tests of homogeneity are calculated as

$$\sum \left\{ \ln(R_{ri}) - \ln(\hat{R}_r) \right\}^2 / \text{var}\{\ln(R_{ri})\},$$

where $R_{ri}$ are the stratum-specific odds ratios and $\hat{R}_r$ is the pooled estimate (Mantel–Haenszel or directly pooled). The number of degrees of freedom is one less than the number of strata ($R - 2$).

The Breslow–Day $\chi^2$ test of homogeneity is available with the bd option. Let $\hat{\psi}$ be the Mantel–Haenszel estimate of the common odds ratio, and let $A_i(\hat{\psi})$ be the fitted count for cell $a$; $A_i(\hat{\psi})$ is found by solving the quadratic equation

$$A(M_0 - N_1 + A) = (\hat{\psi})(M_1 - A)(N_1 - A)$$

and choosing the root that makes all cells in stratum $i$ positive. Let $\text{Var}(a_i; \hat{\psi})$ be the estimated variance of $a_i$ conditioned on the margins and on an odds ratio of $\hat{\psi}$:

$$\text{Var}(a_i; \hat{\psi}) = \left\{ \frac{1}{A_i(\hat{\psi})} + \frac{1}{M_{1i} - A_i(\hat{\psi})} + \frac{1}{N_{1i} - A_i(\hat{\psi})} + \frac{1}{M_{0i} - N_{1i} + A_i(\hat{\psi})} \right\}^{-1}$$

The Breslow–Day $\chi^2$ statistic is then

$$\sum_i \frac{(a_i - A_i(\hat{\psi}))^2}{\text{Var}(a_i; \hat{\psi})}$$

The Tarone $\chi^2$ test of homogeneity (the tarone option) is calculated as

$$\sum_i \frac{(a_i - A_i(\hat{\psi}))^2}{\text{Var}(a_i; \hat{\psi})} - \frac{\sum_i a_i - \sum_i A_i(\hat{\psi})^2}{\sum_i \text{Var}(a_i; \hat{\psi})}$$

Tarone (1985) provides this correction to the Breslow–Day statistic to ensure that its distribution is asymptotically chi-squared. Without the correction, the Breslow–Day statistic does not necessarily follow a chi-squared distribution because it is based on the Mantel–Haenszel estimate, $\hat{\psi}$, which is an inefficient estimator of the common odds ratio.

When the exposure variable has multiple levels, mhodds calculates an approximate estimate of the log odds-ratio for a one-unit increase in exposure as the ratio of the score statistic, $U$, to its variance, $V$ (Clayton and Hills 1993, 103), which are defined below. This is a one-step Newton-Raphson approximation to the maximum likelihood estimate. Within-stratum estimates are combined with Mantel–Haenszel weights.

By default, both tabodds and mhodds produce test statistics and confidence intervals based on score statistics (Clayton and Hills 1993). tabodds reports confidence intervals for the odds of the $i$th exposure level, unless the adjust() or or option is specified. The confidence interval for odds $i$, $i = 1, \ldots, k$, is given by

$$\text{odds}_i \cdot \exp\left( \pm \frac{z}{\sqrt{1/a_i + 1/c_i}} \right)$$

The score $\chi^2$ test of homogeneity of odds is calculated as

$$\chi^2_{k-1} = \frac{T(T - 1)}{M_1M_0} \sum_{i=1}^{k} \frac{(a_i - E_i)^2}{N_i}$$

where $E_i = (M_1N_i)/T$. 
Let $l_i$ denote the value of the exposure at the $i$th level. The score $\chi^2$ test for trend of odds is calculated as

$$\chi^2_1 = U^2/V$$

where

$$U = \frac{M_1 M_0}{T} \left( \sum_{i=1}^{k} a_i l_i M_1 - \sum_{i=1}^{k} c_i l_i M_0 \right)$$

and

$$V = \frac{M_1 M_0}{T} \left\{ \sum_{i=1}^{k} N_i l_i^2 - \left( \sum_{i=1}^{k} N_i l_i \right)^2 / T \right\}$$

**Acknowledgments**

We thank Hal Morgenstern, professor emeritus of the Department of Epidemiology at the University of Michigan, Ardythe Morrow of Cincinnati Children’s Hospital, and the late Stewart West of Baylor College of Medicine for their assistance in designing these commands.

We thank Jonathan Freeman (1939–2000) of the Department of Epidemiology at Harvard School of Public Health for encouraging us to extend these commands to include tests for homogeneity, for helpful comments on the default behavior of the commands, and for his comments on an early draft of this section.

We thank David Clayton (retired) of the Cambridge Institute for Medical Research and Michael Hills (retired) of the London School of Hygiene and Tropical Medicine, who wrote the original versions of mhodds and tabodds.

Finally, we thank William Dupont and Dale Plummer, both at the Department of Biostatistics, Vanderbilt University, for their contribution to the implementation of exact confidence intervals for the odds ratios for cc and cci.
John Snow (1813–1858) was born in York, England. From age 14, he worked as an apprentice and assistant to surgeons in northeast England and Yorkshire. In 1836, Snow moved to London; he was admitted to the Royal College of Surgeons in 1838 and the Royal College of Physicians in 1850. He made outstanding contributions to the adoption of anesthesia and is considered one of the originators of modern epidemiology. Snow died following a stroke in 1858.

Snow calculated dosages for ether and chloroform. He personally administered chloroform to Queen Victoria for the births of her last two children, which helped obstetric anesthesia gain wider acceptance.

Snow was skeptical of the miasma theory that cholera was caused by foul air. His essay On the Mode of Communication of Cholera was first published in 1849 and then greatly enlarged in 1855 with the results of his very detailed investigation of the role of water supply in the epidemic of 1854 in the Soho district of London. Snow identified the source of the outbreak as the public water pump on Broad Street (now Broadwick Street), leading the local council to remove the pump handle. It was later discovered that the well had been dug very close to an old cesspit. He also mapped the clustering of cholera cases around the pump and related mortality to water sources, clearly showing higher death rates in areas supplied by the Southwark and Vauxhall Waterworks Company, which was taking water from sewage-polluted sections of the River Thames. Snow is widely regarded as a pioneer in public health, epidemiology, and medical geography.

Janet Elizabeth Lane-Claypon (1877–1967) was a pioneer in the use of cohort and case–control studies. She was born in Lincolnshire county, England, and began her studies at the London School of Medicine for Women in 1898. From 1907 to 1912, she was at the Lister Institute of Preventive Medicine, where she was a colleague of Major Greenwood. By the end of her studies, she had obtained a doctorate in both physiology and medicine.

In 1912, Lane-Claypon published one of the first retrospective cohort studies, examining the weight gain of babies fed cow’s milk versus babies fed breast milk. Using statistical techniques, she determined that babies fed breast milk gained weight faster; she later employed that knowledge to become a public health advocate for breast feeding.

She also conducted one of the first case–control studies, examining risk factors associated with breast cancer. Her study included 500 women without breast cancer and 500 women with breast cancer. To obtain what was at the time a remarkably large sample, she coordinated data collection from nine different hospitals. Carefully controlling for variables including occupation and infant mortality, she determined that factors like age at first pregnancy, age at menopause, and number of children all influence the incidence of breast cancer; these factors are still considered to be among the prime determinants.

In conjunction with the Ministry of Health, in 1926 Lane-Claypon published one of the first studies to contain long-term follow-up results. In that study, she followed patients who had undergone surgery for breast cancer for up to 10 years after the operation. As is still the case today, her study showed that the sooner the cancer was treated, the better the woman’s chance for long-term survival. Notably, her study was also among the first to consider survivorship bias.

[U] 19 Immediate commands
Description

Whenever Stata detects that something is wrong—that what you typed is uninterpretable, that you are trying to do something you should not be trying to do, or that you requested the impossible—Stata responds by typing a message describing the problem, together with a return code. For instance,

```
. lsit
  command lsit is unrecognized
  r(199);
. list myvar
  variable myvar not found
  r(111);
. test a=b
  last estimates not found
  r(301);
```

In each case, the message is probably sufficient to guide you to a solution. When we typed `lsit`, Stata responded with “unrecognized command”. We meant to type `list`. When we typed `list myvar`, Stata responded with “variable myvar not found”. There is no variable named `myvar` in our data. When we typed `test a=b`, Stata responded with “last estimates not found”. `test` tests hypotheses about previously fit models, and we have not yet fit a model.

The numbers in parentheses in the `r(199)`, `r(111)`, and `r(301)` messages are called the return codes. To find out more about these messages, type `search rc #`, where `#` is the number returned in the parentheses.

> Example 1

```
. search rc 301
  [P] error messages ................................ Return code 301
  last estimates not found;
  You typed an estimation command, such as `regress`, without arguments
  or attempted to perform a `test` or typed `predict`, but there were no
  previous estimation results.
```

Programmers should see [P] error for details on programming error messages.

esize — Effect size based on mean comparison

Description

esize calculates effect sizes for comparing the difference between the means of a continuous variable for two groups. In the first form, esize calculates effect sizes for the difference between the mean of varname for two groups defined by groupvar. In the second form, esize calculates effect sizes for the difference between varname1 and varname2, assuming unpaired data.

esizei is the immediate form of esize; see [U] 19 Immediate commands. In the first form, esizei calculates the effect size for comparing the difference between the means of two groups. In the second form, esizei calculates the effect size for an F test after an ANOVA.

Quick start

Cohen’s d and Hedges’s g comparing the difference in means of v for two independent groups in catvar

```
esize twosample v, by(catvar)
```

As above, but with group data stored in v1 and v2

```
esize unpaired v1==v2
```

As above, but use 90% confidence level

```
esize unpaired v1==v2, level(90)
```

Cohen’s d and Hedges’s g for means of v for groups in catvar1 calculated over each level of catvar2

```
by catvar2: esize twosample v, by(catvar1)
```

by is allowed with `esize`; see [D] by.

Options

`by(groupvar)` specifies the `groupvar` that defines the two groups that `esize` will use to estimate the effect sizes. Do not confuse the `by()` option with the `by` prefix; you can specify both.

- `cohensd` specifies that Cohen’s $d$ (1988) be reported.
- `hedgesg` specifies that Hedges’s $g$ (1981) be reported.
- `glassdelta` specifies that Glass’s Δ (Smith and Glass 1977) be reported.
- `pbcorr` specifies that the point-biserial correlation coefficient (Pearson 1909) be reported.
- `all` specifies that all estimates of effect size be reported. The default is Cohen’s $d$ and Hedges’s $g$.
- `unequal` specifies that the data not be assumed to have equal variances.
- `welch` specifies that the approximate degrees of freedom for the test be obtained from Welch’s formula (1947) rather than from Satterthwaite’s approximation formula (1946), which is the default when `unequal` is specified. Specifying `welch` implies `unequal`. 
level(#) specifies the confidence level, as a percentage, for confidence intervals. The default is level(95) or as set by `set level`; see [U] 20.8 Specifying the width of confidence intervals.

Remarks and examples

Remarks are presented under the following headings:

- Introduction
- Estimating effect sizes
- Immediate form
- Video example

Introduction

Whereas \( p \)-values are used to assess the statistical significance of a result, measures of effect size are used to assess the practical significance of a result. Effect sizes can be broadly categorized as “measures of group differences” (the \( d \) family) and “measures of association” (the \( r \) family); see Ellis (2010, table 1.1). The \( d \) family includes estimators such as Cohen’s \( d \), Hedges’s \( g \), and Glass’s \( \Delta \). The \( r \) family includes estimators such as the point-biserial correlation coefficient, \( \eta^2 \), \( \varepsilon^2 \), and \( \omega^2 \) (also see `estat esize` in [R] `regress postestimation`). For an introduction to the concepts and calculation of effect sizes, see Kline (2013) and Thompson (2006). For a more detailed discussion, see Kirk (1996), Ellis (2010), Cumming (2012), Grissom and Kim (2012), and Kelley and Preacher (2012).

It should be noted that there is much variation in the definitions of measures of effect size (Kline 2013). As Ellis (2010, 27) cautions, “However, beware the inconsistent terminology. What is labeled here as \( g \) was labeled by Hedges and Olkin as \( d \) and vice versa. For these authors writing in the early 1980s, \( g \) was the mainstream effect-size index developed by Cohen and refined by Glass (hence \( g \) for Glass). However, since then \( g \) has become synonymous with Hedges’s equation (not Glass’s) and the reason it is called Hedges’s \( g \) and not Hedges’s \( h \) is because it was originally named after Glass—even though it was developed by Larry Hedges. Confused?”

To avoid confusion, `esize` and `esizei` closely follow the notation of Hedges (1981), Smithson (2001), Kline (2013), and Ellis (2010).
Estimating effect sizes

Example 1: Effect size for two independent samples using by()

Suppose we are interested in question 1 from the fictitious depression.dta: “My statistical software makes me feel sad”. We might have conducted a t test to test the null hypothesis that there is no difference in response by sex. We could then compute various measures of effect size to describe the magnitude of the effect of sex.

```
use https://www.stata-press.com/data/r16/depression
(Fictitious Depression Inventory data based on the Beck Depression Inventory)
esize twosample qu1, by(sex) all
```

</tbody>
</table>

Cohen’s d, Hedges’s g, and both estimates of Glass’s Δ indicate that the score for females is 0.05 standard deviations lower than the score for males. The point-biserial correlation coefficient indicates that there is a small, negative correlation between the scores for females and males.

Technical note

Glass’s Δ has traditionally been estimated for experimental studies using the control group standard deviation rather than the pooled standard deviation. Kline (2013) notes that the choice of group becomes arbitrary for data arising from observational studies and recommends the reporting of Glass’s Δ using each group standard deviation.
Example 2: Effect size for two independent samples by a third variable

If we are interested in the same effect sizes from example 1 stratified by race, we could use the by prefix with the sort option to accomplish this task.

. by race, sort: esize twosample qu1, by(sex)

-> race = Hispanic
Effect size based on mean comparison

Example 3: Bootstrap confidence intervals for effect sizes

Simulation studies have shown that bootstrap confidence intervals may be preferable to confidence intervals based on the noncentral \( t \) distribution when the variable of interest does not have a normal distribution (Kelley 2005; Algina, Keselman, and Penfield 2006). Bootstrap confidence intervals can be easily estimated for effect sizes using the `bootstrap` prefix.

```stata
use https://www.stata-press.com/data/r16/depression
(Fictitious Depression Inventory data based on the Beck Depression Inventory)
set seed 12345
bootstrap r(d) r(g), reps(1000) nodots nowarn: esize twosample qu1, by(sex)
```

<td>-.0512032</td>
<td>.0742134</td>
</tr>
</tbody>
</table>

Example 4: Effect sizes for two independent samples using variables

Sometimes, the data of interest are stored in two separate variables. We can calculate effect sizes for the two groups by using the `unpaired` version of `esize`.

```stata
use https://www.stata-press.com/data/r16/fuel
esize unpaired mpg1==mpg2
```

**Effect size based on mean comparison**

<table>
<thead>
<tr>
<th>Effect Size</th>

<tbody>
<tr>
<td>Cohen’s ( d )</td>
<td>-.5829654</td>
<td>-1.394934</td>
</tr>
<tr>
<td>Hedges’s ( g )</td>
<td>-.5628243</td>
<td>-1.34674</td>
</tr>
</tbody>
</table>
Immediate form

Example 5: Immediate form for effect sizes for two means

Often we do not have access to raw data, but we are given summary statistics in a report or manuscript. To calculate the effect sizes from summary statistics, we can use the immediate command esizei. For example, Kline (2013) in table 4.2 shows summary statistics for a hypothetical sample where mean$_1$ = 13, sd$_1$ = 2.74, mean$_2$ = 11, and sd$_2$ = 2.24; there are 30 people in each group. We can estimate the effect sizes from these summary data using esizei:

```
. esizei 30 13 2.74 30 11 2.24
Obs per group:
Group 1 = 30
Group 2 = 30

<table>
<thead>
<tr>
<th>Effect Size</th>
<th>Estimate</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>Cohen's d</td>
<td>.7991948</td>
<td>.2695509 1.322465</td>
</tr>
<tr>
<td>Hedges's g</td>
<td>.7888081</td>
<td>.2660477 1.305277</td>
</tr>
</tbody>
</table>
```

Example 6: Immediate form for effect sizes for F tests after an ANOVA

esizei can also be used to compute $\eta^2$, $\varepsilon^2$, and $\omega^2$ for $F$ tests after an ANOVA. The following example from Smithson (2001, 623) illustrates the use of esizei for df$_{num}$ = 4, df$_{den}$ = 50, and $F$ = 4.2317.

```
. esizei 4 50 4.2317, level(90)
Obs per group:
Group 1 = 30
Group 2 = 30

<table>
<thead>
<tr>
<th>Effect Size</th>
<th>Estimate</th>
<th>[90% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>Eta-Squared</td>
<td>.2529151</td>
<td>.0521585 .3603621</td>
</tr>
<tr>
<td>Epsilon-Squared</td>
<td>.1931483</td>
<td></td>
</tr>
<tr>
<td>Omega-Squared</td>
<td>.1903049</td>
<td></td>
</tr>
</tbody>
</table>
```

Video example

Tour of effect sizes
stored results

esize and esizei for comparing two means store the following in r():

Scalars

- r(d): Cohen's d
- r(lb_d): lower confidence bound for Cohen's d
- r(ub_d): upper confidence bound for Cohen's d
- r(g): Hedges's g
- r(lb_g): lower confidence bound for Hedges's g
- r(ub_g): upper confidence bound for Hedges's g
- r(delta1): Glass's Δ for group 1
- r(lb_delta1): lower confidence bound for Glass's Δ for group 1
- r(ub_delta1): upper confidence bound for Glass's Δ for group 1
- r(delta2): Glass's Δ for group 2
- r(lb_delta2): lower confidence bound for Glass's Δ for group 2
- r(ub_delta2): upper confidence bound for Glass's Δ for group 2
- r(r_pb): point-biserial correlation coefficient
- r(lb_r_pb): lower confidence bound for the point-biserial correlation coefficient
- r(ub_r_pb): upper confidence bound for the point-biserial correlation coefficient
- r(N_1): sample size n₁
- r(N_2): sample size n₂
- r(df_t): degrees of freedom
- r(level): confidence level

esizei for F tests after ANOVA stores the following in r():

Scalars

- r(eta2): η²
- r(lb_eta2): lower confidence bound for η²
- r(ub_eta2): upper confidence bound for η²
- r(epsilon2): ε²
- r(omega2): ω²
- r(level): confidence level

Methods and formulas

For the d family, the effect-size parameter of interest is the scaled difference between the means given by

$$\delta = \frac{(\mu_1 - \mu_2)}{\sigma}$$

One of the most popular estimators of effect size is Cohen's d, given by

$$\text{Cohen's } d = \frac{(\bar{x}_1 - \bar{x}_2)}{s^*}$$

where

$$s^* = \sqrt{\frac{(n_1 - 1)s_1^2 + (n_2 - 1)s_2^2}{n_1 + n_2 - 2}}$$
Hedges (1981) showed that Cohen’s $d$ is biased and proposed the unbiased estimator

$$Hedges’s \ g = Cohen’s \ d \times c(m)$$

where $m = n_1 + n_2 - 2$ and

$$c(m) = \frac{\Gamma\left(\frac{m}{2}\right)}{\sqrt{\frac{m}{2}} \Gamma\left(\frac{m-1}{2}\right)}$$

Glass (Smith and Glass 1977) proposed an estimator for $\delta$ in the context of designed experiments,

$$Glass’s \ \Delta = \frac{\bar{x}_{treated} - \bar{x}_{control}}{s_{control}}$$

where $s_{control}$ is the standard deviation for the control group.

As noted above, $esize$ and $esizei$ report two estimates of Glass’s $\Delta$: one using the standard deviation for group 1 and the other using the standard deviation for group 2:

$$Glass’s \ \Delta_1 = \frac{\bar{x}_1 - \bar{x}_2}{s_1}$$

and

$$Glass’s \ \Delta_2 = \frac{\bar{x}_1 - \bar{x}_2}{s_2}$$

For the $r$ family, the effect-size parameter of interest is the ratio of the variance attributable to an effect and the total variance:

$$\eta^2 = \frac{\sigma_{\text{effect}}^2}{\sigma_{\text{total}}^2}$$

A popular estimator of $\eta$ when there are two groups is the point-biserial correlation coefficient,

$$r_{PB} = \frac{t}{\sqrt{t^2 + df}}$$

where $t$ is the $t$ statistic for the difference between the means of the two groups, and $df$ is the corresponding degrees of freedom. Satterthwaite’s or Welch’s adjustment (see [R] $ttest$ for details) to the degrees of freedom can be used to calculate $r_{PB}$ by specifying the unequal or welch option, respectively.

When more than two means are being compared, as in the case of an ANOVA with $p$ groups, a popular estimator of effect size is the correlation ratio denoted $\eta^2$ (Fisher 1925; Kerlinger and Lee 2000). $\eta^2$ can be computed directly as the ratio of the $SS_{\text{effect}}$ and the $SS_{\text{total}}$ or as a function of the $F$ statistic with numerator degrees of freedom equal to $df_{num}$ and denominator degrees of freedom equal to $df_{den}$.

$$\hat{\eta}^2 = \frac{F}{F + df_{den}/df_{num}}$$

Like its equivalent estimator $R^2$, $\eta^2$ has an upward bias. Less biased estimators of effect size are $\hat{\varepsilon}^2$ and $\omega^2$ (Grissom and Kim 2012).

$$\hat{\varepsilon}^2 = \frac{F - 1}{F + df_{den}/df_{num}} = \hat{\eta}^2 - \frac{df_{num}}{df_{den}} (1 - \hat{\eta}^2)$$
\[ \hat{\omega}^2 = \frac{F - 1}{F + (\text{df}_{\text{den}} + 1)/\text{df}_{\text{num}}} \]

To calculate \( \hat{\eta}^2 \), \( \hat{\varepsilon}^2 \), and \( \hat{\omega}^2 \) directly after `anova` or `regress`, see `estat esize` in [R] `regress postestimation`.

Cohen’s \( d \), Hedges’s \( g \), and Glass’s \( \Delta \) have been shown to have a noncentral \( t \) distribution (Hedges 1981) with noncentrality parameter equal to

\[ \lambda = \delta \sqrt{\frac{n_1 n_2}{n_1 + n_2}} \]

Confidence intervals are calculated by finding the noncentrality parameters \( \lambda_{\text{lower}} \) and \( \lambda_{\text{upper}} \) that correspond to

\[ \Pr(\text{df}, \delta, \lambda_{\text{lower}}) = 1 - \frac{\alpha}{2} \]

and

\[ \Pr(\text{df}, \delta, \lambda_{\text{upper}}) = \frac{\alpha}{2} \]

using the function `npnt(df, t, p)`. The noncentrality parameters are then transformed back to the effect-size scale:

\[ \delta_{\text{lower}} = \lambda_{\text{lower}} \sqrt{\frac{n_1 + n_2}{n_1 n_2}} \]

and

\[ \delta_{\text{upper}} = \lambda_{\text{upper}} \sqrt{\frac{n_1 + n_2}{n_1 n_2}} \]

(see Venables [1975]; Steiger and Fouladi [1997]; Cumming and Finch [2001]; Smithson [2001]).

Confidence intervals for the point-biserial correlation coefficient are calculated similarly and transformed back to the effect-size scale as

\[ r_{\text{lower}} = \frac{\lambda_{\text{lower}}}{\sqrt{\lambda_{\text{lower}}^2 + df}} \]

and

\[ r_{\text{upper}} = \frac{\lambda_{\text{upper}}}{\sqrt{\lambda_{\text{upper}}^2 + df}} \]

Following Smithson’s (2001) notation, the \( F \) statistic is written as

\[ F_{\text{df}_{\text{num}}, \text{df}_{\text{den}}} = f^2(\text{df}_{\text{num}}/\text{df}_{\text{den}}) \]

This equation has a noncentral \( F \) distribution with noncentrality parameter:

\[ \lambda = f^2(\text{df}_{\text{num}} + \text{df}_{\text{den}} + 1) \]

where \( f^2 = \eta^2/(1 - \eta^2) \).
Confidence intervals for $\hat{\eta}^2$ are calculated by finding the noncentrality parameters $\lambda_{\text{lower}}$ and $\lambda_{\text{upper}}$ for a noncentral $F$ distribution that correspond to

$$\Pr(df_{\text{num}}, df_{\text{den}}, F, \lambda_{\text{lower}}) = 1 - \frac{\alpha}{2}$$

and

$$\Pr(df_{\text{num}}, df_{\text{den}}, F, \lambda_{\text{upper}}) = \frac{\alpha}{2}$$

using the function npnF($df_1, df_2, f, p$). The noncentrality parameters are transformed back to the $\hat{\eta}^2$ scale as

$$\hat{\eta}^2_{\text{lower}} = \frac{\lambda_{\text{lower}}}{\lambda_{\text{lower}} + df_{\text{num}} + df_{\text{den}} + 1}$$

and

$$\hat{\eta}^2_{\text{upper}} = \frac{\lambda_{\text{upper}}}{\lambda_{\text{upper}} + df_{\text{num}} + df_{\text{den}} + 1}$$

While confidence intervals for $\varepsilon^2$ can be constructed using the same transformation that links it with $\hat{\eta}^2$, there are several arguments for not using them in practice. See Smithson (2003, 54) for further details.

Fred Nichols Kerlinger (1910–1991) was born in New York City. He studied music at New York University and graduated magna cum laude with a degree in education and philosophy. After graduation, he joined the U.S. Army and served as a counterintelligence officer in Japan in 1946. Kerlinger earned an MA and a PhD in educational psychology from the University of Michigan and held faculty appointments at several universities, including New York University. He was president of the American Educational Research Association and is best known for his popular and influential book Foundations of Behavioral Research (1964), which introduced Fisher’s (1925) $\eta^2$ statistic to behavioral researchers.

William Lee Hays (1926–1995) was born in Clarksville, Texas. He studied mathematics and psychology at Paris Junior College in Paris, Texas, and at East Texas State College. He earned BS and MS degrees from North Texas State University. Upon completion of his PhD in psychology at the University of Michigan, he joined the faculty, where he eventually became associate vice president for academic affairs. In 1977, Hays accepted an appointment as vice president for academic affairs at the University of Texas at Austin, where he remained until his death in 1995. Hays is best known for his book Statistics for Psychologists (1963), which introduced the $\omega^2$ statistic (and is actually denoted here by $\varepsilon^2$).

**Description**

`estat` displays scalar- and matrix-valued statistics after estimation; it complements `predict`, which calculates variables after estimation. Exactly what statistics `estat` can calculate depends on the previous estimation command.

Three sets of statistics are so commonly used that they are available after all estimation commands that store the model log likelihood. `estat ic` displays Akaike’s and Schwarz’s Bayesian information criteria. `estat summarize` summarizes the variables used by the command and automatically restricts the sample to `e(sample)`; it also summarizes the weight variable and cluster structure, if specified. `estat vce` displays the covariance or correlation matrix of the parameter estimates of the previous model.

### options Description

<table>
<thead>
<tr>
<th>Main</th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>all</td>
<td>display summary statistics for all observations in the data</td>
</tr>
<tr>
<td>cutoff(#)</td>
<td>positive outcome threshold; default is cutoff(0.5)</td>
</tr>
</tbody>
</table>

fweights are allowed; see [U] 11.1.6 weight.
estat classification is not appropriate after the svy prefix.

### Options

- **all** requests that the statistic be computed for all observations in the data, ignoring any if or in restrictions specified by the estimation command.
- **cutoff(#)** specifies the value for determining whether an observation has a predicted positive outcome. An observation is classified as positive if its predicted probability is $\geq #$. The default is 0.5.

### Remarks and examples

`estat classification` presents the classification statistics and classification table after `logistic`, `logit`, `probit`, or `ivprobit`.

Statistics are produced either for the estimation sample (the default) or for any set of observations. When weights, if, or in is used with the estimation command, it is not necessary to repeat the qualifier when you want statistics computed for the estimation sample. Specify if, in, or the all option only when you want statistics computed for a set of observations other than the estimation sample. Specify weights only when you want to use a different set of weights.
Example 1

We illustrate `estat classification` after `logistic`; see [R] `logistic`.

```
. use https://www.stata-press.com/data/r16/lbw
(Hosmer & Lemeshow data)

False + rate for true ~D | Pr( + | ~D) | 9.23%
False - rate for true D   | Pr( - | D) | 64.41%
False + rate for classified + | Pr( ~D | +) | 36.36%
False - rate for classified - | Pr( D | -) | 24.36%

Correctly classified 73.54%

The overall rate of correct classification is estimated to be 73.54, with 90.77% of the normal weight group correctly classified (specificity) and only 35.59% of the low weight group correctly classified (sensitivity). Classification is sensitive to the relative sizes of each component group, and always favors classification into the larger group. This phenomenon is evident here.

By default, `estat classification` uses a cutoff of 0.5, although you can vary this with the `cutoff()` option. You can use the `lsens` command to review the potential cutoffs; see [R] `lsens`.

Stored results

`estat classification` stores the following in `r()`: Scalars

- `r(P_corr)` percent correctly classified
- `r(P_p1)` sensitivity
- `r(P_n0)` specificity
- `r(P_p0)` false-positive rate given true negative
- `r(P_n1)` false-negative rate given true positive
- `r(P_1p)` positive predictive value
- `r(P_0n)` negative predictive value
- `r(P_0p)` false-positive rate given classified positive
- `r(P_in)` false-negative rate given classified negative

Matrices

- `r(ctable)` classification table
Methods and formulas

Let \( j \) index observations. Define \( c \) as the \texttt{cutoff()} specified by the user or, if not specified, as 0.5. Let \( p_j \) be the predicted probability of a positive outcome and \( y_j \) be the actual outcome, which we will treat as 0 or 1, although Stata treats it as 0 and non-0, excluding missing observations.

A prediction is classified as \textit{positive} if \( p_j \geq c \) and otherwise is classified as \textit{negative}. The classification is \textit{correct} if it is \textit{positive} and \( y_j = 1 \) or if it is \textit{negative} and \( y_j = 0 \).

\textit{Sensitivity} is the fraction of \( y_j = 1 \) observations that are correctly classified. \textit{Specificity} is the percentage of \( y_j = 0 \) observations that are correctly classified.

</table>

Options

\texttt{fweight} is allowed; see [U] \texttt{11.1.6 weight}.
\texttt{estat gof} is not appropriate after the \texttt{svy} prefix.

Remarks and examples

Remarks are presented under the following headings:

\textit{Introduction}
\textit{Samples other than the estimation sample}

Introduction

\texttt{estat gof} computes goodness-of-fit tests: either the Pearson $\chi^2$ test or the Hosmer–Lemeshow test.

By default, \texttt{estat gof} computes statistics for the estimation sample by using the last model fit by \texttt{logistic}, \texttt{logit}, or \texttt{probit}. However, samples other than the estimation sample can be specified; see \textit{Samples other than the estimation sample} later in this entry.
Example 1

`estat gof`, typed without options, presents the Pearson $\chi^2$ goodness-of-fit test for the fitted model. The Pearson $\chi^2$ goodness-of-fit test is a test of the observed against expected number of responses using cells defined by the covariate patterns; see `predict with the number option` in [R] logistic postestimation for the definition of covariate patterns.

```
use https://www.stata-press.com/data/r16/lbw
(logistic & Lemeshow data)
.logistic low age lwt i.race smoke ptl ht ui
(output omitted)
.estat gof
```

**Logistic model for low, goodness-of-fit test**

| number of observations = | 189 |
| number of covariate patterns = | 182 |
| Pearson chi2(173) = | 179.24 |
| Prob > chi2 = | 0.3567 |

Our model fits reasonably well. However, the number of covariate patterns is close to the number of observations, making the applicability of the Pearson $\chi^2$ test questionable but not necessarily inappropriate. Hosmer, Lemeshow, and Sturdivant (2013, 157–160) suggest regrouping the data by ordering on the predicted probabilities and then forming, say, 10 nearly equal-sized groups. `estat gof` with the `group()` option does this:

```
.estat gof, group(10)
```

**Logistic model for low, goodness-of-fit test**

</tbody>
</table>

number of observations = 189
number of groups = 10
Hosmer-Lemeshow chi2(8) = 9.65
Prob > chi2 = 0.2904
Technical note

`estat gof` with the `group()` option puts all observations with the same predicted probabilities into the same group. If, as in the previous example, we request 10 groups, the groups that `estat gof` makes are \([p_0, p_{10}], (p_{10}, p_{20}), (p_{20}, p_{30}), \ldots, (p_{90}, p_{100})\], where \(p_k\) is the \(k\)th percentile of the predicted probabilities, with \(p_0\) the minimum and \(p_{100}\) the maximum.

If there are many ties at the quantile boundaries, as will often happen if all independent variables are categorical and there are only a few of them, the sizes of the groups will be uneven. If the totals in some of the groups are small, the \(\chi^2\) statistic for the Hosmer–Lemeshow test may be unreliable. In this case, fewer groups should be specified, or the Pearson goodness-of-fit test may be a better choice.

> Example 2

The `table` option can be used without the `group()` option. We would not want to specify this for our current model because there were 182 covariate patterns in the data, caused by including the two continuous variables, `age` and `lwt`, in the model. As an aside, we fit a simpler model and specify `table` with `estat gof`:

```stata
. logistic low i.race smoke ui
Logistic regression
Number of obs = 189
LR chi2(4) = 18.80
Prob > chi2 = 0.0009
Log likelihood = -107.93404 Pseudo R2 = 0.0801

</table>

number of observations = 189
number of covariate patterns = 11
Pearson chi2(6) = 5.71
Prob > chi2 = 0.4569

Technical note

logistic, logit, or probit and estat gof keep track of the estimation sample. If you type, for instance, logistic ... if x==1, then when you type estat gof, the statistics will be calculated on the x==1 subsample of the data automatically.

You should specify if or in with estat gof only when you wish to calculate statistics for a set of observations other than the estimation sample. See Samples other than the estimation sample later in this entry.

If the logistic model was fit with fweights, estat gof properly accounts for the weights in its calculations. (estat gof only allows fweights.) You do not have to specify the weights when you run estat gof. Weights should be specified with estat gof only when you wish to use a different set of weights.
### Samples other than the estimation sample

`estat gof` can be used with samples other than the estimation sample. By default, `estat gof` remembers the estimation sample used with the last `logistic`, `logit`, or `probit` command. To override this, simply use an `if` or `in` restriction to select another set of observations, or specify the all option to force the command to use all the observations in the dataset.

If you use `estat gof` with a sample that is completely different from the estimation sample (that is, no overlap), you should also specify the `outsample` option so that the $\chi^2$ statistic properly adjusts the degrees of freedom upward. For an overlapping sample, the conservative thing to do is to leave the degrees of freedom the same as they are for the estimation sample.

### Example 3

We want to develop a model for predicting low-birthweight babies. One approach would be to divide our data into two groups, a developmental sample and a validation sample. See Lemeshow and Gall (1994) and Tilford, Roberson, and Fiser (1995) for more information on developing prediction models and severity-scoring systems.

We will do this with the low-birthweight data that we considered previously. First, we randomly divide the data into two samples.

```stata
  . use https://www.stata-press.com/data/r16/lbw, clear
  (Hosmer & Lemeshow data)
  . set seed 1
  . generate r = runiform()
  . sort r
  . generate group = 1 if _n <= _N/2
       (95 missing values generated)
  . replace group = 2 if group==.
       (95 real changes made)
```

Then we fit a model using the first sample (group = 1), which is our developmental sample.

```stata
  . logistic low age lwt i.race smoke ptl ht ui if group==1
  Logistic regression
  Number of obs = 94
  LR chi2(8) = 18.81
  Prob > chi2 = 0.0159
  Log likelihood = -50.87653  Pseudo R2 = 0.1561
  | Odds Ratio Std. Err.    z  P>|z|     [95% Conf. Interval]

number of observations = 95
number of groups = 10
Hosmer-Lemeshow chi2(10) = 7.74
Prob > chi2 = 0.6544

We must acknowledge that our model does not fit well on the validation sample. The model’s discrimination in the validation sample is appreciably lower, as well.

. lroc if group==2, nograph

Logistic model for low

number of observations = 95
area under ROC curve = 0.7255
stored results

`estat gof` stores the following in `r()`:

Scalars
- `r(N)` number of observations
- `r(m)` number of covariate patterns or groups
- `r(df)` degrees of freedom
- `r(chi2)` $\chi^2$
- `r(p)` $p$-value for $\chi^2$ test

Methods and formulas

Let $M$ be the total number of covariate patterns among the $N$ observations. View the data as collapsed on covariate patterns $j = 1, 2, \ldots, M$, and define $m_j$ as the total number of observations having covariate pattern $j$ and $y_j$ as the total number of positive responses among observations with covariate pattern $j$. Define $p_j$ as the predicted probability of a positive outcome in covariate pattern $j$.

The Pearson $\chi^2$ goodness-of-fit statistic is

$$\chi^2 = \sum_{j=1}^{M} \frac{(y_j - m_j p_j)^2}{m_j p_j (1 - p_j)}$$

This $\chi^2$ statistic has approximately $M - k$ degrees of freedom for the estimation sample, where $k$ is the number of independent variables, including the constant. For a sample outside the estimation sample, the statistic has $M$ degrees of freedom.

The Hosmer–Lemeshow goodness-of-fit $\chi^2$ (Hosmer and Lemeshow 1980; Lemeshow and Hosmer 1982; Hosmer, Lemeshow, and Klar 1988) is calculated similarly, except that rather than using the $M$ covariate patterns as the group definition, the quantiles of the predicted probabilities are used to form groups. Let $G = \#$ be the number of quantiles requested with `group(#)`. The smallest index $1 \leq q(i) \leq M$, such that

$$W_{q(i)} = \sum_{j=1}^{q(i)} m_j \geq \frac{N}{G}$$

gives $p_{q(i)}$ as the upper boundary of the $i$th quantile for $i = 1, 2, \ldots, G$. Let $q(0) = 1$ denote the first index.

The groups are then

$$[p_{q(0)}; p_{q(1)}]; (p_{q(1)}; p_{q(2)}]; \ldots; (p_{q(G-1)}; p_{q(G)}]$$

If the `table` option is given, the upper boundaries $p_{q(1)}, \ldots, p_{q(G)}$ of the groups appear next to the group number on the output.

The resulting $\chi^2$ statistic has approximately $G - 2$ degrees of freedom for the estimation sample. For a sample outside the estimation sample, the statistic has $G$ degrees of freedom.

Description

`estat ic` displays Akaike’s and Schwarz’s Bayesian information criteria.

Quick start

Display Akaike’s and Schwarz’s Bayesian information criteria

```
estat ic
```

Specify the $N$ to be used in calculating BIC as 500

```
estat ic, n(500)
```

Menu for estat

Statistics > Postestimation

Syntax

```
estat ic [ , n(#) ]
```

Option

$n(#)$ specifies the $N$ to be used in calculating BIC; see [R] BIC note.

Remarks and examples

`estat ic` calculates two information criteria used to compare models. Unlike likelihood-ratio, Wald, and similar testing procedures, the models need not be nested to compare the information criteria. Because they are based on the log-likelihood function, information criteria are available only after commands that report the log likelihood.

In general, “smaller is better”: given two models, the one with the smaller AIC fits the data better than the one with the larger AIC. As with the AIC, a smaller BIC indicates a better-fitting model. For AIC and BIC formulas, see Methods and formulas.
Example 1

In [R] mlogit, we fit a model explaining the type of insurance a person has on the basis of age, gender, race, and site of study. Here we refit the model with and without the site dummies and compare the models.

```stata
. use https://www.stata-press.com/data/r16/sysdsn1
 (Health insurance data)
. mlogit insure age male nonwhite
 (output omitted)
. estat ic

Akaike’s information criterion and Bayesian information criterion

<table>
<thead>
<tr>
<th>Model</th>
<th>N</th>
<th>ll(null)</th>
<th>ll(model)</th>
<th>df</th>
<th>AIC</th>
<th>BIC</th>
</tr>
</thead>
<tbody>
<tr>
<td>.</td>
<td>615</td>
<td>-555.8545</td>
<td>-545.5833</td>
<td>8</td>
<td>1107.167</td>
<td>1142.54</td>
</tr>
</tbody>
</table>

Note: BIC uses N = number of observations. See [R] BIC note.

. mlogit insure age male nonwhite i.site
 (output omitted)
. estat ic

Akaike’s information criterion and Bayesian information criterion

<table>
<thead>
<tr>
<th>Model</th>
<th>N</th>
<th>ll(null)</th>
<th>ll(model)</th>
<th>df</th>
<th>AIC</th>
<th>BIC</th>
</tr>
</thead>
<tbody>
<tr>
<td>.</td>
<td>615</td>
<td>-555.8545</td>
<td>-534.3616</td>
<td>12</td>
<td>1092.723</td>
<td>1145.783</td>
</tr>
</tbody>
</table>

Note: BIC uses N = number of observations. See [R] BIC note.

The AIC indicates that the model including the site dummies fits the data better, whereas the BIC indicates the opposite. As is often the case, different model-selection criteria have led to conflicting conclusions.

Technical note

glm and binreg, ml report a slightly different version of AIC and BIC; see [R] glm for the formulas used. That version is commonly used within the GLM literature; see, for example, Hardin and Hilbe (2018). The literature on information criteria is vast; see, among others, Akaike (1973), Sawa (1978), and Raftery (1995). Judge et al. (1985) contains a discussion of using information criteria in econometrics. Royston and Sauerbrei (2008, chap. 2) examine the use of information criteria as an alternative to stepwise procedures for selecting model variables.

Stored results

estat ic stores the following in r():

Matrices

r(S) 1 x 6 matrix of results:
1. sample size
2. log likelihood of null model
3. log likelihood of full model
4. degrees of freedom
5. AIC
6. BIC
Methods and formulas

Akaike’s (1974) information criterion is defined as

\[ \text{AIC} = -2 \ln L + 2k \]

where \( \ln L \) is the maximized log-likelihood of the model and \( k \) is the number of parameters estimated. Some authors define the AIC as the expression above divided by the sample size.

Schwarz’s (1978) Bayesian information criterion is another measure of fit defined as

\[ \text{BIC} = -2 \ln L + k \ln N \]

where \( N \) is the sample size. See [R] BIC note for additional information on calculating and interpreting BIC.

Hirotugu Akaike (1927–2009) was born in Fujinomiya City, Shizuoka Prefecture, Japan. He was the son of a silkworm farmer. He gained BA and DSc degrees from the University of Tokyo. Akaike’s career from 1952 at the Institute of Statistical Mathematics in Japan culminated in service as Director General; after 1994, he was Professor Emeritus. His best known work in a prolific career is on what is now known as the Akaike information criterion (AIC), which was formulated to help selection of the most appropriate model from a number of candidates.

Gideon E. Schwarz (1933–2007) was a professor of Statistics at the Hebrew University, Jerusalem. He was born in Salzburg, Austria, and obtained an MSc in 1956 from the Hebrew University and a PhD in 1961 from Columbia University. His interests included stochastic processes, sequential analysis, probability, and geometry. He is best known for the Bayesian information criterion (BIC).

estat summarize — Summarize estimation sample

Description

_estat summarize_ summarizes the variables used by the command and automatically restricts the sample to the estimation sample; it also summarizes the weight variable and cluster structure, if specified.

Quick start

Summary statistics for all variables in the model using estimation sample

_estat summarize_

Add variable labels to output

_estat summarize, labels_

Obtain summary of estimation sample for each equation

_estat summarize, equation_

Ignore weights when calculating summary statistics after weighted estimation

_estat summarize, noweights_

Menu for estat

Statistics > Postestimation
estat summarize — Summarize estimation sample

Syntax

    estat summarize [ eqlist ] [ , estat_summ_options ]

Description

    equation          display summary by equation
    group             display summary by group; only after sem and gsem
    labels            display variable labels
    noheader          suppress the header
    noweights         ignore weights
    display_options   control row spacing, line width, display of omitted variables
                      and base and empty cells, and factor-variable labeling

The estat summarize command is rarely used and specifies the variables, with optional equation name, to be summarized. eqlist may be
    varlist or (eqname1: varlist) (eqname2: varlist) . . . varlist may contain time-series operators; see [U] 11.4.4 Time-series varlists.

Options

    equation requests that the dependent variables and the independent variables in the equations be
displayed in the equation-style format of estimation commands, repeating the summary information
about variables entered in more than one equation.

    group displays summary information separately for each group. group is only allowed after sem or
gsem with a group() variable specified.

    labels displays variable labels.

    noheader suppresses the header.

    noweights ignores the weights, if any, from the previous estimation command. The default when
weights are present is to perform a weighted summarize on all variables except the weight variable
itself. An unweighted summarize is performed on the weight variable.

    display_options: noomitted, vsquish, noemptycells, baselevels, allbaselevels,
nofvlabel, fvwrap(#), and fvwrapon(style); see [R] Estimation options.

Remarks and examples

Often when fitting a model, you will also be interested in obtaining summary statistics, such as
the sample means and standard deviations of the variables in the model. estat summarize makes
this process simple. The output displayed is similar to that obtained by typing

    . summarize varlist if e(sample)

without the need to type the varlist containing the dependent and independent variables.
Example 1

Continuing with the example in [R] `estat ic`, here we summarize the variables by using `estat summarize`.

```
. use https://www.stata-press.com/data/r16/sysdsn1
(Health insurance data)
. mlogit insure age male nonwhite i.site
(output omitted)
. estat summarize, noomitted

Estimation sample mlogit Number of obs = 615

<table>
<thead>
<tr>
<th>Variable</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>insure</td>
<td>1.596748</td>
<td>.6225846</td>
<td>1</td>
<td>3</td>
</tr>
<tr>
<td>age</td>
<td>44.46832</td>
<td>14.18523</td>
<td>18.11087</td>
<td>86.07254</td>
</tr>
<tr>
<td>male</td>
<td>.2504065</td>
<td>.4335998</td>
<td>0</td>
<td>1</td>
</tr>
<tr>
<td>nonwhite</td>
<td>.196748</td>
<td>.3978638</td>
<td>0</td>
<td>1</td>
</tr>
<tr>
<td>site</td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>2</td>
<td>.3707317</td>
<td>.4833939</td>
<td>0</td>
<td>1</td>
</tr>
<tr>
<td>3</td>
<td>.3138211</td>
<td>.4644224</td>
<td>0</td>
<td>1</td>
</tr>
</tbody>
</table>
```

The output in the previous example contains all the variables in one table, though `mlogit` presents its results in a multiple-equation format. For models in which the same variables appear in all equations, that is fine; but for other multiple-equation models, we may prefer to have the variables separated by the equation in which they appear. The equation option makes this possible.
Example 2

Systems of simultaneous equations typically have different variables in each equation, and the `equation` option of `estat summarize` is helpful in such situations. In example 2 of `[R] reg3`, we have a model of supply and demand. We first refit the model and then call `estat summarize`.

```
. use https://www.stata-press.com/data/r16/supDem
. reg3 (Demand:quantity price pcompete income) (Supply:quantity price praw), endog(price)
(output omitted)
. estat summarize, equation
```

### Estimation sample reg3 Number of obs = 49

<table>
<thead>
<tr>
<th>Variable</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>depvar</td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>quantity</td>
<td>12.61818</td>
<td>2.774952</td>
<td>7.710694</td>
<td>20.04767</td>
</tr>
<tr>
<td>quantity</td>
<td>12.61818</td>
<td>2.774952</td>
<td>7.710694</td>
<td>20.04767</td>
</tr>
<tr>
<td>demale</td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>price</td>
<td>32.70944</td>
<td>2.882684</td>
<td>26.38185</td>
<td>38.47692</td>
</tr>
<tr>
<td>pcompete</td>
<td>5.929975</td>
<td>3.508264</td>
<td>.2076465</td>
<td>11.55491</td>
</tr>
<tr>
<td>income</td>
<td>7.811735</td>
<td>4.18859</td>
<td>.5704173</td>
<td>14.00767</td>
</tr>
<tr>
<td>Supply</td>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>price</td>
<td>32.70944</td>
<td>2.882684</td>
<td>26.38185</td>
<td>38.47692</td>
</tr>
<tr>
<td>praw</td>
<td>4.740891</td>
<td>2.962565</td>
<td>.1510276</td>
<td>9.79881</td>
</tr>
</tbody>
</table>

The first block of the table contains statistics on the dependent (or, more accurately, left-hand-side) variables, and because we specified quantity as the left-hand-side variable in both equations, it is listed twice. The second block refers to the variables in the first equation we specified, which we labeled “Demand” in our call to `reg3`; and the final block refers to the supply equation.

### Stored results

`estat summarize` stores the following in `r()`:

- Scalars
  - `r(N_groups)` number of groups (group only)

- Matrices
  - `r(stats)` `k` × `4` matrix of means, standard deviations, minimums, and maximums
  - `r(stats[_#])` `k` × `4` matrix of means, standard deviations, minimums, and maximums for group `_#` (group only)

### Also see

- `[R] estat` — Postestimation statistics
- `[R] estat ic` — Display information criteria
- `[R] estat vce` — Display covariance matrix estimates
**Description**

`estat vce` displays the covariance or correlation matrix of the parameter estimates of the previous model.

**Quick start**

Display variance–covariance matrix of the estimates (VCE) from the previous model

```
estat vce
```

Matrix of correlations rather than covariances

```
estat vce, correlation
```

As above, but report correlations using three decimal places

```
estat vce, correlation format(%6.3f)
```

After fitting a multiple-equation model, display VCE for each equation in separate blocks

```
estat vce, block
```

Show VCE for equation `y1` only

```
estat vce, equation(y1)
```

**Menu for estat**

Statistics > Postestimation
Syntax

```
estat vce [, estat_vce_options]
```

<table>
<thead>
<tr>
<th>estat_vce_options</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>covariance</strong></td>
<td>display as covariance matrix; the default</td>
</tr>
<tr>
<td><strong>correlation</strong></td>
<td>display as correlation matrix</td>
</tr>
<tr>
<td><strong>equation(spec)</strong></td>
<td>display only specified equations</td>
</tr>
<tr>
<td><strong>block</strong></td>
<td>display submatrices by equation</td>
</tr>
<tr>
<td><strong>diag</strong></td>
<td>display submatrices by equation; diagonal blocks only</td>
</tr>
<tr>
<td><strong>format(%fmt)</strong></td>
<td>display format for covariances and correlations</td>
</tr>
<tr>
<td><strong>nolines</strong></td>
<td>suppress lines between equations</td>
</tr>
</tbody>
</table>

**Options**

covariance displays the matrix as a variance–covariance matrix; this is the default.
correlation displays the matrix as a correlation matrix rather than a variance–covariance matrix.
rho is a synonym.
equation(spec) selects part of the VCE to be displayed. If `spec` is eqlist, the VCE for the listed equations is displayed. If `spec` is eqlist1 \ eqlist2, the part of the VCE associated with the equations in eqlist1 (rowwise) and eqlist2 (columnwise) is displayed. If `spec` is *, all equations are displayed.
equation() implies block if diag is not specified.
block displays the submatrices pertaining to distinct equations separately.
diag displays the diagonal submatrices pertaining to distinct equations separately.
format(%fmt) specifies the number format for displaying the elements of the matrix. The default is `format(%10.0g)` for covariances and `format(%8.4f)` for correlations. See [U] 12.5 Formats: Controlling how data are displayed for more information.
nolines suppresses lines between equations.
display_options: noomitted, noemptycells, baselevels, allbaselevels; see [R] Estimation options.

**Remarks and examples**

`estat vce` allows you to display the VCE of the parameters of the previously fit model, as either a covariance matrix or a correlation matrix.

**Example 1**

Returning to the example in [R] estat ic, here we display the covariance matrix of the parameters of the mlogit model by using `estat vce`. 
. use https://www.stata-press.com/data/r16/sysdsn1
  (Health insurance data)
. mlogit insure age male nonwhite
  (output omitted)
. estat vce, block

</table>
The block option is particularly useful for multiple-equation estimators. The first block of output here corresponds to the VCE of the estimated parameters for the first equation—the square roots of the diagonal elements of this matrix are equal to the standard errors of the first equation’s parameters. Similarly, the final block corresponds to the VCE of the parameters for the second equation. The middle block shows the covariances between the estimated parameters of the first and second equations.

### Stored results

`estat vce` stores the following in `r()`:

Matrices

- `r(V)` VCE or correlation matrix

### Also see

- [R] `estat` — Postestimation statistics
- [R] `estat ic` — Display information criteria
- [R] `estat summarize` — Summarize estimation sample
estimates — Save and manipulate estimation results

Description

estimates allows you to store and manipulate estimation results:

- You can save estimation results in a file for use in later sessions.
- You can store estimation results in memory so that you can
  a. switch among separate estimation results and
  b. form tables combining separate estimation results.

Syntax

<table>

</table>
estimates is for use after you have fit a model, be it with `regress`, `logistic`, etc. You can use `estimates` after any estimation command, whether it be an official estimation command of Stata or a community-contributed one.

`estimates` has three separate but related capabilities:

1. You can save estimation results in a file on disk so that you can use them later, even in a different Stata session.
2. You can store up to 300 estimation results in memory so that they are at your fingertips.
3. You can make tables comparing any results you have stored in memory.

Remarks are presented under the following headings:

**Saving and using estimation results**

After you have fit a model, say, with `regress`, type

```
. use https://www.stata-press.com/data/r16/auto
(1978 Automobile Data)
. regress mpg weight displ foreign
(output omitted)
```

You can save the results in a file:

```
. estimates save basemodel
(file basemodel.ster saved)
```

Later, say, in a different session, you can reload those results:

```
. estimates use basemodel
```

The situation is now nearly identical to what it was immediately after you fit the model. You can replay estimation results:

```
. regress
(output omitted)
```

You can perform tests:

```
. test foreign==0
(output omitted)
```
And you can use any postestimation command or postestimation capability of Stata. The only difference is that Stata no longer knows what the estimation sample, `e(sample)` in Stata jargon, was. When you reload the estimation results, you might not even have the original data in memory. That is okay. Stata will know to refuse to calculate anything that can be calculated only on the original estimation sample.

If it is important that you use a postestimation command that can be used only on the original estimation sample, there is a way you can do that. You use the original data and then use `estimates esample:` to tell Stata what the original sample was.

See [R] estimates save for details.

### Storing and restoring estimation results

Storing and restoring estimation results in memory is much like saving them to disk. You type

```
. estimates store base
```

to save the current estimation results under the name `base`, and you type

```
. estimates restore base
```

to get them back later. You can find out what you have stored by typing

```
. estimates dir
```

Saving estimation results to disk is more permanent than storing them in memory, so why would you want merely to store them? The answer is that, once they are stored, you can use other estimates commands to produce tables and reports from them.

See [R] estimates store for details about the `estimates store` and `restore` commands.

### Comparing estimation results

Let’s say that you have done the following:

```
. use https://www.stata-press.com/data/r16/auto
   (1978 Automobile Data)
. regress mpg weight displ
   (output omitted)
. estimates store base
. regress mpg weight displ foreign
   (output omitted)
. estimates store alt
```

You can now get a table comparing the coefficients:

```
. estimates table base alt
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>base</th>
<th>alt</th>
</tr>
</thead>
<tbody>
<tr>
<td>weight</td>
<td>-.00656711</td>
<td>-.00677449</td>
</tr>
<tr>
<td>displacement</td>
<td>.00528078</td>
<td>.00192865</td>
</tr>
<tr>
<td>foreign</td>
<td>-1.6006312</td>
<td></td>
</tr>
<tr>
<td>_cons</td>
<td>40.084522</td>
<td>41.847949</td>
</tr>
</tbody>
</table>
```

`estimates table` can do much more; see [R] estimates table. Also see [R] estimates stats. `estimates stats` works similarly to `estimates table` but produces model comparisons in terms of BIC and AIC.
Jargon

You know that if you fit a model, say, by typing

```
.regress mpg weight displacement
```

then you can later replay the results by typing

```
.regress
```

and you can do tests and calculate other postestimation statistics by typing

```
.test displacement==0
.estat vif
.predict mpghat
```

As a result, we often refer to the estimation results or the current estimation results or the most recent estimation results or the last estimation results or the estimation results in memory.

With estimates store and estimates restore, you can have many estimation results in memory. One set of those, the set most recently estimated, or the set most recently restored, are the current or active estimation results, which you can replay, which you can test, or from which you can calculate postestimation statistics.

Current and active are the two words we will use interchangeably from now on.

Also see

[P] _estimates — Manage estimation results
estimates describe — Describe estimation results

Description

estimates describe describes the current (active) estimates. Reported are the command line that produced the estimates, any title that was set by estimates title (see [R] estimates title), and any notes that were added by estimates notes (see [R] estimates notes).

estimates describe name does the same but reports results for estimates stored by estimates store (see [R] estimates store).

estimates describe using filename does the same but reports results for estimates saved by estimates save (see [R] estimates save). If filename contains multiple sets of estimates (saved in it by estimates save, append), the number of sets of estimates is also reported. If filename is specified without an extension, .ster is assumed.

Quick start

Describe current estimation results

estimates describe

Describe estimation results stored in m1

estimates describe m1

Describe estimates from first model saved in mymodels.ster

estimates describe using mymodels

Same as above

estimates describe using mymodels, number(1)

Describe estimates from third model saved in mymodels.ster

estimates describe using mymodels, number(3)

Menu

Statistics > Postestimation
estimates describe — Describe estimation results

Syntax

estimates describe

estimates describe name

estimates describe using filename [ , number(#) ]

Option

number(#) specifies that the #th set of estimation results from filename be described. This assumes that multiple sets of estimation results have been saved in filename by estimates save, append. The default is number(1).

Remarks and examples

estimates describe can be used to describe the estimation results currently in memory,

. estimates describe
Estimation results produced by
   . regress mpg weight displ if foreign

or to describe results saved by estimates save in a .ster file:

. estimates describe using final
Estimation results "Final results" saved on 12apr2018 14:20, produced by
   . logistic myopic age sex drug1 drug2 if complete==1

Notes:
1. Used file patient.dta
2. "datasignature myopic age sex drug1 drug2 if complete==1"
   reports 148:5(58763):2252897466:3722318443
3. must be reviewed by rgg

Example 1

. use https://www.stata-press.com/data/r16/auto
   (1978 Automobile Data)
   . regress mpg weight displ if foreign
      (output omitted)
   . estimates notes: file 'c(filename)'
   . datasignature
      74:12(71728):3831085005:1395876116
   . estimates notes: datasignature report 'r(datasignature)'
   . estimates save foreign
      file foreign.ster saved
   . regress mpg weight displ if !foreign
      (output omitted)
. estimates describe using foreign
  Estimation results saved on 25feb2019 16:34, produced by
    . regress mpg weight displ if foreign
Notes:
  1. file https://www.stata-press.com/data/r16/auto.dta
  2. datasignature report 74:12(71728):3831085005:1395876116

Stored results

estimates describe and estimates describe name store the following in r():

Macros
  r(title)     title
  r(cmdline)   original command line

estimates describe using filename stores the above and the following in r():

Scalars
  r(datetime)  %tc value of date/time file saved
  r(nestresults) number of sets of estimation results in file

Also see

[R] estimates — Save and manipulate estimation results
estimates for — Repeat postestimation command across models

Description

estimates for performs postestimation_command on each estimation result specified.

Quick start

Test for no effect of continuous covariate x1 in stored estimates m1 and m2

estimates for m1 m2: test x1==0

As above, but test interaction of binary covariate a and x1

estimates for m1 m2: test 0.a#c.x1==1.a#c.x1

Linear combination of coefficients of x1 and x2 in all stored estimates

estimates for _all: lincom x1 + x2

Tables of margins for each level of a and confidence intervals using estimates m1 and m2

estimates for m1 m2: pwcompare i.a, cimargins
Syntax

\texttt{estimates for namelist [, options]: postestimation\_command}

where \textit{namelist} is a name, a list of names, \_\_all, or \_*\_. A name may be ., meaning the current (active) estimates. \_\_all and \_*\_ mean the same thing.

\textbf{options} \hspace{2cm} \textbf{Description}

| noheader   | do not display title |
| nostop     | do not stop if command fails |

\section*{Options}

\texttt{noheader} suppresses the display of the header as \textit{postestimation\_command} is executed each time.

\texttt{nostop} specifies that execution of \textit{postestimation\_command} is to be performed on the remaining models even if it fails on some.

\section*{Remarks and examples}

In the example that follows, we fit a model two different ways, store the results, and then use \texttt{estimates for} to perform the same test on both of them:

\subsection*{Example 1}

\begin{verbatim}
. use https://www.stata-press.com/data/r16/auto
(1978 Automobile Data)
. generate gpm = 1/mpg
. regress gpm i.foreign i.foreign#c.weight displ
(output omitted)
. estimates store reg
. qreg gpm i.foreign i.foreign#c.weight displ
(output omitted)
. estimates store qreg
. estimates for reg qreg: test 0.foreign#c.weight==1.foreign#c.weight

Model \texttt{reg}

( 1) 0b.foreign#c.weight - 1.foreign#c.weight = 0
F( 1, 69) = 4.87
Prob > F = 0.0307

Model \texttt{qreg}

( 1) 0b.foreign#c.weight - 1.foreign#c.weight = 0
F( 1, 69) = 0.03
Prob > F = 0.8554
\end{verbatim}

\section*{Also see}

[R] \texttt{estimates} — Save and manipulate estimation results
estimates notes — Add notes to estimation results

Description

estimates notes: text adds a note to the current (active) estimation results.
estimates notes and estimates notes list list the current notes.
estimates notes drop in noterange eliminates the specified notes.

Quick start

Add “My note” to current estimation results
estimates notes: My note

List all notes for current estimation results
estimates notes list

Same as above
estimates notes

Drop notes 1 to 3 from current estimation results
estimates notes drop in 1/3

Drop last note applied to current estimation results
estimates notes drop in 1
Syntax

estimates notes: text

estimates notes

estimates notes list [ in noterange ]

estimates notes drop in noterange

where noterange is # or #/# and where # may be a number, the letter f (meaning first), or the letter l (meaning last).

Remarks and examples

After adding or removing notes, if estimates have been stored, do not forget to store them again. If estimates have been saved, do not forget to save them again.

Notes are most useful when you intend to save estimation results in a file; see [R] estimates save. For instance, after fitting a model, you might type

. estimates note: I think these are final
. estimates save lock2

and then, later when going through your files, you could type

. estimates use lock2
. estimates notes
  1. I think these are final

Up to 9,999 notes can be attached to estimation results. If estimation results are important, we recommend that you add a note identifying the .dta dataset you used. The best way to do that is to type

. estimates notes: file ‘c(filename)’

because ‘c(filename)’ will expand to include not just the name of the file but also its full path; see [P] creturn.

If estimation results took a long time to estimate—say, they were produced by cmmprobit or gllamm (see [CM] cmmprobit and http://www.gllamm.org)—it is also a good idea to add a data signature. A data signature takes less time to compute than reestimation when you need proof that you really have the right dataset. The easy way to do that is to type

. datasignature
  74:12(71728):3831085005:1395876116
. estimates notes: datasignature reports ‘r(datasignature)’

Now when you ask to see the notes, you will see

. estimates notes
  1. I think these are final
  2. file C:\project\one\pat4.dta
  3. datasignature reports 74:12(71728):3831085005:1395876116

See [D] datasignature.

Notes need not be positive. You might set a note to be, “I need to check that age is defined correctly.”
Example 1

```stata
. use https://www.stata-press.com/data/r16/auto
(1978 Automobile Data)
. regress mpg weight displ if foreign
(output omitted)
. estimates notes: file `c(filename)'
. datasignature
   74:12(71728):3831085005:1395876116
. estimates notes: datasignature report `r(datasignature)'
. estimates save foreign
file foreign.ster saved
. estimates notes list in 1/2
   1. file https://www.stata-press.com/data/r16/auto.dta
   2. datasignature report 74:12(71728):3831085005:1395876116
. estimates notes drop in 2
(1 note dropped)
. estimates notes
   1. file https://www.stata-press.com/data/r16/auto.dta
```

[R] estimates — Save and manipulate estimation results
estimates replay — Redisplay estimation results

Description

estimates replay redisplay the current (active) estimation results, just as typing the name of the estimation command would do.

estimates replay namelist redisplay each specified estimation result. The active estimation results are left unchanged.

Quick start

Redisplay current estimation results
estimates replay

Redisplay estimation results stored as m1
estimates replay m1

Redisplay all stored estimation results
estimates replay *

Same as above
estimates replay _all

Menu

Statistics > Postestimation
Syntax

```
estimates replay

estimates replay namelist
```

where `namelist` is a name, a list of names, `._all`, or `*`. A name may be `.`, meaning the current (active) estimates. `.all` and `*` mean the same thing.

Remarks and examples

In the example that follows, we fit a model two different ways, store the results, use `estimates for` to perform the same test on both of them, and then replay the results:

> Example 1

```
. use https://www.stata-press.com/data/r16/auto
(1978 Automobile Data)
. generate gpm = 1/mpg
. regress gpm i.foreign i.foreign#c.weight displ
(output omitted)
. estimates store reg
. qreg gpm i.foreign i.foreign#c.weight displ
(output omitted)
. estimates store qreg
. estimates for reg qreg: test 0.foreign#c.weight==1.foreign#c.weight
```

Model `reg`

```
( 1)  0b.foreign#c.weight - 1.foreign#c.weight = 0
F(  1,   69) =  4.87
   Prob > F = 0.0307
```

Model `qreg`

```
( 1)  0b.foreign#c.weight - 1.foreign#c.weight = 0
F(  1,   69) =  0.03
   Prob > F = 0.8554
```
. estimates replay

Model *qreg*

| gpm         | Coef.    | Std. Err. | t    | P>|t| | [95% Conf. Interval] |

Also see

[R] estimates — Save and manipulate estimation results
estimates save — Save and use estimation results

Description

estimates save filename saves the current (active) estimation results in filename.

estimates use filename loads the results saved in filename into the current (active) estimation results.

In both cases, if filename is specified without an extension, .ster is assumed.

estimates esample: (note the colon) resets e(sample). After estimates use filename, e(sample) is set to contain 0, meaning that none of the observations currently in memory was used in obtaining the estimates.

estimates esample (without a colon) displays how e(sample) is currently set.

Quick start

Save current estimation results to mymodels.ster
    estimates save mymodels

Add current estimation results to existing file mymodels.ster
    estimates save mymodels, append

Make active third estimation results saved in mymodels.ster
    estimates use mymodels, number(3)

Reset e(sample) to original estimation sample assuming command regress y x1 x2
    estimates esample: y x1 x2

Menu

Statistics > Postestimation
estimates save — Save and use estimation results

Syntax

estsmales save filename [ , append replace]
estimates use filename [ , number(#) ]
estimates esample: [ varlist ] [ if ] [ in ] [ weight ]
[ , replace stringvars(varlist) zeroweight ]
estimates esample

Options

append, used with estimates save, specifies that results be appended to an existing file. If the file does not already exist, a new file is created.
replace, used with estimates save, specifies that filename can be replaced if it already exists.
number(#), used with estimates use, specifies that the #th set of estimation results from filename be loaded. This assumes that multiple sets of estimation results have been saved in filename by estimates save, append. The default is number(1).
replace, used with estimates esample:, specifies that e(sample) can be replaced even if it is already set.
stringvars(varlist), used with estimates esample:, specifies string variables. Observations containing variables that contain "" will be omitted from e(sample).
zeroweight, used with estimates esample:, specifies that observations with zero weights are to be included in e(sample).

Remarks and examples

See [R] estimates for an overview of the estimates commands.
For a description of estimates save and estimates use, see Saving and using estimation results in [R] estimates.

The rest of this entry concerns e(sample).

Remarks are presented under the following headings:

Setting e(sample)
Resetting e(sample)
Determining who set e(sample)

Setting e(sample)

After estimates use filename, the situation is nearly identical to what it was immediately after you fit the model. The one difference is that e(sample) is set to 0.

e(sample) is Stata’s function to mark which observations among those currently in memory were used in producing the estimates. For instance, you might type
and `summarize` would report the summary statistics for the observations `regress` in fact used, which would exclude not only observations for which `foreign = 0` but also any observations for which `mpg`, `weight`, or `displ` was missing.

If you saved the above estimation results and then reloaded them, however, `summarize mpg if e(sample)` would produce

```
Variable |Obs  | Mean  | Std. Dev. | Min  | Max
---------|-----|-------|-----------|------|-----
          |     |       |           |      |     
mpg      | 0   |       |           |      |     
```

Stata thinks that none of these observations was used in producing the estimates currently loaded.

What else could Stata think? When you `estimates use filename`, you do not have to have the original data in memory. Even if you do have data in memory that look like the original data, they might not be. Setting `e(sample)` to 0 is the safe thing to do. There are some postestimation statistics, for instance, that are appropriate only when calculated on the estimation sample. Setting `e(sample)` to 0 ensures that if you ask for one of them, you will get back a null result.

We recommend that you leave `e(sample)` set to 0. But what if you really need to calculate that postestimation statistic? Well, you can get it, but you are going to be responsible for setting `e(sample)` correctly. Here we just happen to know that all the observations with `foreign = 1` were used, so we can type

```
   estimates esample: if foreign
```

If all the observations had been used, we could simply type

```
   estimates esample:
```

The safe thing to do, however, is to look at the estimation command—`estimates describe` will show it to you—and then type

```
   estimates esample: mpg weight displ if foreign
```

We include all observations with `foreign = 1`, excluding any with missing values in the `mpg`, `weight`, or `displ` variable, that are to be treated as the estimation sample.

### Resetting `e(sample)`

`estimates esample:` will allow you to not only set but also reset `e(sample)`. If `e(sample)` has already been set (say that you just fit the model) and you try to set it, you will see

```
   estimates esample: mpg weight displ if foreign
   no; e(sample) already set
   r(322);
```

Here you can specify the `replace` option:

```
   estimates esample: mpg weight displ if foreign, replace
```

We do not recommend resetting `e(sample)`, but the situation can arise where you need to. Imagine that you `estimates use filename`, you set `e(sample)`, and then you realize that you set it wrong. Here you would want to reset it.
Determining who set e(sample)

`estimates esample` without a colon will report whether and how `e(sample)` was set. You might see

```
. estimates esample
  e(sample) set by estimation command
```

or

```
. estimates esample
  e(sample) set by user
```

or

```
. estimates esample
  e(sample) not set (0 assumed)
```

Stored results

`estimates esample` without the colon saves macro `r(who)`, which will contain `cmd`, `user`, or `zero'd`.

Also see

[R] estimates — Save and manipulate estimation results
estimates selected — Show selected coefficients

Description

estimates selected reports on coefficients from one or more estimation results. It creates a table that indicates which coefficients were estimated in each model and, if requested, reports the value of those coefficients. The results may be sorted based on the values of the estimated coefficients or based on variable names.

Quick start

Compare coefficients for stored estimates m1 and m2
estimates selected m1 m2

As above, but display a u for covariates that are not specified in the model
estimates selected m1 m2, display(u)

Compare stored estimates l1 and l2, and order the rows by absolute values of the coefficients
estimates selected l1 l2, sort(coef)

Menu

Statistics > Postestimation

Syntax

estimates selected [namelist] [, options]

namelist is the name given to previously stored estimation results, a list of names, _all, or *. A name may be ., meaning the current (active) estimates. _all and * mean the same thing.

options Description

Main

display(info) display info; default is display(x)
sort(on) sort rows in order of on

Reporting

noabbrev do not abbreviate variable names
display_options control row spacing, line width, and display of omitted variables and base and empty cells

624
Options

Main

display(info) specifies what to display in the table. The default is display(x).

Blank cells in the table indicate that the corresponding covariate does not have a fitted value. For some covariates without fitted values, a code that indicates the reason for omission is reported in the table. Base levels of factors and interactions are coded with the letter b. Empty levels of factors and interactions are coded with the letter e. Covariates omitted because of collinearity are coded with the letter o.

display(x) displays an x in the cell of the table where a covariate has a fitted value. This is the default.

display(u) is the same as display(x), except that when a covariate was not specified in the model, u (for unavailable) is displayed instead of a blank cell.

display(coef [, eform format(%fmt)]) specifies that coefficient values be displayed in the table.

eform displays coefficients in exponentiated form. For each coefficient, $e^b$ rather than $b$ is displayed. This option can be used to display odds ratios, incidence-rate ratios, relative-risk ratios, hazard ratios, and subhazard ratios after the appropriate estimation command.

format(%fmt) specifies the display format for the coefficients in the table. The default is format(%9.0g).

sort(on) specifies how to sort the rows of the table. By default, coefficients are displayed in the order in which they appear in the estimation results.

sort(none) specifies that the rows are not sorted. This is the default. The order of the coefficients is taken from their order in e(b).

sort(names) orders rows alphabetically by the variable names of the covariates. In the case of factor variables, main effects and nonfactor variables are displayed first in alphabetical order; then all two-way interactions are displayed in alphabetical order, then all three-way interactions, and so on.

sort(coef) orders rows in descending order by the absolute values of the coefficients. When results from two or more estimation results are displayed, results are sorted first by the ordering for the first estimation result with rows representing coefficients not in the first estimation result last. Within the rows representing coefficients not in the first estimation result, the rows are sorted by the ordering for the second estimation result with rows representing coefficients not in the first or second estimation results last. And so on.

Reporting

noabbrev prevents variable names from being abbreviated in the row titles of the table. Long variable names are split onto multiple lines if they do not fit.

display_options: vsquish, fvwrap(#), fvwrapon(style), and nolstretch; see [R] Estimation options.

Remarks and examples

estimates selected produces a table based on estimated coefficients from one or more models. Results can be sorted by the values of the estimated coefficients or by variable names. Multiple
models are displayed side-by-side, making it easy to compare which covariates were included in each model or to compare the estimated values of those coefficients.

Example 1: Compare coefficients across models

To compare coefficients from two or more models, we first need to store the results of each model using `estimates store`; see `[R] estimates store`. Then we use `estimates selected` to obtain a table comparing which coefficients were estimated in each model. By default, the table reports an `x` for each coefficient that was estimated.

```
. use https://www.stata-press.com/data/r16/auto
   (1978 Automobile Data)
. regress mpg gear turn
   (output omitted)
. estimates store small
   (output omitted)
. regress mpg gear turn length
   (output omitted)
. estimates store large
   (output omitted)
. estimates selected small large

  small   large
    gear_ratio    x    x
       turn    x    x
      length    x
        _cons    x    x
```

Legend:

- `b` - base level
- `e` - empty cell
- `o` - omitted
- `x` - estimated

There is only one difference in the two `regress` commands; the `large` model includes `length` as a covariate, but the `small` model does not. Therefore, the above table displays `x`’s for all but the `length` coefficient in the `small` model. When working with larger models or with more models, this type of table makes it easy to spot the differences in the model specification.

By default, the rows of the table in the order that covariates appear in the models. To sort the results on the covariate names, we add the `sort(names)` option.

```
. estimates selected small large, sort(names)

  small   large
    gear_ratio    x    x
      length    x
       turn    x    x
        _cons    x    x
```

Legend:

- `b` - base level
- `e` - empty cell
- `o` - omitted
- `x` - estimated

We could have instead sorted on the values of the estimated coefficients by including the `sort(coef)` option.
To display the coefficients values instead of the x’s, we add the `display(coef)` option.

```
. estimates selected small large, sort(names) display(coef)
```

<table>
<thead>
<tr>
<th></th>
<th>small</th>
<th>large</th>

- e - empty cell
- o - omitted

Stored results

`estimates selected` stores the following in `r()`:

**Macros**
- `r(names)` names of results used

**Matrices**
- `r(coef)` matrix $M$: $n \times m$
  
  $M[i, j] = i$th coefficient estimate for model $j$; $i=1,...,n$; $j=1,...,m$

Also see

[R] `estimates` — Save and manipulate estimation results

[LASSO] `lassocoeff` — Display coefficients after lasso estimation results
`estimates stats` reports model-selection statistics, including the Akaike information criterion (AIC) and the Bayesian information criterion (BIC). These measures are appropriate for maximum likelihood models.

If `estimates stats` is used for a non–likelihood-based model, such as `qreg`, missing values are reported.

**Quick start**

Display table of statistics for last estimation command

```
estimates stats
```

Display table of statistics for stored estimates `m1` and `m2`

```
estimates stats m1 m2
```

Specify \( N = 1,000 \) for calculation of BIC

```
estimates stats, n(1000)
```

**Menu**

Statistics  >  Postestimation
Syntax

```stata
estimates stats [namelist] [ , n(#) bicdetail]
```

where namelist is a name, a list of names, _all, or *. A name may be ., meaning the current (active) estimates. _all and * mean the same thing.

Options

n(#) specifies the N to be used in calculating the BIC; see [R] BIC note.

bicdetail produces a table showing the type of N used in the BIC calculation. Most estimation commands use the number of observations in the estimation sample for the BIC. For some models, however, other types of N, such as the number of cases in choice models, should be used for the BIC. When the default table of `estimates stats` contains more than one type of N, specifying bicdetail allows you to see the different types of N used for the BIC.

Remarks and examples

If you type `estimates stats` without arguments, a table for the most recent estimation results will be shown:

```stata
use https://www.stata-press.com/data/r16/auto
(1978 Automobile Data)
. logistic foreign mpg weight displ
(output omitted)
. estimates stats
Akaike’s information criterion and Bayesian information criterion

<table>
<thead>
<tr>
<th>Model</th>
<th>N</th>
<th>ll(null)</th>
<th>ll(model)</th>
<th>df</th>
<th>AIC</th>
<th>BIC</th>
</tr>
</thead>
<tbody>
<tr>
<td>.</td>
<td>74</td>
<td>-45.03321</td>
<td>-20.59083</td>
<td>4</td>
<td>49.18167</td>
<td>58.39793</td>
</tr>
</tbody>
</table>

Note: BIC uses N = number of observations. See [R] BIC note.
```

Regarding the note at the bottom of the table, N is an ingredient in the calculation of BIC; see [R] BIC note. The note changes if you specify the n() option, which tells `estimates stats` what N to use. N = Obs is the default.

Regarding the table itself, ll(null) is the log likelihood for the constant-only model, ll(model) is the log likelihood for the model, df is the number of degrees of freedom, and AIC and BIC are the Akaike and Bayesian information criteria.

Models with smaller values of an information criterion are considered preferable.

`estimates stats` can compare estimation results:

```stata
use https://www.stata-press.com/data/r16/auto
(1978 Automobile Data)
. logistic foreign mpg weight displ
(output omitted)
. estimates store full
. logistic foreign mpg weight
(output omitted)
. estimates store sub
```
Akaike’s information criterion and Bayesian information criterion

<table>
<thead>
<tr>
<th>Model</th>
<th>N</th>
<th>ll(null)</th>
<th>ll(model)</th>
<th>df</th>
<th>AIC</th>
<th>BIC</th>
</tr>
</thead>
<tbody>
<tr>
<td>full</td>
<td>74</td>
<td>-45.03321</td>
<td>-20.59083</td>
<td>4</td>
<td>49.18167</td>
<td>58.39793</td>
</tr>
<tr>
<td>sub</td>
<td>74</td>
<td>-45.03321</td>
<td>-27.17516</td>
<td>3</td>
<td>60.35031</td>
<td>67.26251</td>
</tr>
</tbody>
</table>

Note: BIC uses \( N \) = number of observations. See [R] BIC note.

Stored results

estimates stats stores the following in \( r() \):

Matrices

\( r(S) \) matrix with 6 columns (\( N \), \( ll0 \), \( ll \), \( df \), \( AIC \), and \( BIC \)) and rows corresponding to models in table

Methods and formulas

See [R] BIC note.

Also see

[R] estimates — Save and manipulate estimation results
estimates store — Store and restore estimation results

Description

estimates store name stores the current (active) estimation results under the name name.
estimates restore name loads the results stored under name into the current (active) estimation results.
estimates query tells you whether the current (active) estimates have been stored and, if so, the name.
estimates dir displays a list of the stored estimates.
estimates drop namelist drops the specified stored estimation results.
estimates clear drops all stored estimation results.
estimates clear, estimates drop _all, and estimates drop * do the same thing. estimates drop and estimates clear do not eliminate the current (active) estimation results.

Quick start

Store estimation results as m1 for use later in the same session
estimates store m1

Restore estimation results from m2
estimates restore m2

Find out whether the current estimation results have been stored
estimates query

Display table of information about all stored results

Syntax

```
estimates store name [ , nocopy ]
estimates restore name
estimates query
estimates dir [ namelist ]
estimates drop namelist
estimates clear
```

where `namelist` is a name, a list of names, `_all`, or `*`. `_all` and `*` mean the same thing.

Option

`nocopy`, used with `estimates store`, specifies that the current (active) estimation results are to be moved into `name` rather than copied. Typing

```
. estimates store hold, nocopy
```

is the same as typing

```
. estimates store hold
. ereturn clear
```

except that the former is faster. The `nocopy` option is sometimes used by programmers.
Remarks and examples

`estimates store` stores estimation results in memory so that you can access them later.

```
use https://www.stata-press.com/data/r16/auto
(1978 Automobile Data)
.regress mpg weight displ
(output omitted)
estimates store myreg
... you do other things, including fitting other models ...
estimates restore myreg
.regress
(same output shown again)
```

After `estimates restore myreg`, things are once again just as they were, estimationwise, just after you typed `regress mpg weight displ`.

`estimates store` stores results in memory. When you exit Stata, those stored results vanish. If you wish to make a permanent copy of your estimation results, see [R] `estimates save`.

The purpose of making copies in memory is 1) so that you can quickly switch between them and 2) so that you can make tables comparing estimation results. Concerning the latter, see [R] `estimates table` and [R] `estimates stats`.

Stored results

`estimates dir` stores the following in `r()`:

Macros
- `r(names)` names of stored results

References

[LASSO] `estimates store` — Saving and restoring estimates in memory and on disk
**estimates table** — Compare estimation results

### Description

`estimates table` organizes estimation results from one or more models in a single formatted table.

### Quick start

Display a table of coefficients for stored estimates `m1` and `m2`  
`estimates table m1 m2`

As above, but include standard errors  
`estimates table m1 m2, se`

As above, but display coefficients and standard errors to 2 decimal places  
`estimates table m1 m2, b(%7.2f) se(%7.2f)`

As above, but include *p*-values displayed to 3 decimal places  
`estimates table m1 m2, b(%7.2f) se(%7.2f) p(%4.3f)`

Table of coefficients for `m1` and `m2` with sample size and adjusted $R^2$  
`estimates table m1 m2, stats(N r2_a)`

As above, but replace variable names with labels  
`estimates table m1 m2, stats(N r2_a) varlabel`

Table of coefficients with stars to denote significance  
`estimates table m1 m2, star`

Display coefficients in exponentiated form  
`estimates table m3 m4, eform`

Display only a subset of variables and reorder variables in table  
`estimates table m1 m2, keep(v2 v1 v3 _cons)`

### Menu

Statistics > Postestimation
estimates table — Compare estimation results

Syntax

estimates table [namelist] [, options]

namelist is the name given to previously stored estimation results, a list of names, _all, or *. A name may be ., meaning the current (active) estimates. _all and * mean the same thing.

<table>
<thead>
<tr>
<th>options</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Main</td>
<td></td>
</tr>
<tr>
<td>stats(scalarlist)</td>
<td>report scalarlist in table</td>
</tr>
<tr>
<td>star[#1 #2 #3]</td>
<td>use stars to denote significance</td>
</tr>
</tbody>
</table>

Options

| keep(coeflist)   | report coefficients in order specified |
| drop(coeflist)   | omit specified coefficients from table |
| equations(matchlist) | match equations of models as specified |

Numerical formats

| b[fmt]      | how to format coefficients, which are always reported |
| se[fmt]     | report standard errors and use optional format |
| t[fmt]      | report t or z and use optional format |
| p[fmt]      | report p-values and use optional format |
| stfmt(fmt)  | how to format scalar statistics |

General format

| varwidth(#)  | use # characters to display variable names and statistics |
| modelwidth(#) | use # characters to display model names |
| eform       | display coefficients in exponentiated form |
| varlabel    | display variable labels rather than variable names |
| newpanel    | display statistics in separate table from coefficients |
| style(oneline) | put vertical line after variable names; the default |
| style(columns)  | put vertical line separating every column |
| style(noline) | suppress all vertical lines |
| coded        | display compact table |

Reporting

display_options control row spacing, line width, and display of omitted variables and base and empty cells

title(string) title for table

title() does not appear in the dialog box.
Options

`stats(scalarlist)` specifies a list of any of or all the names of scalars stored in `e()` to be displayed in the table. `scalarlist` may also contain the following:

- `aic`: Akaike’s information criterion
- `bic`: Schwarz’s Bayesian information criterion
- `rank`: rank of `e(V)` (# of free parameters in model)

The specified statistics do not have to be available for all estimation results being displayed. For example, `stats(N ll chi2 aic)` specifies that `e(N)`, `e(ll)`, `e(chi2)`, and `AIC` be included. In Stata, `e(N)` records the number of observations; `e(ll)`, the log likelihood; and `e(chi2)`, the chi-squared test that all coefficients in the first equation of the model are equal to zero.

`star` and `star(#1 #2 #3)` specify that stars (asterisks) are to be used to mark significance. The second syntax specifies the significance for one, two, and three stars. If you specify simply `star`, that is equivalent to specifying `star(.05 .01 .001)`, which means one star (*) if `p < 0.05`, two stars (**) if `p < 0.01`, and three stars (***) if `p < 0.001`.

The `star` and `star()` options may not be combined with the `se`, `t`, or `p` option.

`keep(coeflist)` and `drop(coeflist)` are alternatives; they specify coefficients to be included or omitted from the table. The default is to display all coefficients.

If `keep()` is specified, it specifies not only the coefficients to be included but also the order in which they appear.

A `coeflist` is a list of coefficient names, each name of which may be simple (for example, `price`), an equation name followed by a colon (for example, `mean:`), or a full name (for example, `mean:price`). Names are separated from each other by blanks.

When full names are not specified, all coefficients that match the partial specification are included. For instance, `drop(_cons)` would omit `_cons` for all equations.

`equations(matchlist)` specifies how the equations of the models in `namelist` are to be matched. The default is to match equations by name. Matching by name usually works well when all results were fit by the same estimation command. When you are comparing results from different estimation commands, however, specifying `equations()` may be necessary.

The most common usage is `equations(1)`, which indicates that all first equations are to be matched into one equation named #1.

`matchlist` has the syntax

```
term [, term ... ]
```

`term` is

```
[ eqname = ] #:#:...#: (syntax 1)
[ eqname = ] # (syntax 2)
```

In syntax 1, each # is a number or a period (.). If a number, it specifies the position of the equation in the corresponding model; 1:3:1 would indicate that equation 1 in the first model matches equation 3 in the second, which matches equation 1 in the third. A period indicates that there
is no corresponding equation in the model; 1:\ldots:1 indicates that equation 1 in the first matches equation 1 in the third.

In syntax 2, you specify just one number, say, 1 or 2, and that is shorthand for 1:1\ldots:1 or 2:2\ldots:2, meaning that equation 1 matches across all models specified or that equation 2 matches across all models specified.

Now that you can specify a term, you can put that together into a matchlist by separating one term from the other by commas. In what follows, we will assume that three names were specified,

\begin{verbatim}
 . estimates table alpha beta gamma, ...
\end{verbatim}

equations(1) is equivalent to equations(1:1:1); we would be saying that the first equations match across the board.

equations(1:\ldots:1) would specify that equation 1 matches in models alpha and gamma but that there is nothing corresponding in model beta.

equations(1,2) is equivalent to equations(1:1:1, 2:2:2). We would be saying that the first equations match across the board and so do the second equations.

equations(1, 2:\ldots:2) would specify that the first equations match across the board, that the second equations match for models alpha and gamma, and that there is nothing equivalent to equation 2 in model beta.

If equations() is specified, equations not matched by position are matched by name.

---

### Numerical formats

b(\%fmt) specifies how the coefficients are to be displayed. You might specify b(\%9.2f) to make decimal points line up. There is also a b option, which specifies that coefficients are to be displayed, but that is just included for consistency with the se, t, and p options. Coefficients are always displayed.

se, t, and p specify that standard errors, t or z statistics, and p-values are to be displayed. The default is not to display them. se(\%fmt), t(\%fmt), and p(\%fmt) specify that each is to be displayed and specifies the display format to be used to format them.

stfmt(\%fmt) specifies the format for displaying the scalar statistics included by the stats() option.

---

### General format

varwidth(#) specifies the number of character positions used to display the names of the variables and statistics. The default is 12.

modelwidth(#) specifies the number of character positions used to display the names of the models. The default is 12.

eform displays coefficients in exponentiated form. For each coefficient, exp(\beta) rather than \beta is displayed, and standard errors are transformed appropriately. Display of the intercept, if any, is suppressed.

varlabel specifies that variable labels be displayed instead of variable names.

newpanel specifies that the statistics be displayed in a table separated by a blank line from the table with coefficients rather than in the style of another equation in the table of coefficients.

style(stylespec) specifies the style of the coefficient table.

style(oneLine) specifies that a vertical line be displayed after the variables but not between the models. This is the default.
style(columns) specifies that vertical lines be displayed after each column.
style(noline) specifies that no vertical lines be displayed.
coded specifies that a compact table be displayed. This format is especially useful for comparing variables that are included in a large collection of models.

display_options: noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(#), and fvwrapon(style); see [R] Estimation options.

The following option is available with estimates table but is not shown in the dialog box:
title(string) specifies the title to appear above the table.

Remarks and examples

estimates table lets you format estimation results and organize results from multiple models in a single table. You achieve this by combining estimates table with estimates store; see [R] estimates store. When combined with putdocx or putpdf, estimates table lets you create customized tables of results in .docx or .pdf format.

Example 1: Creating the default table

If you type estimates table without arguments, a table of the most recent estimation results will be shown:

```
. use https://www.stata-press.com/data/r16/auto
   (1978 Automobile Data)
. regress mpg weight
   (output omitted)
. regress mpg weight displ
   (output omitted)
. estimates table
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>active</th>
</tr>
</thead>
<tbody>
<tr>
<td>weight</td>
<td>-.00656711</td>
</tr>
<tr>
<td>displacement</td>
<td>.00528078</td>
</tr>
<tr>
<td>_cons</td>
<td>40.084522</td>
</tr>
</tbody>
</table>

In the above output table, only the results from the second regress command are displayed because they are the current (active) estimates.

By default, estimates table displays only coefficient estimates. You can request additional model statistics by specifying the stats() option. Estimation commands store e-class results. To see a list of available results from the last estimation command that can be specified in the stats() option, you can use the ereturn list command.
Example 2: Creating a table with multiple models

If we want to display more than one set of estimation results in a single table, we can use `estimates store` to store each set of estimation results in memory so that they can be accessed later by `estimates table`. This is one of the primary uses of `estimates table`—comparing estimation results:

```
. regress mpg weight displ
(output omitted)
. estimates store base
. regress mpg weight displ i.foreign
(output omitted)
. estimates store alt
. qreg mpg weight displ i.foreign
(output omitted)
. estimates store qreg
. estimates table base alt qreg, stats(r2)
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>base</th>
<th>alt</th>
<th>qreg</th>
</tr>
</thead>
<tbody>
<tr>
<td>weight</td>
<td>-.00656711</td>
<td>-.00677449</td>
<td>-.00595056</td>
</tr>
<tr>
<td>displacement</td>
<td>.00528078</td>
<td>.00192865</td>
<td>.00018552</td>
</tr>
<tr>
<td>foreign</td>
<td>-1.6006312</td>
<td>-2.1326005</td>
<td></td>
</tr>
<tr>
<td>Foreign</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>_cons</td>
<td>40.084522</td>
<td>41.847949</td>
<td>39.213348</td>
</tr>
<tr>
<td>r2</td>
<td>.6529307</td>
<td>.66287957</td>
<td></td>
</tr>
</tbody>
</table>

`estimates table` automatically lines up the point estimates of coefficients on covariates that are common across each model. The `stats(r2)` option specifies that the coefficient of determination ($R^2$) be placed under the models for which it is computed.

The `foreign` variable was included in the models `alt` and `qreg` as a factor variable. Because the values of `foreign` are labeled, the value labels are displayed by default. See `[D] label` for information about managing value labels.

Example 3: Creating and exporting a formatted table

We can add estimates of the standard errors to the table and format them along with the original coefficient estimates by using the `b()` and `se()` options.
As shown in example 2, the labeled values of any factor variables are displayed by default. To see the labels corresponding to the variables that are included in the model rather than the names of the variables, we can specify the `varlabel` option.

```
   . estimates table alt, b(%5.4f) se(%5.4f) varlabel
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>alt</th>
</tr>
</thead>
<tbody>
<tr>
<td>Weight (lbs.)</td>
<td>-0.0068</td>
</tr>
<tr>
<td></td>
<td>0.0012</td>
</tr>
<tr>
<td>Displacement (cu. in.)</td>
<td>0.0019</td>
</tr>
<tr>
<td></td>
<td>0.0101</td>
</tr>
<tr>
<td>Car type</td>
<td>-1.6006</td>
</tr>
<tr>
<td>Foreign</td>
<td>1.1136</td>
</tr>
<tr>
<td>Constant</td>
<td>41.8479</td>
</tr>
<tr>
<td></td>
<td>2.3507</td>
</tr>
</tbody>
</table>

legend: b/se

If we wanted this table to appear in a Word document, we could use the `putdocx` command with the `etable` output type to write it to a new document. To create the new document `myresults.docx`, we would type the following `putdocx` commands:

```
   . putdocx begin
   . putdocx table results = etable
   . putdocx save myresults.docx
```

This creates a table in Word that looks like

![Word Document Table](image-url)
Stored results

_estimates table_ stores the following in _r_():

- **Macros**
  - _r(names)_ names of results used

- **Matrices**
  - _r(coef)_ matrix _M_: _n_ × _2m_  
    - _M[i, 2j−1]_ = _i_th parameter estimate for model _j_;  
    - _M[i, 2j]_ = variance of _M[i, 2j−1]; _i=1,...,n_; _j=1,...,m_
  - _r(stats)_ matrix _S_: _k_×_m_ (if option _stats_() specified)  
    - _S[i, j]_ = _i_th statistic for model _j_; _i=1,...,k_; _j=1,...,m_

Also see

_[R] estimates_ — Save and manipulate estimation results
estimates title — Set title for estimation results

Description

estimates title: (note the colon) sets or clears the title for the current estimation results. The title is used by estimates table and estimates stats (see [R] estimates table and [R] estimates stats).

estimates title without the colon displays the current title.

Quick start

Set title for the current estimation results

estimates title: Base model

Display the title of the current estimation results

estimates title

Menu

Statistics > Postestimation

Syntax

estimates title: [text]

estimates title

Remarks and examples

After setting the title, if estimates have been stored, do not forget to store them again:

. use https://www.stata-press.com/data/r16/auto
   (1978 Automobile Data)
   . regress mpg gear turn
       (output omitted)
   . estimates store reg

Now let’s add a title:

. estimates title: "My regression"
   . estimates store reg

</tr>
</tbody>
</table>
noconstant suppresses the constant term (intercept) in the model.

offset(varname_o) specifies that varname_o be included in the model with the coefficient constrained to be 1.

exposure(varname_e) specifies a variable that reflects the amount of exposure over which the depvar events were observed for each observation; ln(varname_e) with coefficient constrained to be 1 is entered into the log-link function.

callbacks(numlist | matname) specifies the linear constraints to be applied during estimation. The default is to perform unconstrained estimation. See [R] reg3 for the use of constraints in multiple-equation contexts.

callbacks(numlist) specifies the constraints by number after they have been defined by using the callback command; see [R] constraint. Some commands (for example, slogit) allow only callbacks(numlist).

constraints(matname) specifies a matrix containing the constraints; see [P] makecns.

level(#) specifies the confidence level, as a percentage, for confidence intervals. The default is level(95) or as set by set level; see [U] 20.8 Specifying the width of confidence intervals.

lrmodel specifies to conduct a likelihood-ratio test of the full maximum-likelihood model versus the restricted model that includes only a constant term in the regression equation instead of conducting the default Wald test that all coefficients are zero. This option can substantially increase estimation time.

lrmodel may not be specified with the vce(robust), vce(cluster clustvar), vce(jackknife), vce(bootstrap), or noconstant option.

lrmodel may not be combined with constraints; see callbacks(callbacks). In some cases, a likelihood-ratio test is valid for models with constraints. To compute a likelihood-ratio test when constraints have been applied during estimation, use lrtest; see [R] lrtest.

lrmodel may not be specified with the jackknife, bootstrap, svy, or mi estimate prefix.

nocnsreport specifies that no constraints be reported. The default is to display user-specified constraints above the coefficient table.

noc values suppresses confidence intervals from being reported in the coefficient table.

nopvalues suppresses p-values and their test statistics from being reported in the coefficient table.

noomitted specifies that variables that were omitted because of collinearity not be displayed. The default is to include in the table any variables omitted because of collinearity and to label them as “(omitted)”.

vsquish specifies that the blank space separating factor-variable terms or time-series–operated variables from other variables in the model be suppressed.

noemptycells specifies that empty cells for interactions of factor variables not be displayed. The default is to include in the table interaction cells that do not occur in the estimation sample and to label them as “(empty)”.
baselevels and allbaselevels control whether the base levels of factor variables and interactions are displayed. The default is to exclude from the table all base categories.

baselevels specifies that base levels be reported for factor variables and for interactions whose bases cannot be inferred from their component factor variables.

allbaselevels specifies that all base levels of factor variables and interactions be reported.

nofvlabel displays factor-variable level values rather than attached value labels. This option overrides the fvlabel setting; see \[ \text{R} \text{ set showbaselevels} \].

fvwrap(#) specifies how many lines to allow when long value labels must be wrapped. Labels requiring more than # lines are truncated. This option overrides the fvwrap setting; see \[ \text{R} \text{ set showbaselevels} \].

fvwrapon(style) specifies whether value labels that wrap will break at word boundaries or break based on available space.

fvwrapon(word), the default, specifies that value labels break at word boundaries.

fvwrapon(width) specifies that value labels break based on available space.

This option overrides the fvwrapon setting; see \[ \text{R} \text{ set showbaselevels} \].

cformat(\%fmt) specifies how to format coefficients, standard errors, and confidence limits in the coefficient table. The maximum format width is 9. See \[ \text{R} \text{ set cformat} \].

pformat(\%fmt) specifies how to format \( p \)-values in the coefficient table. The maximum format width is 5. See \[ \text{R} \text{ set cformat} \].

sformat(\%fmt) specifies how to format test statistics in the coefficient table. The maximum format width is 8. See \[ \text{R} \text{ set cformat} \].

nolstretch specifies that the width of the coefficient table not be automatically widened to accommodate longer variable names. The default, lstretch, is to automatically widen the coefficient table up to the width of the Results window. To change the default, use set lstretch off. nolstretch is not shown in the dialog box.

intmethod(intmethod) specifies the integration method to be used for the random-effects model.

It accepts one of four arguments: mvaghermite, the default for all but a crossed random-effects model, performs mean and variance adaptive Gauss–Hermite quadrature; mcaghermite performs mode and curvature adaptive Gauss–Hermite quadrature; ghermite performs nonadaptive Gauss–Hermite quadrature; and laplace, the default for crossed random-effects models, performs the Laplacian approximation.

intpoints(#) specifies the number of integration points to use for integration by quadrature. The default is intpoints(12); the maximum is intpoints(195). Increasing this value improves the accuracy but also increases computation time. Computation time is roughly proportional to its value.

The following options are not shown in the dialog box:

collinear specifies that the estimation command not omit collinear variables. This option is seldom used because collinear variables make a model unidentified. However, you can add constraints to a model that will identify it even with collinear variables. For example, if variables x1 and x2 are collinear, but you constrain the coefficient on x2 to be a multiple of the coefficient on x1, then your model is identified even with collinear variables. In such cases, you specify collinear so that both x1 and x2 are retained in the model.
coeflegend specifies that the legend of the coefficients and how to specify them in an expression be displayed rather than displaying the statistics for the coefficients.

Also see

[U] 20 Estimation and postestimation commands
Description

Typing `exit` causes Stata to stop processing and return control to the operating system. If the dataset in memory has changed since the last `save` command, you must specify the `clear` option before Stata will let you exit.

If you wish to use `exit` in do-files or programs to set return codes or terminate programs, see `[P] exit`.

Stata for Windows users may also exit Stata by clicking on the Close button or by pressing `Alt+F4`. Stata for Mac users may also exit Stata by pressing `Command+Q`. Stata for Unix(GUI) users may also exit Stata by clicking on the Close button.

Syntax

```
exit [, clear]
```

Option

clear permits you to `exit`, even if the current dataset has not been saved.

Remarks and examples

Type `exit` to leave Stata and return to the operating system. If the dataset in memory has changed since the last time it was saved, however, Stata will refuse. At that point, you can either save the dataset and then type `exit`, or type `exit, clear`:

```
. exit
no; dataset in memory has changed since last saved
r(4);
. exit, clear
```

Also see

[P] exit — Exit from a program or do-file
**Description**

exlogistic fits an exact logistic regression model, which produces more accurate inference in small samples than the standard maximum-likelihood–based logistic regression estimator. It can also better deal with completely determined outcomes. exlogistic with the group(varname) option conditions on the number of positive outcomes within stratum and is an alternative to the conditional (fixed-effects) logistic regression estimator.

Unlike Stata’s other estimation commands, exlogistic must perform hypothesis tests during estimation rather than during postestimation with standard postestimation commands.

**Quick start**

Exact logistic regression of y on x1, x2, and x3

\[ \text{exlogistic } y \text{ x1 x2 x3} \]

As above, but condition on values of x3 to save time and memory

\[ \text{exlogistic } y \text{ x1 x2, condvars(x3)} \]

As above, and allow more memory for computing the conditional distribution of sufficient statistics

\[ \text{exlogistic } y \text{ x1 x2, condvars(x3) memory(100m)} \]

Using data stored in binomial form with ys successes out of n trials

\[ \text{exlogistic } ys \text{ x1 x2 x3, binomial(n)} \]

Report coefficients rather than odds ratios

\[ \text{exlogistic } y \text{ x1 x2 x3, coef} \]

Report conditional scores tests

\[ \text{exlogistic } y \text{ x1 x2 x3, test(score)} \]

As above, and report joint test for x1 and x2

\[ \text{exlogistic } y \text{ x1 x2 x3, test(score) terms(t1=x1 x2)} \]

Include strata-specific constant terms for each level of svar for an exact version of conditional logistic regression

\[ \text{exlogistic } y \text{ x1 x2 x3, group(svar)} \]

**Menu**

Statistics > Exact statistics > Exact logistic regression
Syntax

```
exlogistic depvar indepvars [if] [in] [weight] [, options]
```

depvar can be specified as a zero or nonzero variable or the number of positive outcomes within each trial. For a zero or nonzero variable, zero indicates failure and nonzero indicates success. To specify depvar as the number of positive outcomes, you must also specify binomial(varname | #).

**options**

by, statsby, and xi are allowed; see [U] 11.1.10 Prefix commands.

fweights are allowed; see [U] 11.1.6 weight.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

**Options**

condvars(varlist) specifies variables whose parameter estimates are not of interest to you. You can save substantial computer time and memory moving such variables from indepvars to condvars(). Understand that you will get the same results for x1 and x3 whether you type

```
. exlogistic y x1 x2 x3 x4
```

or

```
. exlogistic y x1 x3, condvars(x2 x4)
```
group(varname) specifies the variable defining the strata, if any. A constant term is assumed for each stratum identified in varname, and the sufficient statistics for indepvars are conditioned on the observed number of successes within each group. This makes the model estimated equivalent to that estimated by clogit, Stata’s conditional logistic regression command (see [R] clogit). group() may not be specified with noconstant or estconstant.

binomial(varname | #) indicates that the data are in binomial form and depvar contains the number of successes. varname contains the number of trials for each observation. If all observations have the same number of trials, you can instead specify the number as an integer. The number of trials must be a positive integer at least as great as the number of successes. If binomial() is not specified, the data are assumed to be Bernoulli, meaning that depvar equaling zero or nonzero records one failure or success.

estconstant estimates the constant term. By default, the models are assumed to have an intercept (constant), but the value of the intercept is not calculated. That is, the conditional distribution of the sufficient statistics for the indepvars is computed given the number of successes in depvar, thus conditioning out the constant term of the model. Use estconstant if you want the estimate of the intercept reported. estconstant may not be specified with group().

noconstant; see [R] Estimation options. noconstant may not be specified with group().

terms(termname = variable ... variable , termname = variable ... variable ...) defines additional terms of the model on which you want exlogistic to perform joint-significance hypothesis tests. By default, exlogistic reports tests individually on each variable in indepvars. For instance, if variables x1 and x3 are in indepvars, and you want to jointly test their significance, specify terms(t1=x1 x3). To also test the joint significance of x2 and x4, specify terms(t1=x1 x3, t2=x2 x4). Each variable can be assigned to only one term.

Joint tests are computed only for the conditional scores tests and the conditional probabilities tests. See test() below.

memory(# b | k | m | g) sets a limit on the amount of memory exlogistic can use when computing the conditional distribution of the parameter sufficient statistics. The default is memory(10m), where m stands for megabyte, or 1,048,576 bytes. The following are also available: b stands for byte; k stands for kilobyte, which is equal to 1,024 bytes; and g stands for gigabyte, which is equal to 1,024 megabytes. The minimum setting allowed is 1m and the maximum is 2048m or 2g, but do not attempt to use more memory than is available on your computer. Also see the first technical note under example 4 on counting the conditional distribution.

saving(filename [, replace]) saves the joint conditional distribution to filename. This distribution is conditioned on those variables specified in condvars(). Use replace to replace an existing file with filename. A Stata data file is created containing all the feasible values of the parameter sufficient statistics. The variable names are the same as those in indepvars, in addition to a variable named _f_ containing the feasible value frequencies (sometimes referred to as the condition numbers).

level(#) ; see [R] Estimation options. The level(#) option will not work on replay because confidence intervals are based on estimator-specific enumerations. To change the confidence level, you must refit the model.
coef reports the estimated coefficients rather than odds ratios (exponentiated coefficients). coef may be specified when the model is fit or upon replay. coef affects only how results are displayed and not how they are estimated.

test(sufficient|score|probability) reports the p-value associated with the observed sufficient statistics, the conditional scores tests, or the conditional probabilities tests, respectively. The default is test(sufficient). If terms() is included in the specification, the conditional scores test and the conditional probabilities test are applied to each term providing conditional inference for several parameters simultaneously. All the statistics are computed at estimation time regardless of which is specified. Each statistic may thus also be displayed postestimation without having to refit the model; see [R] exlogistic postestimation.

mue(varlist) specifies that median unbiased estimates (MUEs) be reported for the variables in varlist. By default, the conditional maximum likelihood estimates (CMLEs) are reported, except for those parameters for which the CMLEs are infinite. Specify mue(_all) if you want MUEs for all the indepvars.

midp instructs exlogistic to use the mid-p-value rule when computing the MUEs, p-values, and confidence intervals. This adjustment is for the discreteness of the distribution and halves the value of the discrete probability of the observed statistic before adding it to the p-value. The mid-p-value rule cannot be applied to MUEs whose corresponding parameter CMLE is infinite.

log and nolog specify whether to display the enumeration log, which shows the progress of computing the conditional distribution of the sufficient statistics. The enumeration log is displayed by default unless you used set iterlog off to suppress it; see set iterlog in [R] set iter.

Remarks and examples

Exact logistic regression is the estimation of the logistic model parameters by using the conditional distribution of the parameter sufficient statistics. The estimates are referred to as the conditional maximum likelihood estimates (CMLEs). This technique was first introduced by Cox and Snell (1989) as an alternative to using maximum likelihood estimation, which can perform poorly for small sample sizes. For stratified data, exact logistic regression is a small-sample alternative to conditional logistic regression. See [R] logit, [R] logistic, and [R] clogit to obtain maximum likelihood estimates (MLEs) for the logistic model and the conditional logistic model. For a comprehensive overview of exact logistic regression, see Mehta and Patel (1995).

Let $Y_i$ denote a Bernoulli random variable where we observe the outcome $Y_i = y_i$, $i = 1, \ldots, n$. Associated with each independent observation is a $1 \times p$ vector of covariates, $x_i$. We will denote $\pi_i = \Pr(Y_i \mid x_i)$ and let the logit function model the relationship between $Y_i$ and $x_i$,

$$\log \left( \frac{\pi_i}{1 - \pi_i} \right) = \theta + x_i' \beta$$

where the constant term $\theta$ and the $1 \times p$ vector of regression parameters $\beta$ are unknown. The probability of observing $Y_i = y_i$, $i = 1, \ldots, n$, is

$$\Pr(Y = y) = \prod_{i=1}^{n} \pi_i^{y_i} (1 - \pi_i)^{1-y_i}$$

where $Y = (Y_1, \ldots, Y_n)$ and $y = (y_1, \ldots, y_n)$. The MLEs for $\theta$ and $\beta$ maximize the log of this function.
The sufficient statistics for $\theta$ and $\beta_j$, $j = 1, \ldots, p$, are $M = \sum_{i=1}^{n} Y_i$ and $T_j = \sum_{i=1}^{n} Y_i x_{ij}$, respectively, and we observe $M = m$ and $T_j = t_j$. By default, `exlogistic` tallies the conditional distribution of $T = (T_1, \ldots, T_p)$ given $M = m$. This distribution will have a size of $\binom{n}{m}$. (It would have a size of $2^n$ without conditioning on $M = m$.) Denote one of these vectors $T^{(k)} = (t^{(k)}_1, \ldots, t^{(k)}_p)$, $k = 1, \ldots, N$, with combinatorial coefficient (frequency) $c_k$, $\sum_{k=1}^{N} c_k = \binom{n}{m}$. For each independent variable $x_j$, $j = 1, \ldots, p$, we reduce the conditional distribution further by conditioning on all other observed sufficient statistics $T_l = t_l$, $l \neq j$. The conditional probability of observing $T_j = t_j$ has the form

$$\Pr(T_j = t_j \mid T_l = t_l, l \neq j, M = m) = \frac{c \ e^{t_j \beta_j}}{\sum_k c_k e^{t^{(k)}_j \beta_j}}$$

where the sum is over the subset of $T$ vectors such that $(T_1^{(k)} = t_1, \ldots, T_j^{(k)} = t_j^{(k)}, \ldots, T_p^{(k)} = t_p)$ and $c$ is the combinatorial coefficient associated with the observed $t$. The CMLE for $\beta_j$ maximizes the log of this function.

Specifying nuisance variables in `condvars()` will reduce the size of the conditional distribution by conditioning on their observed sufficient statistics as well as conditioning on $M = m$. This reduces the amount of memory consumed at the cost of not obtaining regression estimates for those variables specified in `condvars()`.

Inferences from MLEs rely on asymptotics, and if your sample size is small, these inferences may not be valid. On the other hand, inferences from the CMLEs are exact in the sense that they use the conditional distribution of the sufficient statistics outlined above.

For small datasets, it is common for the dependent variable to be completely determined by the data. Here the MLEs and the CMLEs are unbounded. `exlogistic` will instead compute the MUE, the regression estimate that places the observed sufficient statistic at the median of the conditional distribution.

### Example 1

One example presented by Mehta and Patel (1995) is data from a prospective study of perinatal infection and human immunodeficiency virus type 1 (HIV-1). We use a variation of this dataset. There was an investigation Hutto et al. (1991) into whether the blood serum levels of glycoproteins CD4 and CD8 measured in infants at 6 months of age may predict their development of HIV infection. The blood serum levels are coded as ordinal values 0, 1, and 2.

\end{verbatim}

\texttt{exlogistic} produced a log showing how many records are generated as it processes each observation. The primary purpose of the log is to provide feedback because generating the distribution can be time consuming, but we also see from the last entry that the joint distribution for the sufficient statistics for \texttt{cd4} and \texttt{cd8} conditioned on the total number of successes has 326 unique values (but a size of \( \binom{47}{14} = 341,643,774,795 \)).

The statistics for \texttt{logistic} are based on asymptotics: for a large sample size, each \( Z \) statistic will be approximately normally distributed (with a mean of zero and a standard deviation of one) if the associated regression parameter is zero. The question is whether a sample size of 47 is large enough.

On the other hand, the \( p \)-values computed by \texttt{exlogistic} are from the conditional distributions of the sufficient statistics for each parameter given the sufficient statistics for all other parameters. In this sense, these \( p \)-values are exact. By default, \texttt{exlogistic} reports the sufficient statistics for the regression parameters and the probability of observing a more extreme value. These are single-parameter tests for \( H_0: \beta_{cd4} = 0 \) and \( H_0: \beta_{cd8} = 0 \) versus the two-sided alternatives. The conditional scores test, located in the coefficient table header, is testing that both \( H_0: \beta_{cd4} = 0 \) and \( H_0: \beta_{cd8} = 0 \). We find these \( p \)-values to be in fair agreement with the Wald and likelihood-ratio tests from \texttt{logistic}.

The confidence intervals for \texttt{exlogistic} are computed from the exact conditional distributions. The exact confidence intervals are asymmetrical about the estimate and are wider than the normal-based confidence intervals from \texttt{logistic}.

Both estimation techniques indicate that the incidence of HIV infection decreases with increasing \texttt{CD4} blood serum levels and increases with increasing \texttt{CD8} blood serum levels. The constant term is
missing from the exact logistic coefficient table because we conditioned out its observed sufficient statistic when tallying the joint distribution of the sufficient statistics for the cd4 and cd8 parameters.

The `test()` option provides two other test statistics used in exact logistic: the conditional scores test, `test(score)`, and the conditional probabilities test, `test(probability)`. For comparison, we display the individual parameter conditional scores tests.

```
  . exlogistic, test(score) coef
  Exact logistic regression
  Number of obs = 47
  Model score = 13.34655
  Pr >= score = 0.0006

          Coef.  Score  Pr>=Score  [95% Conf. Interval]
  hiv
  cd4   -2.387632    12.88022    0.0003    -4.699633   -.8221807
  cd8    1.592366    4.604816    0.0410    -.0137905   3.907876
```

For the probabilities test, the probability statistic is computed from (1) in *Methods and formulas* with $\beta = 0$. For this example, the $p$-value for the probabilities tests matches the scores tests so they are not displayed here.

---

### Technical note

Typically, the value of $\theta$, the constant term, is of little interest, as well as perhaps some of the parameters in $\beta$, but we need to include all parameters in the model to correctly specify it. By conditioning out the nuisance parameters, we can reduce the size of the joint conditional distribution that is used to estimate the regression parameters of interest. The `condvars()` option allows you to specify a `varlist` of nuisance variables. By default, `exlogistic` conditions on the sufficient statistic of $\theta$, which is the number of successes. You can save computation time and computer memory by using the `condvars()` option because infeasible values of the sufficient statistics associated with the variables in `condvars()` can be dropped from consideration before all $n$ observations are processed.

Specifying some of your independent variables in `condvars()` will not change the estimated regression coefficients of the remaining independent variables. For instance, in example 1, if we instead type

```
  . exlogistic hiv cd4, condvars(cd8) coef
```

the regression coefficient for cd4 (as well as all associated inference) will be identical.

One reason to have multiple variables in `indepvars` is to make conditional inference of several parameters simultaneously by using the `terms()` option. If you do not wish to test several parameters simultaneously, it may be more efficient to obtain estimates for individual variables by calling `exlogistic` multiple times with one variable in `indepvars` and all other variables listed in `condvars()`. The estimates will be the same as those with all variables in `indepvars`.

---

### Technical note

If you fit a `clogit` (see [R] `clogit`) model to the HIV data from example 1, you will find that the estimates differ from those with `exlogistic`. (To fit the `clogit` model, you will have to create a group variable that includes all observations.) The regression estimates will be different because `clogit` conditions on the constant term only, whereas the estimates from `exlogistic` condition on the sufficient statistic of the other regression parameter as well as the constant term.
Example 2

The HIV data presented in table IV of Mehta and Patel (1995) are in a binomial form, where the variable hiv contains the HIV cases that tested positive and the variable n contains the number of individuals with the same CD4 and CD8 levels, the binomial number-of-trials parameter. Here depvar is hiv, and we use the binomial(n) option to identify the number-of-trials variable.

```

Further, the cd4 and cd8 variables of the hiv dataset are actually factor variables, where each has the ordered levels of (0, 1, 2). Another approach to the analysis is to use indicator variables, and following Mehta and Patel (1995), we used a 0–1 coding scheme that will give us the odds ratio of level 0 versus 2 and level 1 versus 2.

```
. generate byte cd4_0 = (cd4==0)

```
Here we used `terms()` to specify two terms in the model, `cd4` and `cd8`, that make up the `cd4` and `cd8` indicator variables. By doing so, we obtained a conditional probabilities test for `cd4`, simultaneously testing both `cd4_0` and `cd4_1`, and for `cd8`, simultaneously testing both `cd8_0` and `cd8_1`. The p-values for the two terms are 0.0055 and 0.0323, respectively.

This example also illustrates instances where the dependent variable is completely determined by the independent variables and CMLEs are infinite. If we try to obtain MLEs, `logistic` will drop each variable and then terminate with a no-data error, error number 2000.

In example 2, `exlogistic` generated the joint conditional distribution of $T_{cd4_0}$, $T_{cd4_1}$, $T_{cd8_0}$, and $T_{cd8_1}$ given $M = 14$ (the number of individuals that tested positive), and for reference, we listed the observed sufficient statistics that are stored in the matrix `e(sufficient)`. Below we take that distribution and further condition on $T_{cd4_1} = 8$, $T_{cd8_0} = 6$, and $T_{cd8_1} = 4$, giving the conditional distribution of $T_{cd4_0}$. Here we see that the observed sufficient statistic $T_{cd4_0} = 5$ is last in the sorted listing or, equivalently, $T_{cd4_0}$ is at the domain boundary of the conditional probability distribution. When this occurs, the conditional probability distribution is monotonically increasing in $\beta_{cd4_0}$ and a maximum does not exist.
When the CMLEs are infinite, the MUEs are computed (Hirji, Tsiatis, and Mehta 1989). For the cd4_0 estimate, we compute the value $\beta_{cd4\_0}$ such that

$$\Pr \left( T_{cd4\_0} \geq 5 \mid \beta_{cd4\_0} = \beta_{cd4\_0}, T_{cd8\_0} = 8, T_{cd8\_1} = 6, M = 14 \right) = 1/2$$

using (1) in Methods and formulas.

The output is in agreement with example 1: there is an increase in risk of HIV infection for a CD4 blood serum level of 0 relative to a level of 2 and for a level of 1 relative to a level of 2; there is a decrease in risk of HIV infection for a CD8 blood serum level of 0 relative to a level of 2 and for a level of 1 relative to a level of 2.

We also displayed $e(n_{\text{possible}})$. This is the combinatorial coefficient associated with the observed sufficient statistics. The same value is found in the $\_f\_$ variable of the conditional distribution dataset listed above. The size of the distribution is $\binom{47}{14} = 341,643,774,795$. This can be verified by summing the $\_f\_$ variable of the generated conditional distribution dataset.

```
. use dist, clear
. summarize _f_, meanonly
. di %15.1f r(sum)
341643774795.0
```

### Example 3

One can think of exact logistic regression as a covariate-adjusted exact binomial. To demonstrate this point, we will use `exlogistic` to compute a binomial confidence interval for $m$ successes of $n$ trials, by fitting the constant-only model, and we will compare it with the confidence interval computed by `ci proportions` (see [R] `ci`). We will use the `saving()` option to retain the dataset containing the feasible values for the constant term sufficient statistic, namely, the number of successes, $m$, given $n$ trials and their associated combinatorial coefficients $\binom{n}{m}$, $m = 0, 1, \ldots, n$.

```
. input y
   1. 1

Example 3
We use the postestimation program `estat predict` to transform the estimated constant term and its confidence bounds by using the inverse logit function, `invlogit()` (see [FN] Mathematical functions). The standard error for the estimated probability is computed using the delta method.

Examining the listing of the generated data, the values contained in the variable `cons` are the feasible values of \(M\), and the values contained in the variable `f` are the binomial coefficients \(\binom{6}{m}\) with total \(\sum_{m=0}^{6} \binom{6}{m} = 2^6 = 64\). In the coefficient table, the sufficient statistic for the constant term, labeled `Suff.`, is \(m = 4\). This value is located at record 5 of the dataset. Therefore, the two-tailed probability of the sufficient statistic is computed as 0.6875 = \(2(15 + 6 + 1)/64\).

The constant term is the value of \(\theta\) that maximizes the probability of observing \(M = 4\); see (1) of Methods and formulas:

\[
\Pr(M = 4|\theta) = \frac{15e^{4\alpha}}{1 + 6e^{\alpha} + 15e^{2\alpha} + 20e^{3\alpha} + 15e^{4\alpha} + 6e^{5\alpha} + e^{6\alpha}}
\]

The maximum is at the value \(\theta = \log2\), which is demonstrated in the figure below.
The lower and upper confidence bounds are the values of $\theta$ such that $\Pr(M \geq 4|\theta) = 0.025$ and $\Pr(M \leq 4|\theta) = 0.025$, respectively. These probabilities are plotted in the figure below for $\theta \in [-2, 4]$. 
Example 4

This example demonstrates the `group()` option, which allows the analysis of stratified data. Here the logistic model is

\[
\log \left( \frac{\pi_{ik}}{1 - \pi_{ik}} \right) = \theta_k + x_{ki}\beta
\]

where \( k \) indexes the \( s \) strata, \( k = 1, \ldots, s \), and \( \theta_k \) is the strata-specific constant term whose sufficient statistic is \( M_k = \sum_{i=1}^{n_k} Y_{ki} \).

Mehta and Patel (1995) use a case–control study to demonstrate this model, which is useful in comparing the estimates from `exlogistic` and `clogit`. This study was intended to determine the role of birth complications in people with schizophrenia (Garsd 1988). Siblings from seven families took part in the study, and each individual was classified as normal or schizophrenic. A birth complication index is recorded for each individual that ranges from 0, an uncomplicated birth, to 15, a very complicated birth. Some of the frequencies contained in variable \( f \) are greater than 1, and these count different births at different times where the individual has the same birth complications index, found in variable BCindex.

The asymptotic alternative for this model can be estimated using clogit (equivalently, xtlogit, fe) and is listed below for comparison. We must expand the data because clogit will not accept frequency weights if they are not constant within the groups.

. expand f
(7 observations created)

. clogit schizo BCindex, group(family) nolog

Conditional (fixed-effects) logistic regression

|          | Coef.  | Std. Err. | z      | P>|z|   | [95% Conf. Interval] |
|----------|--------|-----------|--------|-------|----------------------|
| schizo   | .3251178 | .1678981 | 1.94   | 0.053 | -.0039565 .654192   |

Both techniques compute the same regression estimate for the BCindex, which might not be too surprising because both estimation techniques condition on the total number of successes in each group. The difference lies in the \( p \)-values and confidence intervals. The \( p \)-value testing \( H_0: \beta_{BCindex} = 0 \) is approximately 0.0167 for the exact conditional scores test and 0.053 for the asymptotic Wald test. Moreover, the exact confidence interval is asymmetric about the estimate and does not contain zero.

Technical note

The \texttt{memory(\#)} option limits the amount of memory that \texttt{exlogistic} will consume when computing the conditional distribution of the parameter sufficient statistics. \texttt{memory()} is independent of the data maximum memory setting (see \texttt{set max\_memory} in \texttt{[D] memory}), and it is possible
for exlogistic to exceed the memory limit specified in set max_memory without terminating. By default, a log is provided that displays the number of enumerations (the size of the conditional distribution) after processing each observation. Typically, you will see the number of enumerations increase, and then at some point they will decrease as the multivariate shift algorithm (Hirji, Mehta, and Patel 1987) determines that some of the enumerations cannot achieve the observed sufficient statistics of the conditioning variables. When the algorithm is complete, however, it is necessary to store the conditional distribution of the parameter sufficient statistics as a dataset. It is possible, therefore, to get a memory error when the algorithm has completed if there is not enough memory to store the conditional distribution.

Technical note

Computing the conditional distributions and reported statistics requires data sorting and numerical comparisons. If there is at least one single-precision variable specified in the model, exlogistic will make comparisons with a relative precision of $2^{-5}$. Otherwise, a relative precision of $2^{-11}$ is used. Be careful if you use recast to promote a single-precision variable to double precision (see [D] recast). You might try listing the data in full precision (maybe %20.15g; see [D] format) to make sure that this is really what you want. See [D] Data types for information on precision of numeric storage types.

Stored results

exlogistic stores the following in e():

Scalars
- e(N) number of observations
- e(k_groups) number of groups
- e(n_possible) number of distinct possible outcomes where sum(sufficient) equals observed
  - e(sufficient)
- e(n_trials) binomial number-of-trials parameter
- e(sum_y) sum of depvar
- e(k_indvars) number of independent variables
- e(k_terms) number of model terms
- e(k_condvars) number of conditioning variables
- e(condcons) conditioned on the constant(s) indicator
- e(midp) mid-p-value rule indicator
- e(eps) relative difference tolerance

Macros
- e(cmd) exlogistic
- e(cmdline) command as typed
- e(title) title in estimation output
- e(depvar) name of dependent variable
- e(indvars) independent variables
- e(condvars) conditional variables
- e(groupvar) group variable
- e(binomial) binomial number-of-trials variable
- e(terms) term names set in option terms()
- e(level) confidence level
- e(wtype) weight type
- e(wexp) weight expression
- e(datasignature) the checksum
- e(datasignaturevars) variables used in calculation of checksum
- e(properties) b
- e(estat_cmd) program used to implement estat
- e(marginsnotok) predictions disallowed by margins
Matrices

Methods and formulas

Methods and formulas are presented under the following headings:

- Sufficient statistics
- Conditional distribution and CMLE
- Median unbiased estimates and exact CI
- Conditional hypothesis tests
- Sufficient-statistic p-value

Sufficient statistics

Let \( \{Y_1, Y_2, \ldots, Y_n\} \) be a set of \( n \) independent Bernoulli random variables, each of which can realize two outcomes, \( \{0, 1\} \). For each \( i = 1, \ldots, n \), we observe \( Y_i = y_i \), and associated with each observation is the covariate row vector of length \( p \), \( x_i = (x_{i1}, \ldots, x_{ip}) \). Denote \( \beta = (\beta_1, \ldots, \beta_p)^T \) to be the column vector of regression parameters and \( \theta \) to be the constant. The sufficient statistic for \( \beta_j \) is \( T_j = \sum_{i=1}^n Y_i x_{ij}, j = 1, \ldots, p \), and for \( \theta \) is \( M = \sum_{i=1}^n Y_i \). We observe \( T_j = t_j, t_j = \sum_{i=1}^n y_i x_{ij} \), and \( M = m, m = \sum_{i=1}^n y_i \). The probability of observing \( (Y_1 = y_1, Y_2 = y_2, \ldots, Y_n = y_n) \) is

\[
Pr(Y_1 = y_1, \ldots, Y_n = y_n \mid \beta, X) = \frac{\exp(m\theta + t\beta)}{\prod_{i=1}^n \{1 + \exp(\theta + x_i\beta)\}}
\]

where \( t = (t_1, \ldots, t_p) \) and \( X = (x_1^T, \ldots, x_n^T)^T \).

The joint distribution of the sufficient statistics \( T \) is obtained by summing over all possible binary sequences \( Y_1, \ldots, Y_n \) such that \( T = t \) and \( M = m \). This probability function is

\[
Pr(T_1 = t_1, \ldots, T_p = t_p, M = m \mid \beta, X) = \frac{c(t, m) \exp(m\theta + t\beta)}{\prod_{i=1}^n \{1 + \exp(\theta + x_i\beta)\}}
\]

where \( c(t, m) \) is the combinatorial coefficient of \( (t, m) \) or the number of distinct binary sequences \( Y_1, \ldots, Y_n \) such that \( T = t \) and \( M = m \) (Cox and Snell 1989).
Conditional distribution and CMLE

Without loss of generality, we will restrict our discussion to computing the CMLE of $\beta_1$. If we condition on observing $M = m$ and $T_2 = t_2, \ldots, T_p = t_p$, the probability function of $(T_1 \mid \beta_1, T_2 = t_2, \ldots, T_p = t_p, M = m)$ is

$$
\Pr(T_1 = t_1 \mid \beta_1, T_2 = t_2, \ldots, T_p = t_p, M = m) = \frac{c(t, m)e^{t_1\beta_1}}{\sum_u c(u, t_2, \ldots, t_p, m)e^{u\beta_1}}
$$

(1)

where the sum in the denominator is over all possible values of $T_1$ such that $M = m$ and $T_2 = t_2, \ldots, T_p = t_p$ and $c(u, t_2, \ldots, t_p, m)$ is the combinatorial coefficient of $(u, t_2, \ldots, t_p, m)$ (Cox and Snell 1989). The CMLE for $\beta_1$ is the value $\hat{\beta}_1$ that maximizes the log of (1). This optimization task is carried out by m1, using the conditional frequency distribution of $(T_1 \mid T_2 = t_2, \ldots, T_p = t_p, M = m)$ as a dataset. Generating the joint conditional distribution is efficiently computed using the multivariate shift algorithm described by Hirji, Mehta, and Patel (1987).

Difficulties in computing $\hat{\beta}_1$ arise if the observed $(T_1 = t_1, \ldots, T_p = t_p, M = m)$ lies on the boundaries of the distribution of $(T_1 \mid T_2 = t_2, \ldots, T_p = t_p, M = m)$, where the conditional probability function is monotonically increasing (or decreasing) in $\beta_1$. Here the CMLE is plus infinity if it is on the upper boundary, $\Pr(T_1 \leq t_1 \mid T_2 = t_2, \ldots, T_p = t_p, M = m) = 1$, and is minus infinity if it is on the lower boundary of the distribution, $\Pr(T_1 \geq t_1 \mid T_2 = t_2, \ldots, T_p = t_p, M = m) = 1$. This concept is demonstrated in example 2. When infinite CMLEs occur, the MUE is computed.

Median unbiased estimates and exact CI

The MUE is computed using the technique outlined by Hirji, Tsiatis, and Mehta (1989). First, we find the values of $\beta_1^{(u)}$ and $\beta_1^{(l)}$ such that

$$
\Pr(T_1 \leq t_1 \mid \beta_1 = \beta_1^{(u)}, T_2 = t_2, \ldots, T_p = t_p, M = m) =
$$

$$
\Pr(T_1 \geq t_1 \mid \beta_1 = \beta_1^{(l)}, T_2 = t_2, \ldots, T_p = t_p, M = m) = 1/2
$$

(2)

The MUE is then $\overline{\beta}_1 = (\beta_1^{(l)} + \beta_1^{(u)})/2$. However, if $T_1$ is equal to the minimum of the domain of the conditional distribution, $\beta_1^{(l)}$ does not exist and $\overline{\beta}_1 = \beta_1^{(u)}$. If $T_1$ is equal to the maximum of the domain of the conditional distribution, $\beta_1^{(u)}$ does not exist and $\overline{\beta}_1 = \beta_1^{(l)}$.

Confidence bounds for $\beta$ are computed similarly, except that we substitute $\alpha/2$ for $1/2$ in (2), where $1 - \alpha$ is the confidence level. Here $\beta_1^{(l)}$ would then be the lower confidence bound and $\beta_1^{(u)}$ would be the upper confidence bound (see example 3).

Conditional hypothesis tests

To test $H_0: \beta_1 = 0$ versus $H_1: \beta_1 \neq 0$, we obtain the exact $p$-value from $\sum_{u \in E} f_1(u) - f_1(t_1)/2$ if the mid-$p$-value rule is used and $\sum_{u \in E} f_1(u)$ otherwise. Here $E$ is a critical region, and we define $f_1(u) = \Pr(T_1 = u \mid \beta_1 = 0, T_2 = t_2, \ldots, T_p = t_p, M = m)$ for ease of notation. There are two popular ways to define the critical region: the conditional probabilities test and the conditional scores test (Mehta and Patel 1995). The critical region when using the conditional probabilities test is all values of the sufficient statistic for $\beta_1$ that have a probability less than or equal to that of the observed $t_1$, $E_p = \{u : f_1(u) \leq f_1(t_1)\}$. The critical region of the conditional scores test is defined as all values of the sufficient statistic for $\beta_1$ such that its score is greater than or equal to that of $t_1$,

$$
E_s = \{u : (u - \mu_1)^2/\sigma_1^2 \geq (t_1 - \mu_1)^2/\sigma_1^2\}
$$

Here $\mu_1$ and $\sigma_1^2$ are the mean and variance of $(T_1 \mid \beta_1 = 0, T_2 = t_2, \ldots, T_p = t_p, M = m)$. 

The score statistic is defined as

\[
\left\{ \frac{\partial \ell(\beta)}{\partial \beta} \right\}^2 \left[ -E \left\{ \frac{\partial^2 \ell(\beta)}{\partial \beta^2} \right\} \right]^{-1}
\]

evaluated at \( H_0: \beta = 0 \), where \( \ell \) is the log of \( (1) \). The score test simplifies to \( (t - E [T|\beta])^2 / \text{var}(T|\beta) \) (Hirji 2006), where the mean and variance are computed from the conditional distribution of the sufficient statistic with \( \beta = 0 \) and \( t \) is the observed sufficient statistic.

**Sufficient-statistic p-value**

The \( p \)-value for testing \( H_0: \beta_1 = 0 \) versus the two-sided alternative when \( (T_1 = t_1|T_2 = t_2, \ldots, T_p = t_p) \) is computed as \( 2 \times \min(p_l, p_u) \), where

\[
p_l = \frac{\sum_{u \leq t_1} c(u, t_2, \ldots, t_p, m)}{\sum_u c(u, t_2, \ldots, t_p, m)}
\]

\[
p_u = \frac{\sum_{u \geq t_1} c(u, t_2, \ldots, t_p, m)}{\sum_u c(u, t_2, \ldots, t_p, m)}
\]

It is the probability of observing a more extreme \( T_1 \).

Postestimation commands

The following postestimation commands are of special interest after `exlogistic`:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>estat predict</td>
<td>single-observation prediction</td>
</tr>
<tr>
<td>estat se</td>
<td>report ORs or coefficients and their asymptotic standard errors</td>
</tr>
</tbody>
</table>

The following standard postestimation commands are also available:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>estat summarize</td>
<td>summary statistics for the estimation sample</td>
</tr>
<tr>
<td>estimates</td>
<td>cataloging estimation results</td>
</tr>
</tbody>
</table>

`estat summarize` is not allowed if the `binomial()` option was specified in `exlogistic`. 
estat

Description for estat

estat predict computes a predicted probability (or linear predictor), its asymptotic standard error, and its exact confidence interval for 1 observation. Predictions are carried out by estimating the constant coefficient after shifting the independent variables and conditioned variables by the values specified in the at() option or by their medians. Therefore, predictions must be done with the estimation sample in memory. If a different dataset is used or if the dataset is modified, then an error will result.

estat se reports odds ratio or coefficients and their asymptotic standard errors. The estimates are stored in the matrix r(estimates).

</tr>
</tbody>
</table>

These statistics are available only for the estimation sample.

Options for estat predict

pr, the default, calculates the probability.
xb calculates the linear effect.

at( varname = # [[ varname = # ] [...] ]) specifies values to use in computing the predicted value. Here varname is one of the independent variables, indepvars, or the conditioned variables, condvars(). The default is to use the median of each independent and conditioned variable.

level(#) specifies the confidence level, as a percentage, for confidence intervals. The default is level(95) or as set by set level; see [U] 20.8 Specifying the width of confidence intervals.
memory(\#b\,k\,m\,g) sets a limit on the amount of memory estat predict can use when generating the conditional distribution of the constant parameter sufficient statistic. The default is memory(10m), where m stands for megabyte, or 1,048,576 bytes. The following are also available: b stands for byte; k stands for kilobyte, which is equal to 1,024 bytes; and g stands for gigabyte, which is equal to 1,024 megabytes. The minimum setting allowed is 1m and the maximum is 512m or 0.5g, but do not attempt to use more memory than is available on your computer. Also see Remarks and examples in [R] exlogistic for details on enumerating the conditional distribution.

log and nolog specify whether to display the enumeration log, which shows the progress of enumerating the distribution of the observed successes conditioned on the independent variables shifted by the values specified in at() (or by their medians). See Methods and formulas in [R] exlogistic for details of the computations. The enumeration log is displayed by default unless you used set iterlog off to suppress it; see set iterlog in [R] set iter.

**Option for estat se**

coeff requests that the estimated coefficients and their asymptotic standard errors be reported. The default is to report the odds ratios and their asymptotic standard errors.

**Remarks and examples**

Predictions must be done using the estimation sample. This is because the prediction is really an estimated constant coefficient (the intercept) after shifting the independent variables and conditioned variables by the values specified in at() or by their medians. The justification for this approach can be seen by rewriting the model as

$$\log \left( \frac{\pi_i}{1 - \pi_i} \right) = (\alpha + x_0 \beta) + (x_i - x_0) \beta$$

where $x_0$ are the specified values for the indepvars (Mehta and Patel 1995). Because the estimation of the constant term is required, this technique is not appropriate for stratified models that used the group() option.

**Example 1**

To demonstrate, we return to the example 2 in [R] exlogistic using data from a prospective study of perinatal infection and HIV-1. Here there was an investigation into whether the blood serum levels of CD4 and CD8 measured in infants at 6 months of age might predict their development of HIV infection. The blood serum levels are coded as ordinal values 0, 1, and 2. These data are used by Mehta and Patel (1995) as an exposition of exact logistic.

```
use https://www.stata-press.com/data/r16/hiv_n (prospective study of perinatal infection of HIV-1; binomial form)
. generate byte cd4_0 = (cd4==0)
. generate byte cd4_1 = (cd4==1)
. generate byte cd8_0 = (cd8==0)
. generate byte cd8_1 = (cd8==1)
. exlogistic hiv cd4_0 cd4_1 cd8_0 cd8_1, terms(cd4=cd4_0 cd4_1, cd8=cd8_0 cd8_1) binomial(n) test(probability) saving(dist)
(output omitted)

(*) identifies median unbiased estimates (MUE); because an MUE is computed, there is no SE estimate.

Because we did not specify values by using the at() option, the median values of the indepvars are used for the prediction. By default, medians are used instead of means because we want to use values that are observed in the dataset. If the means of the binary variables cd4_0–cd8_1 were used, we would have created floating point variables in (0,1) that not only do not properly represent the indicator variables but also would be a source of computational inefficiency in generating the conditional distribution. Because the MUE is computed for the predicted value, there is no standard-error estimate.

From the example discussions in [R] exlogistic, the infants at highest risk are those with a CD4 level of 0 and a CD8 level of 2. Below we use the at() option to make a prediction at these blood serum levels.

Stored results

estat predict stores the following in r():

Scalars
- r(imue) 1 if r(pred) is an MUE and 0 if a CMLE
- r(pred) estimated probability or the linear effect
- r(se) asymptotic standard error of r(pred)

Macros
- r(estimate) prediction type: pr or xb
- r(level) confidence level

Matrices
- r(ci) confidence interval
- r(x) indepvars and condvars() values

Title

expoisson — Exact Poisson regression

Description

expoisson fits an exact Poisson regression model, which produces more accurate inference in small samples than standard maximum-likelihood–based Poisson regression. For stratified data, expoisson conditions on the number of events in each stratum and is an alternative to fixed-effects Poisson regression.

Quick start

Exact Poisson regression of $y$ on $x_1$, $x_2$, and $x_3$

expoisson $y$ $x_1$ $x_2$ $x_3$

Add exposure variable evar

expoisson $y$ $x_1$ $x_2$ $x_3$, exposure(evar)

As above, but condition on values of $x_3$ to save time and memory

expoisson $y$ $x_1$ $x_2$, exposure(evar) condvars(x3)

As above, and allow more memory for computing the conditional distribution of sufficient statistics

expoisson $y$ $x_1$ $x_2$, exposure(evar) condvars(x3) memory(100m)

Report incidence-rate ratios rather than coefficients

expoisson $y$ $x_1$ $x_2$ $x_3$, irr

Report conditional scores tests

expoisson $y$ $x_1$ $x_2$ $x_3$, test(score)

Include strata-specific constant terms for each level of svar for an exact version of fixed-effects Poisson regression

expoisson $y$ $x_1$ $x_2$ $x_3$, group(svar)

Menu

Statistics > Exact statistics > Exact Poisson regression
Syntax

```
expoisson  depvar  indepvars  [if]  [in]  [weight]  [,  options]
```

## options Description

**Model**

- `condvars(varlist)` condition on variables in `varlist`
- `group(varname)` groups/strata are stratified by unique values of `varname`
- `exposure(varname_e)` include \( \ln(varname_e) \) in model with coefficient constrained to 1
- `offset(varname_o)` include `varname_o` in model with coefficient constrained to 1

**Options**

- `memory(# [b | k | m | g])` set limit on memory usage; default is `memory(25m)`
- `saving(filename)` save the joint conditional distribution to `filename`

**Reporting**

- `level(#)` set confidence level; default is `level(95)`
- `irr` report incidence-rate ratios
- `test(testopt)` report \( p \)-value for observed sufficient statistic, conditional scores test, or conditional probabilities test
- `mue(varlist)` compute the median unbiased estimates for `varlist`
- `midp` use the mid-\( p \)-value rule
- `[no] log` display or suppress the enumeration log; default is to display

by, statsby, and `xi` are allowed; see [U] 11.1.10 Prefix commands.

`fweights` are allowed; see [U] 11.1.6 weight.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

## Options

`condvars(varlist)` specifies variables whose parameter estimates are not of interest to you. You can save substantial computer time and memory by moving such variables from `indepvars` to `condvars()`. Understand that you will get the same results for `x1` and `x3` whether you type

```
  . expoisson y  x1  x2  x3  x4
```

or

```
  . expoisson y  x1  x3,  condvars(x2  x4)
```

`group(varname)` specifies the variable defining the strata, if any. A constant term is assumed for each stratum identified in `varname`, and the sufficient statistics for `indepvars` are conditioned on the observed number of successes within each group (as well as other variables in the model). The group variable must be integer valued.

`exposure(varname_e)`, `offset(varname_o)`; see [R] Estimation options.
expoisson — Exact Poisson regression

memory(#[b|k|m|g]) sets a limit on the amount of memory expoisson can use when computing the conditional distribution of the parameter sufficient statistics. The default is memory(25m), where m stands for megabyte, or 1,048,576 bytes. The following are also available: b stands for byte; k stands for kilobyte, which is equal to 1,024 bytes; and g stands for gigabyte, which is equal to 1,024 megabytes. The minimum setting allowed is 1m and the maximum is 2048m or 2g, but do not attempt to use more memory than is available on your computer. Also see the first technical note under example 3 on counting the conditional distribution.

saving([filename [, replace]]) saves the joint conditional distribution for each independent variable specified in indepvars. There is one file for each variable, and it is named using the prefix filename with the variable name appended. For example, saving(mydata) with an independent variable named X would generate a data file named mydata_X.dta. Use replace to replace an existing file. Each file contains the conditional distribution for one of the independent variables specified in indepvars conditioned on all other indepvars and those variables specified in condvars(). There are two variables in each data file: the feasible sufficient statistics for the variable’s parameter and their associated weights. The weights variable is named _w_.

level(#) ; see [R] Estimation options. The level(#) option will not work on replay because confidence intervals are based on estimator-specific enumerations. To change the confidence level, you must refit the model.

irr reports estimated coefficients transformed to incidence-rate ratios, that is, exp(β) rather than β. Standard errors and confidence intervals are similarly transformed. This option affects how results are displayed, not how they are estimated or stored. irr may be specified at estimation or when replaying previously estimated results.

test(sufficient|score|probability) reports the p-value associated with the observed sufficient statistic, the conditional scores test, or the conditional probabilities test. The default is test(sufficient). All the statistics are computed at estimation time, and each statistic may be displayed postestimation; see [R] expoisson postestimation.

mue(varlist) specifies that median unbiased estimates (MUEs) be reported for the variables in varlist. By default, the conditional maximum likelihood estimates (CMLEs) are reported, except for those parameters for which the CMLEs are infinite. Specify mue(_all) if you want MUEs for all the indepvars.

midp instructs expoisson to use the mid-p-value rule when computing the MUEs, p-values, and confidence intervals. This adjustment is for the discreteness of the distribution by halving the value of the discrete probability of the observed statistic before adding it to the p-value. The mid-p-value rule cannot be applied to MUEs whose corresponding parameter CMLE is infinite.

log and nolog specify whether to display the enumeration log, showing the progress of computing the conditional distribution of the sufficient statistics. The enumeration log is displayed by default unless you used set iterlog off to suppress it; see set iterlog in [R] set iter.

Remarks and examples

Exact Poisson regression estimates the model parameters by using the conditional distributions of the parameters’ sufficient statistics, and the resulting parameter estimates are known as CMLEs. Exact Poisson regression is a small-sample alternative to the maximum-likelihood ML Poisson model. See [R] poisson and [XT] xtpoisson to obtain maximum likelihood estimates (MLEs) for the Poisson model and the fixed-effects Poisson model.
Let $Y_i$ denote a Poisson random variable where we observe the outcome $Y_i = y_i$, $i = 1, \ldots, n$. Associated with each independent observation is a $1 \times p$ vector of covariates, $x_i$. We will denote $\mu_i = E[Y_i | x_i]$ and use the log linear model to model the relationship between $Y_i$ and $x_i$, 

$$\log(\mu_i) = \theta + x_i \beta$$

where the constant term, $\theta$, and the $p \times 1$ vector of regression parameters, $\beta$, are unknown. The probability of observing $Y_i = y_i$, $i = 1, \ldots, n$, is

$$\Pr(Y = y) = \prod_{i=1}^{n} \frac{\mu_i^{y_i} e^{-\mu_i}}{y_i!}$$

where $Y = (Y_1, \ldots, Y_n)$ and $y = (y_1, \ldots, y_n)$. The MLEs for $\theta$ and $\beta$ maximize the log of this function.

The sufficient statistics for $\theta$ and $\beta_j$, $j = 1, \ldots, p$, are $M = \sum_{i=1}^{n} Y_i$ and $T_j = \sum_{i=1}^{n} Y_i x_{ij}$, respectively, and we observe $M = m$ and $T_j = t_j$. expoisson tallies the conditional distribution for each $T_j$, given the other sufficient statistics $T_l = t_l$, $l \neq j$ and $M = m$. Denote one of these values to be $t_j^{(k)}$, $k = 1, \ldots, N$, with weight $w_k$ that accounts for all the generated $Y$ vectors that give rise to $t_j^{(k)}$. The conditional probability of observing $T_j = t_j$ has the form

$$\Pr(T_j = t_j | T_l = t_l, l \neq j, M = m) = \frac{w \ e^{t_j \beta_j}}{\sum_k w_k e^{t_j^{(k)}}}$$

where the sum is over the subset of $T$ vectors such that $(T_1^{(k)} = t_1, \ldots, T_j^{(k)} = t_j^{(k)}, \ldots, T_p^{(k)} = t_p)$ and $w$ is the weight associated with the observed $t$. The CMLE for $\beta_j$ maximizes the log of this function.

Specifying nuisance variables in condvars() prevents expoisson from estimating their associated regression coefficients. These variables are still conditional variables when tallying the conditional distribution for the variables in indepvars().

Inferences from MLEs rely on asymptotics, and if your sample size is small, these inferences may not be valid. On the other hand, inferences from the CMLEs are exact in that they use the conditional distribution of the sufficient statistics outlined above.

For small datasets, the dependent variable can be completely determined by the data. Here the MLEs and the CMLEs are unbounded. When this occurs, expoisson will compute the MUE, the regression estimate that places the observed sufficient statistic at the median of the conditional distribution.

See [R] exlogistic for a more thorough discussion of exact estimation and related statistics.

Example 1

Armitage, Berry, and Matthews (2002, 499–501) fit a log-linear model to data containing the number of cerebrovascular accidents experienced by 41 men during a fixed period, each of whom had recovered from a previous cerebrovascular accident and was hypertensive. Sixteen men received treatment, and in the original data, there are three age groups (40–49, 50–59, 60+), but we pool the first two age groups to simplify the example. Armitage, Berry, and Matthews point out that this was not a controlled trial, but the data are useful to inquire whether there is evidence of fewer accidents for the treatment group and if age may be an important factor. The dependent variable count contains the number of accidents, variable treat is an indicator for the treatment group (1 = treatment, 0 = control), and variable age is an indicator for the age group (0 = 40–59; 1 = 60+).
First, we load the data, list it, and tabulate the cerebrovascular accident counts by treatment and age group.

```

`expoisson` generates an enumeration log for each independent variable in `indepvars`. The conditional distribution of the parameter sufficient statistic is tallied for each independent variable. The conditional distribution for `treat`, for example, has 30 records containing the weights, $w_k$, and feasible sufficient statistics, $t_{treat}^{(k)}$. In essence, the set of points $(w_k, t_{treat}^{(k)})$, $k = 1, \ldots, 30$, tallied by `expoisson` now become the data to estimate the regression coefficient for `treat`, using (1) as the likelihood. Remember that one of the 30 $(w_k, t_{treat}^{(k)})$ must contain the observed sufficient statistic, $t_{treat} = \sum_{i=1}^{41} t_{treat} \times count_i = 4$, and its relative position in the sorted set of points (sorted by $t_{treat}^{(k)}$) is how the sufficient-statistic $p$-value is computed. This algorithm is repeated for the `age` variable.

The regression coefficients for `treat` and `age` are numerically identical for both Poisson models. Both models indicate that the treatment is significant at reducing the rate of cerebrovascular accidents, $\approx e^{-1.59} \approx 0.204$, or a reduction of about 80%. There is no significant age effect.
The $p$-value for the treatment regression-coefficient sufficient statistic indicates that the treatment effect is a bit more significant than for the corresponding asymptotic $Z$ statistic from `poisson`. However, the exact confidence intervals are wider than their asymptotic counterparts.

### Example 2

Agresti (2013, 129) used the data from Laird and Olivier (1981) to demonstrate the Poisson model for modeling rates. The data consist of patient survival after heart valve replacement operations. The sample consists of 109 patients that are classified by type of heart valve (aortic, mitral) and by age ($<55$, $\geq 55$). Follow-up observations cover lengths from 3 to 97 months, and the time at risk, or exposure, is stored in the variable TAR. The response is whether the subject died. First, we take a look at the data and then estimate the incidence rates (IRs) with `expoisson` and `poisson`.

```
use https://www.stata-press.com/data/r16/heartvalve
(list heart valve replacement data)
list
```

<table>
<thead>
<tr>
<th>age</th>
<th>valve</th>
<th>deaths</th>
<th>TAR</th>
</tr>
</thead>
<tbody>
<tr>
<td>&lt; 55</td>
<td>aortic</td>
<td>4</td>
<td>1259</td>
</tr>
<tr>
<td>&lt; 55</td>
<td>mitral</td>
<td>1</td>
<td>2082</td>
</tr>
<tr>
<td>$\geq 55$</td>
<td>aortic</td>
<td>7</td>
<td>1417</td>
</tr>
<tr>
<td>$\geq 55$</td>
<td>mitral</td>
<td>9</td>
<td>1647</td>
</tr>
</tbody>
</table>

The `age` variable is coded 0 for age $<55$ and 1 for age $\geq 55$, and the `valve` variable is coded 0 for the aortic valve and 1 for the mitral valve. The total number of deaths, $M = 21$, is small enough that enumerating the conditional distributions for age and valve type is feasible and asymptotic inferences associated with standard ML Poisson regression may be questionable.

```
.expoisson deaths age valve, exposure(TAR) irr
```

Prob > chi2 = 0.0222

Log likelihood = -8.1747285 Pseudo R2 = 0.3178

| deaths          | IRR  | Std. Err. | z    | P>|z|  | [95% Conf. Interval] |
|-----------------|------|-----------|------|-------|---------------------|
| age             | 3.390401 | 1.741967  | 2.38 | 0.017 | 1.238537 9.280965   |
| valve           | .7190197 | .3150492  | -0.75| 0.452 | .3046311 1.6971     |
| _cons           | .0018142 | .0009191  | -12.46| 0.000 | .0006722 .0048968   |
| ln(TAR)         | 1 (exposure) |

Note: _cons estimates baseline incidence rate.

The CMLE and the MLE are numerically identical. The death rate for the older age group is about 3.4 times higher than the younger age group, and this difference is significant at the 5% level. This means that for every death in the younger group each month, we would expect about three deaths in the older group. The IR estimate for valve type is approximately 0.72, but it is not significantly different from one. The exact Poisson confidence intervals are a bit wider than the asymptotic CIs.

You can use ir (see [R] Epitab) to estimate IRs and exact CIs for one covariate, and we compare these CIs with those from expoisson, where we estimate the incidence rate by using age only.

mid-p-value computed for the probabilities and CIs

Both ir and expoisson give identical IRs and p-values. Both report the two-sided exact p-value by using the mid-p-value rule that accounts for the discreteness in the distribution by subtracting \( p_{1/2} = \Pr(T = t)/2 \) from \( p_l = \Pr(T \leq t) \) and \( p_g = \Pr(T \geq t) \), computing \( 2 \times \min(p_l - p_{1/2}, p_g - p_{1/2}) \). By default, expoisson will not use the mid-p-value rule (when you exclude the midp option), and here the two-sided exact p-value would be \( 2 \times \min(p_l, p_g) = 0.0158 \). The confidence intervals differ
because `expoisson` uses the mid-\(p\)-value rule when computing the confidence intervals, yet `ir` does not. You can verify this by executing `expoisson` without the `midp` option for this example; you will get the same CIs as `ir`.

You can replay `expoisson` to view the conditional scores test or the conditional probabilities test by using the `test()` option.

mid-p-value computed for the probabilities and CIs

All the statistics for `expoisson` are defined in *Methods and formulas* of [R] `exlogistic`. Apart from enumerating the conditional distributions for the logistic and Poisson sufficient statistics, computationally, the primary difference between `exlogistic` and `expoisson` is the weighting values in the likelihood for the parameter sufficient statistics.

### Example 3

In this example, we fabricate data that will demonstrate the difference between the CMLE and the MUE when the CMLE is not infinite. A difference in these estimates will be more pronounced when the probability of the coefficient sufficient statistic is skewed when plotted as a function of the regression coefficient.

```stata

( *) median unbiased estimates (MUE)

We observe \((x_i, y_i), \ i = 1, \ldots, 9\). If we condition on \(m = \sum_{i=1}^{9} y_i = 12\), the conditional distribution of \(T_x = \sum_i Y_i x_i\) has a size of 5,479 elements. For each entry in this enumeration, a realization of \(Y_i = y_i^{(k)}, \ k = 1, \ldots, 5,479\), is generated such that \(\sum_i y_i^{(k)} = 12\). One of these realizations produces the observed \(t_x = \sum_i y_i x_i \approx 1.5234\).

Below is a graphical display comparing the CMLE with the MUE. We plot \(\text{Pr}(T_x = t_x | M = 12, \beta_x)\) versus \(\beta_x, -6 \leq \beta_x \leq 1\), in the upper panel and the cumulative probabilities, \(\text{Pr}(T_x \leq t_x | M = 12, \beta_x)\) and \(\text{Pr}(T_x \geq t_x | M = 12, \beta_x)\), in the lower panel.
The location of the CMLE, indicated by the dashed line, is at the mode of the probability profile, and the MUE, indicated by the dotted line, is to the right of the mode. If we solve for the $\beta_x^{(u)}$ and $\beta_x^{(l)}$ such that $\Pr(T_x \leq t_x \mid M = 12, \beta_x^{(u)}) = 1/2$ and $\Pr(T_x \geq t_x \mid M = 12, \beta_x^{(l)}) = 1/2$, the MUE is $(\beta_x^{(u)} + \beta_x^{(l)})/2$. As you can see in the lower panel, the MUE cuts through the intersection of these cumulative probability profiles.
Technical note

The memory (#) option limits the amount of memory that expoisson will consume when computing the conditional distribution of the parameter sufficient statistics. memory() is independent of the data maximum memory setting (see set max_memory in [D] memory), and it is possible for expoisson to exceed the memory limit specified in set max_memory without terminating. By default, a log is provided that displays the number of enumerations (the size of the conditional distribution) after processing each observation. Typically, you will see the number of enumerations increase, and then at some point they will decrease as the multivariate shift algorithm (Hirji, Mehta, and Patel 1987) determines that some of the enumerations cannot achieve the observed sufficient statistics of the conditioning variables. When the algorithm is complete, however, it is necessary to store the conditional distribution of the parameter sufficient statistics as a dataset. It is possible, therefore, to get a memory error when the algorithm has completed if there is not enough memory to store the conditional distribution.

Technical note

Computing the conditional distributions and reported statistics requires data sorting and numerical comparisons. If there is at least one single-precision variable specified in the model, expoisson will make comparisons with a relative precision of $2^{-5}$. Otherwise, a relative precision of $2^{-11}$ is used. Be careful if you use recast to promote a single-precision variable to double precision (see [D] recast). You might try listing the data in full precision (maybe %20.15g; see [D] format) to make sure that this is really what you want. See [D] Data types for information on precision of numeric storage types.

Methods and formulas

Let \{Y_1, Y_2, \ldots, Y_n\} be a set of n independent Poisson random variables. For each \(i = 1, \ldots, n\), we observe \(Y_i = y_i \geq 0\), and associated with each observation is the covariate row vector of length \(p\), \(x_i = (x_{i1}, \ldots, x_{ip})\). Denote \(\beta = (\beta_1, \ldots, \beta_p)^T\) to be the column vector of regression parameters and \(\theta\) to be the constant. The sufficient statistic for \(\beta_j\) is \(T_j = \sum_{i=1}^n y_i x_{ij}, j = 1, \ldots, p\), and for \(\theta\) is \(M = \sum_{i=1}^n y_i\). We observe \(T_j = t_j, t_j = \sum_{i=1}^n y_i x_{ij}\), and \(M = m, m = \sum_{i=1}^n y_i\). Let \(\kappa_i\) be the exposure for the \(i\)th observation. Then the probability of observing \((Y_1 = y_1, Y_2 = y_2, \ldots, Y_n = y_n)\) is

\[
Pr(Y_1 = y_1, \ldots, Y_n = y_n \mid \beta, X, \kappa) = \frac{\exp(m \theta + t \beta)}{\exp\{\sum_{i=1}^n \kappa_i \exp(\theta + x_i \beta)\}} \prod_{i=1}^n \frac{\kappa_i^{y_i}}{y_i!}
\]

where \(t = (t_1, \ldots, t_p)\), \(X = (x_1^T, \ldots, x_n^T)^T\), and \(\kappa = (\kappa_1, \ldots, \kappa_n)^T\).

The joint distribution of the sufficient statistics \((T, M)\) is obtained by summing over all possible sequences \(Y_1 \geq 0, \ldots, Y_n \geq 0\) such that \(T = t\) and \(M = m\). This probability function is

\[
Pr(T_1 = t_1, \ldots, T_p = t_p, M = m \mid \beta, X, \kappa) = \frac{\exp(m \theta + t \beta)}{\exp\{\sum_{i=1}^n \kappa_i \exp(\theta + x_i \beta)\}} \left(\sum_{u} \Pi_{i=1}^n \frac{\kappa_i^{u_i}}{u_i!}\right)
\]

where the sum \(\sum_{u}\) is over all nonnegative vectors \(u\) of length \(n\) such that \(\sum_{i=1}^n u_i = m\) and \(\sum_{i=1}^n u_i x_i = t\).

Conditional distribution

Without loss of generality, we will restrict our discussion to the conditional distribution of the sufficient statistic for \(\beta_1, T_1\). If we condition on observing \(M = m\) and \(T_2 = t_2, \ldots, T_p = t_p\), the probability function of \((T_1 \mid \beta_1, T_2 = t_2, \ldots, T_p = t_p, M = m)\) is

\[
Pr(T_1 = t_1 \mid \beta_1, T_2 = t_2, \ldots, T_p = t_p, M = m) = \frac{\left(\sum_{u} \Pi_{i=1}^n \frac{\kappa_i^{u_i}}{u_i!}\right) e^{t_1 \beta_1}}{\sum_{v} \left(\Pi_{i=1}^n \frac{\kappa_i^{v_i}}{v_i!}\right) e^{\beta_1 \sum_{i} v_i x_{i1}}} (2)
\]
where the sum $\sum_u$ is over all nonnegative vectors $u$ of length $n$ such that $\sum_{i=1}^n u_i = m$ and $\sum_{i=1}^n u_i x_i = t$, and the sum $\sum_v$ is over all nonnegative vectors $v$ of length $n$ such that $\sum_{i=1}^n v_i = m$, $\sum_{i=1}^n v_i x_i^2 = t_2$, ..., $\sum_{i=1}^n v_i x_{ip} = t_p$. The CMLE for $\beta_1$ is the value that maximizes the log of (1). This optimization task is carried out by ml (see [R] ml), using the conditional distribution of $(T_1 \mid T_2 = t_2, \ldots, T_p = t_p, M = m)$ as a dataset. This dataset consists of the feasible values and weights for $T_1$.

$$\left\{ \left( s_1, \prod_{i=1}^n \frac{K_i^{v_i}}{v_i!} \right) : \sum_{i=1}^n v_i = m, \sum_{i=1}^n v_i x_{i1} = s_1, \sum_{i=1}^n v_i x_{i2} = t_2, \ldots, \sum_{i=1}^n v_i x_{ip} = t_p \right\}$$

Computing the CMLE, MUE, confidence intervals, conditional hypothesis tests, and sufficient statistic $p$-values is discussed in Methods and formulas of [R] exlogistic. The only difference between the two techniques is the use of the weights; that is, the weights for exact logistic are the combinatorial coefficients, $c(t, m)$, in (1) of Methods and formulas in [R] exlogistic. expoison and exlogistic use the same ml likelihood evaluator to compute the CMLEs as well as the same ado-programs and Mata functions to compute the MUEs and estimate statistics.

Postestimation commands

The following postestimation command is of special interest after expoisson:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>estat se</td>
<td>report coefficients or IRRs and their asymptotic standard errors</td>
</tr>
</tbody>
</table>

The following standard postestimation commands are also available:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>estat summarize</td>
<td>summary statistics for the estimation sample</td>
</tr>
<tr>
<td>estimates</td>
<td>cataloging estimation results</td>
</tr>
</tbody>
</table>

estat

Description for estat

`estat se` reports regression coefficients or incidence-rate asymptotic standard errors. The estimates are stored in the matrix `r(estimates)`.

Menu for estat

Statistics > Postestimation

Syntax for estat

`estat se [, irr]`

Option for estat

`irr` requests that the incidence-rate ratios and their asymptotic standard errors be reported. The default is to report the coefficients and their asymptotic standard errors.
Remarks and examples

Example 1

To demonstrate `estat se` after `expoisson`, we use the British physicians smoking data.

```
. use https://www.stata-press.com/data/r16/smokes
   (cigarette smoking and lung cancer among British physicians (45-49 years))
. expoisson cases smokes, exposure(peryrs) irr nolog
   Exact Poisson regression
   Number of obs = 7

   cases       IRR    Suff. 2*Pr(Suff.)    [95% Conf. Interval]
   smokes 1.077718   797.4     0.0000     1.04552    1.111866
   ln(peryrs) 1       1 (exposure)
```

```

[U] 20 Estimation and postestimation commands
**Description**

**fp <term>: est_cmd** fits models with the “best”-fitting fractional polynomial substituted for `<term>` wherever it appears in `est_cmd`. `fp <weight>: regress mpg <weight> foreign` would fit a regression model of `mpg` on a fractional polynomial in `weight` and (linear) `foreign`.

By specifying option `fp()`, you may set the exact powers to be used. Otherwise, a search through all possible fractional polynomials up to the degree set by `dimension()` with the powers set by `powers()` is performed.

`fp` without arguments redisplay the previous estimation results, just as typing `est_cmd` would. You can type either one. `fp` will include a fractional polynomial comparison table.

`fp generate` creates fractional polynomial power variables for a given set of powers. For instance, `fp <weight>: regress mpg <weight> foreign` might produce the fractional polynomial `weight^(-2,-1)` and store `weight^(-2)` in `weight_1` and `weight^(-1)` in `weight_2`. Typing `fp generate weight^(-2 -1)` would allow you to create the same variables in another dataset.

See [R] `mfp` for multivariable fractional polynomial models.

**Quick start**

*Fit models with fractional polynomials*

Find optimal second-degree fractional polynomial of `x1` in regression of `y` on `x2` and `x3`

`fp <x1>: regress y <x1> x2 x3`

As above, but search only powers of `-1`, `-0.5`, `1`, and `2`.

`fp <x1>, power(-1 -.5 1 2): regress y <x1> x2 x3`

As above, but allow search to include third-degree fractional polynomials

`fp <x1>, power(-1 -.5 1 2) dimension(3): regress y <x1> x2 x3`

Fit model including `x1^(-2)` and `x1^2` without performing search

`fp <x1>, fp(-2 2): regress y <x1> x2 x3`

Rescale `x1` to nonextreme positive values when computing fractional polynomials

`fp <x1>, scale: regress y <x1> x2 x3`

As above, and center fractional polynomial of `x1` at its scaled mean

`fp <x1>, center scale: regress y <x1> x2 x3`

Set fractional polynomial to zero for nonpositive values of `x1`

`fp <x1>, zero: regress y <x1> x2 x3`
As above, and include an indicator variable in the model for nonpositive values of $x_1$

$$fp <x_1>, \text{catzero: regress } y <x_1> x2 x3$$

Create variables corresponding to fractional polynomial powers

Generate $x_1^{-1}$ and $x_1^2$ corresponding to $x_1^{-2}$ and $x_1^2$

$$fp \text{ generate } x1^{(-2 2)}$$

As above, but generate fractional polynomial variables with automatic scaling and centering

$$fp \text{ generate } x1^{(-2 2)}, \text{center scale}$$

Note: In the above examples, `regress` could be replaced with any estimation command allowing the `fp` prefix.

Menu

`fp`

Statistics > Linear models and related > Fractional polynomials > Fractional polynomial regression

`fp generate`

Statistics > Linear models and related > Fractional polynomials > Create fractional polynomial variables
Syntax

Estimation

```
fp <term> [ , est_options ] : est_cmd
```

*est_cmd* may be almost any estimation command that stores the *e(11)* result. To confirm whether *fp* works with a specific *est_cmd*, see the documentation for that *est_cmd*.

Instances of `<term>` (with the angle brackets) that occur within *est_cmd* are replaced in *est_cmd* by a varlist containing the fractional powers of the variable *term*. These variables will be named *term_1*, *term_2*, . . . .

*fp* performs *est_cmd* with this substitution, fitting a fractional polynomial regression in *term*.

*est_cmd* in either this or the following syntax may not contain other prefix commands; see [U] 11.1.10 Prefix commands.

Estimation (alternate syntax)

```
fp <term> (varname) [ , est_options ] : est_cmd
```

Use this syntax to specify that fractional powers of *varname* are to be calculated. The fractional polynomial power variables will still be named *term_1*, *term_2*, . . . .

Replay estimation results

```
fp [ , replay_options ]
```

Create specified fractional polynomial power variables

```
fp generate [ type ] [ newvar = ] varname^ (numlist) [ if ] [ in ] [ , gen_options ]
```

Options for `fp`

`powers(# # ... #)` specifies that a search be performed and details about the search provided. `powers()` works with the `dimension()` option; see below. The default is `powers(-2 -1 -.5 0 .5 1 2 3)`.

`dimension(#)` specifies the maximum degree of the fractional polynomial to be searched. The default is `dimension(2)`.

If the defaults for both `powers()` and `dimension()` are used, then the fractional polynomial could be any of the following 44 possibilities:

```
  term(-2)
  term(-1)
  ...
  term(3)
  term(-2), term(-2)
  term(-2), term(-1)
  ...
  term(-2), term(3)
  term(-1), term(-2)
  ...
  term(3), term(3)
```

`fp(# # ... #)` specifies that no search be performed and that the fractional polynomial specified be used. `fp()` is an alternative to `powers()` and `dimension()`.

`classic` performs automatic scaling and centering and omits the comparison table. Specifying `classic` is equivalent to specifying `scale`, `center`, and `nocompare`.

`replace` replaces existing fractional polynomial power variables named `term_1`, `term_2`, ... .

`all` specifies that `term_1`, `term_2`, ... be filled in for all observations in the dataset rather than just for those in `e(sample)`.

`srate(#_a #_b)` specifies that `term` be scaled in the way specified, namely, that `(term+a)/b` is calculated. All values of the scaled term are required to be greater than zero unless you specify options `zero` or `catzero`. Values should not be too large or too close to zero, because by default, cubic powers and squared reciprocal powers will be considered. When `scale(a b)` is specified, values in the variable `term` are not modified; `fp` merely remembers to scale the values whenever powers are calculated.

You will probably not use `scale(a b)` for values of `a` and `b` that you create yourself, although you could. It is usually easier just to `generate` a scaled variable. For instance, if `term` is `age`, and `age` in your data is required to be greater than or equal to 20, you might generate an `age5` variable, for use as `term`:

```
. generate age5 = (age-19)/5
```
scale(a b) is useful when you previously fit a model using automatic scaling (option scale) in one dataset and now want to create the fractional polynomials in another. In the first dataset, fp with scale added notes to the dataset concerning the values of a and b. You can see them by typing

    . notes

You can then use fp generate, scale(a b) in the second dataset.

The default is to use term as it is used in calculating fractional powers; thus term’s values are required to be greater than zero unless you specify options zero or catzero. Values should not be too large, because by default, cubic powers will be considered.

scale specifies that term be scaled to be greater than zero and not too large in calculating fractional powers. See Scaling for more details. When scale is specified, values in the variable term are not modified; fp merely remembers to scale the values whenever powers are calculated.

center(#_c) reports results for the fractional polynomial in (scaled) term, centered on c. The default is to perform no centering.

    term^{(p_1,p_2,\ldots,p_m)} - c^{(p_1,p_2,\ldots,p_m)}

is reported. This makes the constant coefficient (intercept) easier to interpret. See Centering for more details.

center performs center(c), where c is the mean of (scaled) term.

zero and catzero specify how nonpositive values of term are to be handled. By default, nonpositive values of term are not allowed, because we will be calculating natural logarithms and fractional powers of term. Thus an error message is issued.

zero sets the fractional polynomial value to zero for nonpositive values of (scaled) term.

catzero sets the fractional polynomial value to zero for nonpositive values of (scaled) term and includes a dummy variable indicating where nonpositive values of (scaled) term appear in the model.

Reporting

nocompare suppresses display of the comparison tests.

reporting_options are any options allowed by est_cmd for replaying estimation results.

Options for fp generate

replace replaces existing fractional polynomial power variables named term_1, term_2, ...

scale(#_a #_b) specifies that term be scaled in the way specified, namely, that (term+a)/b be calculated. All values of the scaled term are required to be greater than zero unless you specify options zero or catzero. Values should not be too large or too close to zero, because by default, cubic powers and squared reciprocal powers will be considered. When scale(a b) is specified, values in the variable term are not modified; fp merely remembers to scale the values whenever powers are calculated.

You will probably not use scale(a b) for values of a and b that you create yourself, although you could. It is usually easier just to generate a scaled variable. For instance, if term is age, and age in your data is required to be greater than or equal to 20, you might generate an age5 variable, for use as term:

    . generate age5 = (age-19)/5
scale($a \ b$) is useful when you previously fit a model using automatic scaling (option scale) in one dataset and now want to create the fractional polynomials in another. In the first dataset, \texttt{fp} with \texttt{scale} added notes to the dataset concerning the values of $a$ and $b$. You can see them by typing

```
   . notes
```

You can then use \texttt{fp generate, scale($a \ b$)} in the second dataset.

The default is to use \texttt{term} as it is used in calculating fractional powers; thus \texttt{term}'s values are required to be greater than zero unless you specify options \texttt{zero} or \texttt{catzero}. Values should not be too large, because by default, cubic powers will be considered.

\texttt{scale} specifies that \texttt{term} be scaled to be greater than zero and not too large in calculating fractional powers. See \texttt{Scaling} for more details. When \texttt{scale} is specified, values in the variable \texttt{term} are not modified; \texttt{fp} merely remembers to scale the values whenever powers are calculated.

\texttt{center($\#\_c$)} reports results for the fractional polynomial in (scaled) \texttt{term}, centered on $c$. The default is to perform no centering.

$\texttt{term}^{(P_1 \ P_2 ... \ P_m)} \times \beta$ is reported. This makes the constant coefficient (intercept) easier to interpret. See \texttt{Centering} for more details.

\texttt{center} performs \texttt{center($c$)}, where $c$ is the mean of (scaled) \texttt{term}.

\texttt{zero} and \texttt{catzero} specify how nonpositive values of \texttt{term} are to be handled. By default, nonpositive values of \texttt{term} are not allowed, because we will be calculating natural logarithms and fractional powers of \texttt{term}. Thus an error message is issued.

\texttt{zero} sets the fractional polynomial value to zero for nonpositive values of (scaled) \texttt{term}.

\texttt{catzero} sets the fractional polynomial value to zero for nonpositive values of (scaled) \texttt{term} and includes a dummy variable indicating where nonpositive values of (scaled) \texttt{term} appear in the model.

### Remarks and examples

Remarks are presented under the following headings:

- Fractional polynomial regression
- Scaling
- Centering
- Examples

### Fractional polynomial regression

Regression models based on fractional polynomial functions of a continuous covariate are described by Royston and Altman (1994).

Fractional polynomials increase the flexibility afforded by the family of conventional polynomial models. Although polynomials are popular in data analysis, linear and quadratic functions are limited in their range of curve shapes, whereas cubic and higher-order curves often produce undesirable artifacts such as edge effects and waves.

Fractional polynomials differ from regular polynomials in that 1) they allow logarithms, 2) they allow noninteger powers, and 3) they allow powers to be repeated.

We will write a fractional polynomial in $x$ as

$$x^{(P_1 \ P_2 ... \ P_m)} \times \beta$$
We will write $x^{(p)}$ to mean a regular power except that $x^{(0)}$ is to be interpreted as meaning $\ln(x)$ rather than $x^{(0)} = 1$.

Then if there are no repeated powers in $(p_1, p_2, \ldots, p_m)$,

$$x^{(p_1, p_2, \ldots, p_m)\prime} \beta = \beta_0 + \beta_1 x^{(p_1)} + \beta_2 x^{(p_2)} + \cdots + \beta_m x^{(p_m)}$$

Powers are allowed to repeat in fractional polynomials. Each time a power repeats, it is multiplied by another $\ln(x)$. As an extreme case, consider the fractional polynomial with all-repeated powers, say, $m$ of them,

$$x^{(p, p, \ldots, p)\prime} \beta = \beta_0 + \beta_1 x^{(p)} + \beta_2 x^{(p)} \ln(x) + \cdots + \beta_m x^{(p)} \{\ln(x)\}^{m-1}$$

Thus the fractional polynomial $x^{(0, 0, 2)\prime} \beta$ would be

$$x^{(0, 0, 2)\prime} \beta = \beta_0 + \beta_1 x^{(0)} + \beta_2 x^{(0)} \ln(x) + \beta_3 x^{(2)}$$

$$= \beta_0 + \beta_1 \ln(x) + \beta_2 \{\ln(x)\}^2 + \beta_3 x^2$$

With this definition, we can obtain a much wider range of shapes than can be obtained with regular polynomials. The following graphs appeared in Royston and Sauerbrei (2008, sec. 4.5). The first graph shows the shapes of differing fractional polynomials.
The second graph shows some of the curve shapes available with different $\beta$s for the degree-2 fractional polynomial, $x^{(-2,2)}$.

In modeling a fractional polynomial, Royston and Sauerbrei (2008) recommend choosing powers from among \{-2, -1, -0.5, 0, 0.5, 1, 2, 3\}. By default, \texttt{fp} chooses powers from this set, but other powers can be explicitly specified in the \texttt{powers()} option.

\texttt{fp <term>: est\_cmd} fits models with the terms of the best-fitting fractional polynomial substituted for \texttt{<term>} wherever it appears in \texttt{est\_cmd}. We will demonstrate with \texttt{auto.dta}, which contains repair records and other information about a variety of vehicles in 1978.

We use \texttt{fp} to find the best fractional polynomial in automobile weight (lbs.) (\texttt{weight}) for the linear regression of miles per gallon (\texttt{mpg}) on \texttt{weight} and an indicator of whether the vehicle is foreign (\texttt{foreign}).

By default, \texttt{fp} will fit degree-2 fractional polynomial (FP2) models and choose the fractional powers from the set \{-2, -1, -0.5, 0, 0.5, 1, 2, 3\}. Because car weight is measured in pounds and will have a cubic transformation applied to it, we shrink it to a smaller scale before estimation by dividing by 1,000.

We modify the existing \texttt{weight} variable for conciseness and to facilitate the comparison of tables. When applying a data transformation in practice, rather than modifying the existing variables, you should create new variables that hold the transformed values.

fp begins by showing the model-comparison table. This table shows the best models of each examined degree, obtained by searching through all possible power combinations. The fractional powers of the models are shown in the Powers column. A separate row is provided for the linear fractional polynomial because it is often the default used when including a predictor in the model. The null model does not include any fractional polynomial terms for weight. The df column shows the count of the additional parameters used in each model beyond the quantity of parameters used in the null model. The model deviance, which we define as twice the negative log likelihood, is given in the Deviance column. The difference of the model deviance from the deviance of the model with the lowest deviance is given in the Dev. dif. column.

The p-value for the partial F test comparing the models and the lowest deviance model is given in the P(*) column. An estimate of the residual standard error is given in the Res. Sd. column. Under linear regression, a partial F test is used in the model-comparison table. In other settings, a likelihood-ratio test is performed. Then a $\chi^2$ statistic is reported.

Under robust variance estimation and some other cases (see [R] lrtest), the likelihood-ratio test cannot be performed. When the likelihood-ratio test cannot be performed on the model specified in est_cmd, fp still reports the model-comparison table, but the comparison tests are not performed.

fp reports the “best” model as the model with the lowest deviance; however, users may choose a more efficient model based on the comparison table. They may choose the lowest degree model that the partial F test (or likelihood-ratio test) fails to reject in favor of the lowest deviance model.

After the comparison table, the results of the estimation command for the lowest deviance model are shown. Here the best model has terms weight($-2,-2$). However, based on the model-comparison
table, we can reject the model without weight and the linear model at the 0.1 significance level. We fail to reject the \( m = 1 \) model at any reasonable level. We will choose the FP1 model, which includes weight\(^{-0.5}\).

We use \texttt{fp} again to estimate the parameters for this model. We use the \texttt{fp()} option to specify what powers we want to use; this option specifies that we do not want to perform a search for the best powers. We also specify the \texttt{replace} option to overwrite the previously created fractional polynomial power variables.

\begin{verbatim}
  . fp <weight>, fp(-.5) replace: regress mpg <weight> foreign
  -> regress mpg weight_1 foreign

  Source | SS df MS Number of obs = 74
  -------+--------------------------------------------------
  Model   | 1689.20865 2 844.604325 Prob > F = 0.0000
  Residual | 754.25081 71 10.6232508 R-squared = 0.6913
  Total   | 2443.45946 73 33.4720474 Root MSE = 3.2593

\end{verbatim}

### Scaling

Fractional polynomials are only defined for positive \texttt{term} variables. By default, \texttt{fp} will assume that the variable \( x \) is positive and attempt to compute fractional powers of \( x \). If the positive value assumption is incorrect, an error will be reported and estimation will not be performed.

If the values of the variable are too large or too small, the reported results of \texttt{fp} may be difficult to interpret. By default, cubic powers and squared reciprocal powers will be considered in the search for the best fractional polynomial in \texttt{term}.

We can scale the variable \( x \) to 1) make it positive and 2) ensure its magnitude is not too large or too small.

Suppose you have data on hospital patients with \texttt{age} as a fractional polynomial variable of interest. \texttt{age} is required to be greater than or equal to 20, so you might generate an \texttt{age5} variable by typing
. generate age5 = (age-19)/5

A unit change in \texttt{age5} is equivalent to a five-year change in age, and the minimum value of \texttt{age5} is 1/5 instead of 20.

In the automobile example of \textit{Fractional polynomial regression}, our \texttt{term} variable was automobile weight (lbs.). Cars weigh in the thousands of pounds, so cubing their weight figures results in large numbers. We prevented this from being a problem by shrinking the weight by 1,000; that is, we typed

. replace weight = weight/1000

Calendar year is another type of variable that can have a problematically large magnitude. We can shrink this by dividing by 10, making a unit change correspond to a decade.

. generate decade = calendar_year/10

You may also have a variable that measures deviation from zero. Perhaps \(x\) has already been demeaned and is symmetrically about zero. The fractional polynomial in \(x\) will be undefined for half of its domain. We can shift the location of \(x\), making it positive by subtracting its minimum and adding a small number to it. Suppose \(x\) ranges from \(-4\) to 4; we could use

. generate newx = x+5

Rescaling ourselves provides easily communicated results. We can tell exactly how the scaling was performed and how it should be performed in similar applications.

Alternatively, \texttt{fp} can scale the fractional polynomial variable so that its values are positive and the magnitude of the values are not too large. This can be done automatically or by directly specifying the scaling values.

Scaling can be automatically performed with \texttt{fp} by specifying the \texttt{scale} option. If \texttt{term} has nonpositive values, the minimum value of \texttt{term} is subtracted from each observation of \texttt{term}. In this case, the counting interval, the minimum distance between the sorted values of \texttt{term}, is also added to each observation of \texttt{term}.

After adjusting the location of \texttt{term} so that its minimum value is positive, creating \texttt{term*}, automatic scaling will divide each observation of \texttt{term} by a power of ten. The exponent of this scaling factor is given by

\[
p = \log_{10}\{\max(\texttt{term}*) - \min(\texttt{term}*)\}
\]

\[
p^* = \text{sign}(p)\text{floor}(|p|)
\]

Rather than letting \texttt{fp} automatically choose the scaling of \texttt{term}, you may specify adjustment and scale factors \(a\) and \(b\) by using the \texttt{scale}(\(a\ b\)) option. Fractional powers are then calculated using the \((\texttt{term}+a)/b\) values.

When \texttt{scale} or \texttt{scale}(\(a\ b\)) is specified, values in the variable \texttt{term} are not modified; \texttt{fp} merely remembers to scale the values whenever powers are calculated.

In addition to \texttt{fp}, both \texttt{scale} and \texttt{scale}(\(a\ b\)) may be used with \texttt{fp generate}.

You will probably not use \texttt{scale}(\(a\ b\)) with \texttt{fp} for values of \(a\) and \(b\) that you create yourself, although you could. As we demonstrated earlier, it is usually easier just to \texttt{generate} a scaled variable.

\texttt{scale}(\(a\ b\)) is useful when you previously fit a model using \texttt{scale} in one dataset and now want to create the fractional polynomials in another. In the first dataset, \texttt{fp} with \texttt{scale} added \texttt{notes} to the dataset concerning the values of \(a\) and \(b\). You can see them by typing

. notes
You can then use `fp generate`, `scale(a b)` in the second dataset.

When you apply the scaling rules of a previously fit model to new data with the `scale(a b)` option, it is possible that the scaled term may have nonpositive values. `fp` will be unable to calculate the fractional powers of the term in this case and will issue an error.

The options `zero` and `catzero` cause `fp` and `fp generate` to output zero values for each fractional polynomial variable when the input (scaled) fractional polynomial variable is nonpositive. Specifying `catzero` causes a dummy variable indicating nonpositive values of the (scaled) fractional polynomial variable to be included in the model. A detailed example of the use of `catzero` and `zero` is shown in example 3 below.

Using the scaling options, we can fit our previous model again using the `auto.dta`. We specify `scale(0 1000)` so that `fp` will shrink the magnitude of `weight` in estimating the regression. This is done for demonstration purposes because our scaling rule is simple. As mentioned before, in practice, you would probably only use `scale(a b)` when applying the scaling rules from a previous analysis. Allowing `fp` to scale does have the advantage of not altering the original variable, `weight`.

```stata
use https://www.stata-press.com/data/r16/auto, clear
(1978 Automobile Data)
.fp <weight>, fp(-.5) scale(0 1000): regress mpg <weight> foreign
 -> regress mpg weight_1 foreign
```

The scaling is clearly indicated in the variable notes for the generated variable `weight_1`.

The intercept of a centered fractional polynomial can be interpreted as the effect at zero for all the covariates. When we center the fractional polynomial terms using `c`, the intercept is now interpreted as the effect at `term = c` and zero values for the other covariates.
Suppose we wanted to center the fractional polynomial of $x$ with powers $(0, 0, 2)$ at $x = c$.

\[
\left( x^{(0,0,2)} - c^{(0,0,2)} \right) \beta \\
= \beta_0 + \beta_1 \left( x^{(0)} - c^{(0)} \right) + \beta_2 \left\{ x^{(0)} \ln(x) - c^{(0)} \ln(c) \right\} + \beta_3 \left( x^{(2)} - c^{(2)} \right) \\
= \beta_0 + \beta_1 \{\ln(x) - \ln(c)\} + \beta_2 \left[ \{\ln(x)\}^2 - \{\ln(c)\}^2 \right] + \beta_3 \left( x^2 - c^2 \right)
\]

When center is specified, fp centers based on the sample mean of (scaled) term. A previously chosen value for centering, $c$, may also be specified in center($c$). This would be done when applying the results of a previous model fitting to a new dataset.

The center and center($c$) options may be used in fp or fp generate.

Returning to the model of mileage per gallon based on automobile weight and foreign origin, we refit the model with the fractional polynomial of weight centered at its scaled mean.

```
. use https://www.stata-press.com/data/r16/auto, clear
(1978 Automobile Data)
. fp <weight>, fp(-.5) scale(0 1000) center: regress mpg <weight> foreign
   -> regress mpg weight_1 foreign

Note that the coefficients for weight_1 and foreign do not change. Only the intercept _cons changes. It can be interpreted as the estimated average miles per gallon of an American-made car of average weight.
Examples

Example 1: Linear regression

Consider the serum immunoglobulin G (IgG) dataset from Isaacs et al. (1983), which consists of 298 independent observations in young children. The dependent variable sqrtigg is the square root of the IgG concentration, and the independent variable age is the age of each child. (Preliminary Box–Cox analysis shows that a square root transformation removes the skewness in IgG.)

The aim is to find a model that accurately predicts the mean of sqrtigg given age. We use fp to find the best FP2 model (the default option). We specify center for automatic centering. The age of each child is small in magnitude and positive, so we do not use the scaling options of fp or scale ourselves.

```
use https://www.stata-press.com/data/r16/igg, clear
(Immunoglobulin in children)
.fp <age>, scale center: regress sqrtigg <age>
(fitting 44 models)
(....10%....20%....30%....40%....50%....60%....70%....80%....90%....100%)
```

The new variables created by fp contain the best-fitting fractional polynomial powers of age, as centered by fp. For example, age_1 is centered by subtracting the mean of age raised to the power $-2$.

The variables created by fp and fp generate are centered or scaled as specified by the user, which is reflected in the estimated regression coefficients and intercept. Centering does have its advantages (see Centering earlier in this entry). By default, fp will not perform scaling or centering. For a more detailed discussion, see Royston and Sauerbrei (2008, sec. 4.11).

The fitted curve has an asymmetric S shape. The best model has powers ($-2, 2$) and deviance 319.448. We reject lesser degree models: the null, linear, and natural log power models at the 0.05 level. As many as 44 models have been fit in the search for the best powers. Now let’s look at models of degree $\leq 4$. The highest allowed degree is specified in dimension(). We overwrite the previously generated fractional polynomial power variables by including replace.

It appears that the FP4 model is not significantly different from the other fractional polynomial models (at the 0.05 level).

Let’s compare the curve shape from the $m = 2$ model with that from a conventional quartic polynomial whose fit turns out to be significantly better than a cubic (not shown). We use the ability of fp both to generate the required powers of age, namely, ($1, 2, 3, 4$) for the quartic and ($-2, 2$) for the second-degree fractional polynomial, and to fit the model. The fp() option is used to specify the powers. We use predict to obtain the fitted values of each regression. We fit both models with fp and graph the resulting curves with twoway scatter.

The quartic curve has an unsatisfactory wavy appearance that is implausible for the known behavior of IgG, the serum level of which increases throughout early life. The fractional polynomial curve (FP2) increases monotonically and is therefore biologically the more plausible curve. The two models have approximately the same deviance.

Example 2: Cox regression

Data from Smith et al. (1992) contain times to complete healing of leg ulcers in a randomized, controlled clinical trial of two treatments in 192 elderly patients. Several covariates were available, of which an important one is \texttt{mthson}, the number of months since the recorded onset of the ulcer. This time is recorded in whole months, not fractions of a month; therefore, some zero values are recorded.

Because the response variable is time to an event of interest and some (in fact, about one-half) of the times are censored, using Cox regression to analyze the data is appropriate. We consider fractional polynomials in \texttt{mthson}, adjusting for four other covariates: \texttt{age}; \texttt{ulcarea}, the area of tissue initially affected by the ulcer; \texttt{deepppg}, a binary variable indicating the presence or absence of deep vein involvement; and \texttt{treat}, a binary variable indicating treatment type.

We fit fractional polynomials of degrees 1 and 2 with \texttt{fp}. We specify \texttt{scale} to perform automatic scaling on \texttt{mthson}. This makes it positive and ensures that its magnitude is not too large. (See \texttt{Scaling} for more details.) The display option \texttt{nohr} is specified before the colon so that the coefficients and not the hazard ratios are displayed.

The \texttt{center} option is specified to obtain automatic centering. \texttt{age} and \texttt{ulcarea} are also demeaned by using \texttt{summarize} and then subtracting the returned result \texttt{r(mean)}.

In Cox regression, there is no constant term, so we cannot see the effects of centering in the table of regression estimates. The effects would be present if we were to graph the baseline hazard or survival function because these functions are defined with all predictors set equal to 0.

In these graphs, we will see the estimated baseline hazard or survival function under no deep vein involvement or treatment and under mean age, ulcer area, and number of months since the recorded onset of the ulcer.

The best-fitting fractional polynomial of degree 2 has powers (0.5, 0.5) and deviance 736.709. However, this model does not fit significantly better than the fractional polynomial of degree 1 (at the 0.05 level), which has power −0.5 and deviance 738.969. We prefer the model with \( m = 1 \).
The hazard for healing is much higher for patients whose ulcer is of recent onset than for those who have had an ulcer for many months.

A more appropriate analysis of this dataset, if one wanted to model all the predictors, possibly with fractional polynomial functions, would be to use mfp; see [R] mfp.

Example 3: Logistic regression

The zero option permits fitting a fractional polynomial model to the positive values of a covariate, taking nonpositive values as zero. An application is the assessment of the effect of cigarette smoking as a risk factor. Whitehall 1 is an epidemiological study, which was examined in Royston and Sauerbrei (2008), of 18,403 male British Civil Servants employed in London. We examine the data collected in Whitehall 1 and use logistic regression to model the odds of death based on a fractional polynomial in the number of cigarettes smoked.

Non-smokers may be qualitatively different from smokers, so the effect of smoking (regarded as a continuous variable) may not be continuous between zero cigarettes and one cigarette. To allow for this possibility, we model the risk as a constant for the non-smokers and as a fractional polynomial function of the number of cigarettes for the smokers, adjusted for age.

The dependent variable all10 is an indicator of whether the individual passed away in the 10 years under study. cigs is the number of cigarettes consumed per day. After loading the data, we demean age and create a dummy variable, nonsmoker. We then use fp to fit the model.

Omission of the zero option would cause fp to halt with an error message because nonpositive covariate values (for example, values of cigs) are invalid unless the scale option is specified.

A closely related approach involves the catzero option. Here we no longer need to have nonsmoker in the model, because fp creates its own dummy variable cigs_0 to indicate whether the individual does not smoke on that day.

| age    | .1194976 | .0045818 | 26.08 | 0.000 | .1105174 | .1284778 |
| _cons  | -3.003767 | .1514909 | -19.83 | 0.000 | -3.300683 | -2.70685 |

The high $p$-value for cigs_0 in the output indicates that we cannot reject that there is no extra effect at zero for nonsmokers.
Stored results

In addition to the results that `est_cmd` stores, `fp` stores the following in `e()`:

Scalars
- `e(fp_dimension)` degree of fractional polynomial
- `e(fp_center_mean)` value used for centering or .
- `e(fp_scale_a)` value used for scaling or .
- `e(fp_scale_b)` value used for scaling or .
- `e(fp_compare_df2)` denominator degree of freedom in $F$ test

Macros
- `e(fp_cmd)` `fp, search();` or `fp, powers();`
- `e(fp_cmdline)` full `fp` command as typed
- `e(fp_variable)` fractional polynomial variable
- `e(fp_terms)` generated `fp` variables
- `e(fp_gen_cmdline)` `fp generate` command to re-create `e(fp_terms)` variables
- `e(fp_catzero)` catzero, if specified
- `e(fp_zero)` zero, if specified
- `e(fp_compare_type)` F or chi2

Matrices
- `e(fp_fp)` powers used in fractional polynomial
- `e(fp_compare)` results of model comparisons
- `e(fp_compare_stat)` $F$ test statistics
- `e(fp_compare_df1)` numerator degree of $F$ test
- `e(fp_compare_fp)` powers of comparison models
- `e(fp_compare_length)` encoded string for display of row titles
- `e(fp_powers)` powers that are searched

`fp generate` stores the following in `r()`:

Scalars
- `r(fp_center_mean)` value used for centering or .
- `r(fp_scale_a)` value used for scaling or .
- `r(fp_scale_b)` value used for scaling or .

Macros
- `r(fp_cmdline)` full `fp generate` command as typed
- `r(fp_variable)` fractional polynomial variable
- `r(fp_terms)` generated `fp` variables
- `r(fp_catzero)` catzero, if specified
- `r(fp_zero)` zero, if specified

Matrices
- `r(fp_fp)` powers used in fractional polynomial

Methods and formulas

The general definition of a fractional polynomial, accommodating possible repeated powers, may be written for functions $H_1(x), \ldots, H_m(x)$ of $x > 0$ as

$$\beta_0 + \sum_{j=1}^{m} \beta_j H_j(x)$$

where $H_1(x) = x^{(p_1)}$ and for $j = 2, \ldots, m$,

$$H_j(x) = \begin{cases} x^{(p_j)} & \text{if } p_j \neq p_{j-1} \\ H_{j-1}(x) \ln(x) & \text{if } p_j = p_{j-1} \end{cases}$$
For example, a fractional polynomial of degree 3 with powers \( (1, 3, 3) \) has \( H_1(x) = x \), \( H_2(x) = x^3 \), and \( H_3(x) = x^3 \ln(x) \) and equals \( \beta_0 + \beta_1 x + \beta_2 x^3 + \beta_3 x^3 \ln(x) \).

We can express a fractional polynomial in vector notation by using \( \mathbf{H}(x) = [H_1(x), \ldots, H_d(x)]' \). We define \( x^{(p_1, p_2, \ldots, p_m)} = [\mathbf{H}(x)', 1]' \). Under this notation, we can write

\[
x^{(1, 3, 3)'} \beta = \beta_0 + \beta_1 x + \beta_2 x^3 + \beta_3 x^3 \ln(x)
\]

The fractional polynomial may be centered so that the intercept can be more easily interpreted. When centering the fractional polynomial of \( x \) at \( c \), we subtract \( c \) from \( x^{(p_1, p_2, \ldots, p_m)} \), where \( c^{(p_1, p_2, \ldots, p_d)} = [\mathbf{H}(x)', 0]' \). The centered fractional polynomial is

\[
\left( x^{(p_1, \ldots, p_d)} - c^{(p_1, \ldots, p_d)} \right)' \beta
\]

The definition may be extended to allow \( x \leq 0 \) values. For these values, the fractional polynomial is equal to the intercept \( \beta_0 \) or equal to a zero-offset term \( \alpha_0 \) plus the intercept \( \beta_0 \).

A fractional polynomial model of degree \( m \) is taken to have \( 2m + 1 \) degrees of freedom (df): one for \( \beta_0 \) and one for each \( \beta_j \) and its associated power. Because the powers in a fractional polynomial are chosen from a finite set rather than from the entire real line, the df defined in this way are approximate.

The deviance \( D \) of a model is defined as \(-2 \) times its maximized log likelihood. For normal-errors models, we use the formula

\[
D = n \left( 1 - \bar{l} + \ln \frac{2\pi \text{RSS}}{n} \right)
\]

where \( n \) is the sample size, \( \bar{l} \) is the mean of the lognormalized weights (\( \bar{l} = 0 \) if the weights are all equal), and RSS is the residual sum of squares as fit by \texttt{regress}.

\texttt{fp} reports a table comparing fractional polynomial models of degree \( k < m \) with the degree \( m \) fractional polynomial model, which will have the lowest deviance.

The \( p \)-values reported by \texttt{fp} are calculated differently for normal and nonnormal regressions. Let \( D_k \) and \( D_m \) be the deviances of the models with degrees \( k \) and \( m \), respectively. For normal-errors models, a variance ratio \( F \) is calculated as

\[
F = \frac{n_2}{n_1} \left\{ \exp \left( \frac{D_k - D_m}{n} \right) - 1 \right\}
\]

where \( n_1 \) is the numerator df, the quantity of the additional parameters that the degree \( m \) model has over the degree \( k \) model. \( n_2 \) is the denominator df and equals the residual degrees of freedom of the degree \( m \) model, minus the number of powers estimated, \( m \). The \( p \)-value is obtained by referring \( F \) to an \( F \) distribution on \( (n_1, n_2) \) df.

For nonnormal models, the \( p \)-value is obtained by referring \( D_k - D_m \) to a \( \chi^2 \) distribution on \( 2m - 2k \) df. These \( p \)-values for comparing models are approximate and are typically somewhat conservative (Royston and Altman 1994).
Acknowledgment

We thank Patrick Royston of the MRC Clinical Trials Unit, London, and coauthor of the Stata Press book *Flexible Parametric Survival Analysis Using Stata: Beyond the Cox Model* for writing `fracpoly` and `fracgen`, the commands on which `fp` and `fp generate` are based. We also thank Professor Royston for his advice on and review of the new `fp` commands.

**fp plot and fp predict**

**Description for fp plot and fp predict**

`fp plot` produces a component-plus-residual plot. The fractional polynomial comprises the component, and the residual is specified by the user in `residuals()`. The component-plus-residuals are plotted against the fractional polynomial variable. If you only want to plot the component fit, without residuals, you would specify `residuals(none)`.

`fp predict` generates the fractional polynomial or the standard error of the fractional polynomial. The fractional polynomial prediction is equivalent to the fitted values prediction given by `predict, xb`, with the covariates other than the fractional polynomial variable set to zero. The standard error may be quite large if the range of the other covariates is far from zero. In this situation, the covariates would be centered and their range would include, or come close to including, zero.

These postestimation commands can be used only when the fractional polynomial variables do not interact with other variables in the specification of `est_cmd`. See [U] 11.4.3 Factor variables for more information about interactions.

**Options for fp plot**

- **residuals(res_option)** specifies what type of residuals to plot in the component-plus-residual plot. *res_option* is the same option that would be specified to predict after est_cmd. Residuals can be omitted from the plot by specifying residuals(none). residuals() is required.

- **equation(eqno)** is relevant only when you have previously fit a multiple-equation model in est_cmd. It specifies the equation to which you are referring.

  - equation(#1) would mean that the calculation is to be made for the first equation, equation(#2) would mean the second, and so on. You could also refer to the equations by their names: equation(income) would refer to the equation name income, and equation(hours) would refer to the equation named hours.

  - If you do not specify equation(), the results are the same as if you specified equation(#1). level(#); see [R] Estimation options.
**fp postestimation** — Postestimation tools for fp

Plot

`plotopts(scatter_options)` affects the rendition of the component-plus-residual scatter points; see [G-2] `graph twoway scatter`.

Fitted line

`lineopts(cline_options)` affects the rendition of the fitted line; see [G-3] `cline_options`.

CI plot

`ciopts(area_options)` affects the rendition of the confidence bands; see [G-3] `area_options`.

Add plots

`addplot(plot)` provides a way to add other plots to the generated graph. See [G-3] `addplot_option`.

Y axis, X axis, Titles, Legend, Overall

`twoway_options` are any of the options documented in [G-3] `twoway_options`, excluding `by()`. These include options for titling the graph (see [G-3] `title_options`) and for saving the graph to disk (see [G-3] `saving_option`).

**Options for fp predict**

Main

`fp` calculates the fractional polynomial, the linear prediction with other variables set to zero. This is the default.

`stdp` calculates the standard error of the fractional polynomial.

`equation(eqno)` is relevant only when you have previously fit a multiple-equation model in `est_cmd`.

It specifies the equation to which you are referring.

`equation(#1)` would mean that the calculation is to be made for the first equation, `equation(#2)` would mean the second, and so on. You could also refer to the equations by their names: `equation(income)` would refer to the equation name `income`, and `equation(hours)` would refer to the equation named `hours`.

If you do not specify `equation()`, the results are the same as if you specified `equation(#1)`.

**Remarks and examples**

After a model is fit using `fp`, the estimated fractional polynomial may be of interest. This is the linear combination of the fractional polynomial terms and the constant intercept using the model coefficients estimated by `fp`. It is equivalent to the fitted values prediction given by `predict,xb`, with the covariates and the fractional polynomial variable set to zero. When these other covariates have been centered, the prediction is made at the centering values of the covariates.

A component-plus-residual plot is generated by `fp plot`. The fractional polynomial comprises the component, and the residual is specified by the user in `residuals()`. The `residuals()` option takes the same argument that would be supplied to `predict` after `est_cmd` to obtain the desired type of residuals. If you only want to plot the component fit, without residuals, you would specify `residuals(none)`. 
**fp predict** generates the fractional polynomial. If the `stdp` option is specified, the standard error of the fractional polynomial is generated instead. This standard error may be quite large if the range of the other covariates is far from zero. In this situation, the covariates would be centered and their range would include, or come close to including, zero.

These postestimation commands can be used only when the fractional polynomial terms do not interact with other variables in the specification of `est_cmd`. See [U] 11.4.3 Factor variables for more information about interactions.

### Examples

#### Example 1: fp plot after linear regression

In example 1 of [R] _fp_, we modeled the mean of the square root of a child’s serum immunoglobulin G (IgG) level as a fractional polynomial function of the child’s age. An FP2 model with powers \((-2, 2)\) is chosen.

We load the data and then fit the model with _fp_. Then we use _fp plot_ to draw the component-plus-residual plot. A 95% confidence interval is produced for the fractional polynomial in age (the component). The residuals prediction option for _regress_ is specified in the `residuals()` option in _fp plot_ so that the residuals are rendered.

```
. use https://www.stata-press.com/data/r16/igg
(Immunoglobulin in children)
. fp <age>, scale center: regress sqrtigg <age>
(output omitted)
. fp plot, residuals(residuals)
```

#### Example 2: fp plot after Cox regression

In example 2 of [R] _fp_, we modeled the time to complete healing of leg ulcers for 192 elderly patients using a Cox regression. A one-degree fractional polynomial in `mthson`, the number of months since the onset of the ulcer, is used as a predictor in the regression. The power \(-0.5\) is used for `mthson`. Other covariates are age (`age`), ulcer area (`ulcarea`), treatment type, and a binary indicator of deep vein involvement (`deepppg`).
We load the data and then demean ulcer area and age. Then we fit the model with `fp` and draw the component-plus-residual plot with `fp plot`. `mgale` is specified in the `residuals()` option to obtain martingale residuals. See [ST] `stcox postestimation` for more details.

```
. use https://www.stata-press.com/data/r16/legulcer1, clear
(Leg ulcer clinical trial)
. quietly stset ttevent, failure(cens)
. quietly summarize age
. replace age = age - r(mean)
    age was byte now float
       (192 real changes made)
. quietly summarize ulcarea
. replace ulcarea = ulcarea - r(mean)
    ulcarea was int now float
       (192 real changes made)
. fp <mthson>, replace center scale nohr fp(-.5): stcox <mthson> age ulcarea
deepppg treat
(output omitted)
. fp plot, residuals(mgale)
```

### Example 3: fp plot and fp predict after logistic regression

In example 3 of [R] `fp`, we used logistic regression to model the odds of death for male civil servants in Britain conditional on cigarette consumption. The dependent variable `all10` is an indicator of whether the individual passed away in the 10 years under study.

Non-smokers may be qualitatively different from smokers, so the effect of smoking (regarded as a continuous variable) may not be continuous between zero cigarettes and one cigarette. To allow for this possibility, we model the risk as constant intercept for the non-smokers and as a fractional polynomial function of the number of cigarettes for the smokers, `cigs`, adjusted for age. An FP1 model with power 0 is chosen.

We load the data and demean age. Then we fit the model using `fp` and graph the fit of the model and 95% confidence interval using `fp plot`. Only the component fit is graphed by specifying `residuals(none)`.
. use https://www.stata-press.com/data/r16/smoking, clear
(Smoking and mortality data)
. quietly summarize age
variable age was byte now float
(17,260 real changes made)
. fp <cigs>, catzero replace fp(0): logit all10 <cigs> age
\[\text{\textbf{logit all10 cigs\_0 cigs\_1 age}}\]
Logistic regression
Number of obs = 17,260
LR chi2(3) = 1027.13
Prob > chi2 = 0.0000
Log likelihood = -4973.3016 Pseudo R2 = 0.0936

| all10 | Coef. Std. Err. z P>|z| [95% Conf. Interval] |
|-------|-----------------|-----------------|-----------------|-----------------|
| cigs\_0 | 0.1883732 | .1553093 | 1.21 | 0.225 | -0.1160274 | .4927738 |
| cigs\_1 | 0.3469842 | .0543552 | 6.38 | 0.000 | .2404499 | .4535185 |
| age | 0.1194976 | .0045818 | 26.08 | 0.000 | .1105174 | .1284778 |
| _cons | -3.003767 | .1514909 | -19.83 | 0.000 | -3.300683 | -2.70685 |

. fp plot, residuals(none)

We see a small spike at zero for cigs because of the effect of cigs\_0 on the fractional polynomial; however, the high p-value for cigs\_0 in the model output indicates that we cannot reject that there is no extra effect at zero for nonsmokers.

We can also use fp predict to predict the fractional polynomial for nonsmokers and the mean of age. This is the value at the spike. We store the result in fp0. We see it is equivalent to the sum of the constant intercept estimate and the estimate of the cigs\_0 coefficient.

. fp predict fp0 if cigs == 0
7,157 missing values generated
. summarize fp0

Methods and formulas

Let the data consist of triplets \((y_i, x_i, z_i)\), \(i = 1, \ldots, n\), where \(z_i\) is the vector of covariates for the \(i\)th observation and \(x_i\) is the fractional polynomial variable.

\(\text{fp predict}\) calculates the fractional polynomial at the centering value \(x_0\), \(\hat{\eta}_i = (x_i(p_1, \ldots, p_d) - x_0(p_1, \ldots, p_m))' \hat{\beta}\). This is equivalent to the linear predictor of the model at \(z_i = 0\). The standard error is calculated from the variance–covariance matrix of \(\hat{\beta}\), ignoring estimation of the powers. When \(x_i \leq 0\), \(H(x_i)\), and thus \(x_i(p_1, \ldots, p_m)\), is either undefined or zero. A zero offset term, \(\alpha_0\), may be added to \(\hat{\eta}_i\) for these nonpositive \(x_i\) values.

The values \(\hat{\eta}_i\) represent the behavior of the fractional polynomial model for \(x\) at fixed values \(z = 0\) of the (centered) covariates. The \(i\)th component-plus-residual is defined as \(\hat{\eta}_i + d_i\), where \(d_i\) is the residual for the \(i\)th observation. The definition of \(d_i\) will change according to the type of model used and the preference of the user. \(\text{fp plot}\) plots \(\hat{\eta}_i + d_i\) versus \(x_i\), overlaying \(\hat{\eta}_i\) and its confidence interval.

Acknowledgment

We thank Patrick Royston of the MRC Clinical Trials Unit, London, and coauthor of the Stata Press book *Flexible Parametric Survival Analysis Using Stata: Beyond the Cox Model* for writing \texttt{fracplot} and \texttt{fracpred}, the commands on which \texttt{fp plot} and \texttt{fp predict} are based. We also thank Professor Royston for his advice on and review of \texttt{fp plot} and \texttt{fp predict}.

fracreg — Fractional response regression

Description

fracreg fits a fractional response model for a dependent variable that is greater than or equal to 0 and less than or equal to 1. It uses a probit, logit, or heteroskedastic probit model for the conditional mean. These models are often used for outcomes such as rates, proportions, and fractional data.

Quick start

Fractional probit model for $y$ with values between 0 and 1 on continuous variable $x_1$

```
fracreg probit y x1
```

As above, but use logit distribution

```
fracreg logit y x1
```

Fractional probit model for $y$ on $x_1$ and use $x_2$ to model the variance of $y$

```
fracreg probit y x1, het(x2)
```

het() may be used only with fracreg probit to compute fractional heteroskedastic probit regression. indepvars may contain factor variables; see [U] 11.4.3 Factor variables.
depvar and indepvars may contain time-series operators; see [U] 11.4.4 Time-series varlists.
bayes, bootstrap, by, fp, jackknife, mi estimate, rolling, statsby, and svy are allowed; see [U] 11.1.10 Prefix commands. For more details, see [BAYES] bayes: fracreg.

vce(bootstrap) and vce(jackknife) are not allowed with the mi estimate prefix; see [MI] mi estimate.
Weights are not allowed with the bootstrap prefix; see [R] bootstrap.
vce(), nocoef, and weights are not allowed with the svy prefix; see [SVY] svy.

options

Model

noconstant, offset(varname), constraints(constraints); see [R] Estimation options.

het(varlist[, offset(varname_o)]) specifies the independent variables and, optionally, the offset variable in the variance function. het() may only be used with fracreg probit to compute fractional heteroskedastic probit regression.

offset(varname_o) specifies that selection offset varname_o be included in the model with the coefficient constrained to be 1.

SE/Robust

vce(vcetype) specifies the type of standard error reported, which includes types that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.

Reporting

level(#); see [R] Estimation options.

or reports the estimated coefficients transformed to odds ratios, that is, \( e^b \) rather than \( b \). Standard errors and confidence intervals are similarly transformed. This option affects how results are displayed, not how they are estimated. or may be specified at estimation or when replaying previously estimated results. This option may only be used with fracreg logit.

colsreport; see [R] Estimation options.

display_options: noci, nopvalues, nomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(#), fvwrapping, cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch; see [R] Estimation options.

Maximization

maximize_options: difficult, technique(algorithm_spec), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(init_specs); see [R] Maximize. These options are seldom used.
The following options are available with `fracreg` but are not shown in the dialog box:

- `nocoef` specifies that the coefficient table not be displayed. This option is sometimes used by programmers but is of no use interactively.
- `collinear`, `coeflegend`; see [R] Estimation options.

## Remarks and examples

Fractional response data may occur when the outcome of interest is measured as a fraction, for example, a patient’s oxygen saturation or Gini coefficient values. These data are also often observed when proportions are generated from aggregated binary outcomes. For example, rather than having data on whether individual students passed an exam, we might simply have data on the proportion of students in each school that passed.

These models are appropriate when you have a dependent variable that takes values between 0 and 1 and may also be equal to 0 or 1, denoted for conciseness with the notation \([0, 1]\). If the dependent variable takes only values between 0 and 1, `betareg` might be a valid alternative. `betareg` provides more flexibility in the distribution of the mean of the dependent variable but is misspecified if the dependent variable is equal to 0 or 1. See [R] `betareg` for more information.

These models have been applied to various topics. For example, Papke and Wooldridge (1996) studied the participation rates of employees in firms’ 401(k) retirement plans. Papke and Wooldridge (2008) also evaluated an education policy by studying the pass rates for an exam administered to fourth grade Michigan students over time.

The models fit by `fracreg` are quasilikelihood estimators like the generalized linear models described in [R] `glm`. Fractional regression is a model of the mean of the dependent variable \(y\) conditional on covariates \(x\), which we denote by \(\mu_x\). Because \(y\) is in \([0, 1]\), we must ensure that \(\mu_x\) is also in \([0, 1]\). We do this by using a probit, logit, or heteroskedastic probit model for \(\mu_x\).

The key insight from quasilikelihood estimation is that you do not need to know the true distribution of the entire model to obtain consistent parameter estimates. In fact, the only information that you need is the correct specification of the conditional mean.

This means that the true model does not need to be, for example, a probit. If the true model is a probit, then fitting a probit regression via maximum likelihood gives you consistent parameter estimates and asymptotically efficient standard errors.

By contrast, if the conditional mean of the model is the same as the conditional mean of a probit but the model is not a probit, the point estimates are consistent, but the standard errors are not asymptotically efficient. The standard errors are not efficient, because no assumptions about the distribution of the unobserved components in the model are made. Thus `fracreg` uses robust standard errors by default.

For further discussion on quasilikelihood estimation in the context of fractional regression, please see Papke and Wooldridge (1996) and Wooldridge (2010).
Example 1: Fractional probit model of rates

In this example, we look at the expected participation rate in 401(k) plans for a cross-section of firms. Participation rate (prate) is defined as the fraction of eligible employees in a firm that participate in a 401(k) plan. We use `summarize` to see the range of the participation rate.

```
use https://www.stata-press.com/data/r16/401k
```

The variable has values between 0 and 1 but also has at least 1 firm for which the participation rate is exactly 1.

As in Papke and Wooldridge (1996), we surmise that the expected participation rate depends on the matching rate of employee 401(k) contributions (mrate), the natural log of the total number of employees (ltotemp), the age of the plan (age), and whether the 401(k) plan is the only retirement plan offered by the employer (sole). We include ltotemp and age, along with their squares, using factor-variable notation; see [U] 11.4.3 Factor variables.

If we believe that the functional form of the expected participation rate is a cumulative normal density, we may use `fracreg probit`.

```
fracreg probit prate mrate c.ltotemp##c.ltotemp c.age##c.age i.sole
```

Like those obtained from `probit`, the parameters provide the sign of the marginal effect of the covariates on the outcome, but the magnitude is difficult to interpret. We can use `margins` to estimate conditional or population-averaged effects; see example 2. The standard errors are robust by default because the true data-generating process need not be a probit, even though we use the probit likelihood to obtain our parameter estimates.
Example 2: Changing the distribution of the conditional mean

Continuing with example 1, we may instead believe that the expected participation rate follows a fractional logistic response. In this case, we should use fractional logistic regression instead of fractional probit regression to obtain consistent estimates of the parameters of the conditional mean.

```
. fracreg logit prate mrate c.ltotemp##c.ltotemp c.age##c.age i.sole
Iteration 0: log pseudolikelihood = -1983.8372
Iteration 1: log pseudolikelihood = -1682.4496

</table>

Like those obtained from `logit`, the parameters provide the sign of the marginal effect of the covariates on the outcome, but the magnitude is again difficult to interpret. As with `fracreg probit` in example 1, we would use `margins` to obtain the marginal effects or other predictions of interest.

Example 3: Odds ratios from a fractional logit model

When the conditional mean of our outcome is interpretable as a probability, it is possible to adopt an odds-ratio interpretation of the results of a fractional logit model. In example 2, this is plausible because expected participation rates can be viewed as estimates of the probability of participation. We obtain the odds ratios by specifying the option `or`.
Among other things, we see that if the 401(k) is the only plan offered by the employer, then the odds of an employee participating increase by a factor of 1.12. We can also see that if the matching rate goes from 0 to 1:1 (exactly matching employee contributions) or from 1:1 to 2:1 (doubling employee contributions), then the odds of participating increase by 3.1.

The use of an odds-ratio interpretation is not appropriate if the conditional mean cannot be viewed as a probability. For example, if the fractional outcome were a Gini coefficient, we could not interpret the expected values of our outcomes as probabilities. The Gini coefficient is a measure of inequality between zero and one and cannot be interpreted as a probability. In this case, using the odds-ratio option would not be sensible.
Stored results

fracreg stores the following in e():

Scalars

- e(N): number of observations
- e(k): number of parameters
- e(k_eq): number of equations in e(b)
- e(k_eq_model): number of equations in overall model test
- e(k_dv): number of dependent variables
- e(df_m): model degrees of freedom
- e(r2_p): pseudo-$R$-squared
- e(ll): log likelihood
- e(ll0): log likelihood, constant-only model
- e(N_clust): number of clusters
- e(chi2): $\chi^2$ p-value for model test

- e(offset): offset
- e(chi2type): Wald; type of model $\chi^2$ test
- e(vce): vcetype specified in vce()
- e(vcetype): title used to label Std. Err.
- e(opt): type of optimization
- e(which): max or min; whether optimizer is to perform maximization or minimization
- e(ml_method): type of ml method
- e(user): name of likelihood-evaluator program
- e(technique): maximization technique
- e(properties): b V
- e(estat_cmd): program used to implement estat
- e(predict): program used to implement predict
- e(marginsnotok): predictions disallowed by margins
- e(asbalanced): factor variables fvset as asbalanced
- e(asobserved): factor variables fvset as asobserved

Matrices

- e(b): coefficient vector
- e(mns): vector of means of the independent variables
- e(Cns): constraints matrix
- e(llog): iteration log (up to 20 iterations)
- e(gradient): gradient vector
- e(V): variance–covariance matrix of the estimators
- e(V_modelbased): model-based variance

Functions

- e(sample): marks estimation sample
Methods and formulas

The log-likelihood function for fractional models is of the form

\[
\ln L = \sum_{j=1}^{N} w_j y_j \ln \left\{ G \left( x'_j \beta \right) \right\} + w_j (1 - y_j) \ln \left\{ 1 - G \left( x'_j \beta \right) \right\}
\]

where \( N \) is the sample size, \( y_j \) is the dependent variable, \( w_j \) denotes the optional weights, \( \ln L \) is maximized, as described in [R] Maximize, and \( G(\cdot) \) can be

<table>
<thead>
<tr>
<th>Model</th>
<th>Functional form for ( G \left( x'_j \beta \right) )</th>
</tr>
</thead>
<tbody>
<tr>
<td>probit</td>
<td>( \Phi \left( x'_j \beta \right) )</td>
</tr>
<tr>
<td>logit</td>
<td>( \exp(x'_j \beta) / {1 + \exp(x'_j \beta)} )</td>
</tr>
<tr>
<td>hetprobit</td>
<td>( \Phi \left{ x'_j \beta / \exp \left( z'_j \gamma \right) \right} )</td>
</tr>
</tbody>
</table>

where \( x_j \) are the covariates for individual \( j \), \( z_j \) are the covariates used to model the variance of the outcome for the heteroskedastic probit model, and \( \Phi \) is the standard normal cumulative density function.

* forecast and hausman are not appropriate with svy estimation results. forecast is also not appropriate with mi estimation results.
predict

Description for predict

`predict` creates a new variable containing predictions such as conditional means, linear predictions, standard errors, and equation-level scores.

Menu for predict

Statistics > Postestimation

Syntax for predict

```
predict [type] newvar [if] [in] [, statistic nooffset]
predict [type] stub*|newvar|newvarlist [if] [in], scores
```

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>cm</td>
<td>conditional mean; the default</td>
</tr>
<tr>
<td>xb</td>
<td>linear prediction</td>
</tr>
<tr>
<td>sigma</td>
<td>standard deviation of the error term (for <code>het()</code>)</td>
</tr>
<tr>
<td>stdp</td>
<td>standard error of the linear prediction</td>
</tr>
<tr>
<td>scores</td>
<td>equation-level score variables</td>
</tr>
</tbody>
</table>

Options for predict

- `cm`, the default, calculates the conditional mean of the outcome.
- `xb` calculates the linear prediction.
- `sigma` calculates the standard deviation of the error term. It is available only when `het()` is specified.
- `stdp` calculates the standard error of the linear prediction.
- `scores` calculates the equation-level score, $\partial \ln L / \partial (x_j \beta)$, in the case of `fracreg probit` and `fracreg logit`, and can also calculate $\partial \ln L / \partial (z_j \gamma)$ if the option `het()` is specified.
- `nooffset` is relevant only if you specified `offset(varname)`. It modifies the calculations made by `predict` so that they ignore the offset variable; the linear prediction is treated as $x_j b$ rather than as $x_j b + \text{offset}_j$.  

margins

Description for margins

margins estimates margins of response for conditional means and linear predictions.

Menu for margins

Statistics > Postestimation

Syntax for margins

```
margins [ marginlist ] , options
margins [ marginlist ] , predict(statistic ...) predict(statistic ...) [ options ]
```

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>

<td>not allowed with margins</td>
</tr>
<tr>
<td>scores</td>
<td>not allowed with margins</td>
</tr>
</tbody>
</table>

Statistics not allowed with margins are functions of stochastic quantities other than e(b).

For the full syntax, see [R] margins.

Remarks and examples

Remarks are presented under the following headings:

Obtaining predicted values
Performing hypothesis tests

Obtaining predicted values

Once you have fit a model using fracreg, you can obtain the conditional mean of the fractional response by using the predict command for both the estimation sample and other samples; see [U] 20 Estimation and postestimation commands and [R] predict.

When you use the fractional probit estimator, fracreg probit, with the option het(), there is an additional statistic available, sigma. With the sigma option, predict calculates the predicted standard deviation, $\sigma_j = \exp(z_j\gamma)$. 
Performing hypothesis tests

Example 1: Conditional means

In example 1 of [R] fracreg, we fit a fractional probit model to see how participation rate (prate) in 401(k) plans is affected by the matching rate of employer contributions (mrate). To obtain the predicted conditional means, we use predict and do not specify the default cm option.

```
. use https://www.stata-press.com/data/r16/401k
   (Firm-level data on 401k participation)
. fracreg probit prate mrate c.ltotemp##c.ltotemp c.age##c.age i.sole
Iteration 0: log pseudolikelihood = -1769.6832
Iteration 1: log pseudolikelihood = -1675.2763
Iteration 2: log pseudolikelihood = -1674.6234
Iteration 3: log pseudolikelihood = -1674.6232
Iteration 4: log pseudolikelihood = -1674.6232
Fractional probit regression
   Number of obs = 4,075
   Wald chi2(6) = 815.88
   Prob > chi2 = 0.0000
   Log pseudolikelihood = -1674.6232
   Pseudo R2 = 0.0632

   Coef.  Std. Err.      z    P>|z|     [95% Conf. Interval]
prate          .5859715   .0387616    15.12   0.000    .5100002    .6619429
   mrate         -.6102767   .0615052    -9.92   0.000   -.7308246   -.4897288

   c.age#c.age   -.000316   .0000843    -3.61   0.000   -.0004841   -.0001482
   sole          .0683196   .0272091     2.51   0.012     .0149908   .1216484
   only plan     .2599311   .2323929    14.03   0.000     .204429   .3154332
   _cons         3.25991   .2323929    14.03   0.000     2.804429   3.715392
```

We can then summarize these conditional mean estimates (cmean) over the population to get the population average conditional mean participation rate in our sample.

```
. predict mpart
   (option cm assumed)
. summarize mpart
   Variable Obs Mean Std. Dev. Min Max
  mpart   4075  .8405767  .0828094  .6251739  .9964518
```

The average of the conditional mean of participation rate in our sample is 84% with a range between 62.5% and 99.6%.
Example 2: Average marginal effects

In example 2 of [R] fracreg, we used the outcome variable and covariates of example 1 but instead of fitting a fractional probit regression, we fit a fractional logit. Using margins, we explore the average marginal effect of mrate on prate for both specifications.

Below we use margins after fracreg logit with the option post to post the average marginal effects as estimates. We then store our results with the name logit. We do the same with our probit estimates.

```
. use https://www.stata-press.com/data/r16/401k, clear
  (Firm-level data on 401k participation)
. fracreg logit prate mrate c.ltotemp##c.ltotemp c.age##c.age i.sole, or

   mrate         .1450106  .0094558    15.34     0.000     .1264776    .1635436
```

The marginal effects from fracreg logit suggest that a small change in the matching rate of employers can increase participation by more than 14%.
. quietly fracreg probit prate mrate c.ltotemp##c.ltotemp c.age##c.age i.sole
. margins, dydx(mrate) post

Average marginal effects
Model VCE : Robust
Expression : Conditional mean of prate, predict()
dy/dx w.r.t. : mrate

|            | dy/dx    | Std. Err. | z    | P>|z|  | [95% Conf. Interval] |
|------------|----------|-----------|------|------|---------------------|
| mrate      | 0.13355  | 0.0087385 | 15.28| 0.000| 0.1164233 0.1506776 |

. estimates store probit

For the probit model, a change in the matching rate increases participation by more than 13%.

Because we stored our margins results as estimates, we can now produce a table showing both the logit and probit results.

. estimates table logit probit, se

<table>
<thead>
<tr>
<th>Variable</th>
<th>logit</th>
<th>probit</th>
</tr>
</thead>
<tbody>
<tr>
<td>mrate</td>
<td>0.14501059</td>
<td>0.13355046</td>
</tr>
<tr>
<td></td>
<td>0.00945578</td>
<td>0.00873852</td>
</tr>
</tbody>
</table>

legend: b/se

As indicated by the standard errors in the table, both average marginal effects are significant. The difference between the two estimates is approximately one percentage point. This relatively small difference is consistent with the intuition that marginal effects obtained from probit and logit conditional means give us analogous results.
Example 3: Average marginal effects for different levels of participation

We can also use `margins` to find the expected participation rate for various levels of employer matching. Using our probit model, we obtain the following by typing

```
. quietly fracreg probit prate mrate c.ltotemp##c.ltotemp c.age##c.age i.sole
. margins, at(mrate=(0(.2)2))
```

```
Predictive margins Number of obs = 4,075
Model VCE : Robust
Expression : Conditional mean of prate, predict()
   1._at : mrate = 0
   2._at : mrate = .2
   3._at : mrate = .4
   4._at : mrate = .6
   5._at : mrate = .8
   6._at : mrate = 1
   7._at : mrate = 1.2
   8._at : mrate = 1.4
   9._at : mrate = 1.6
  10._at : mrate = 1.8
  11._at : mrate = 2
```

| Delta-method | Margin | Std. Err. | z    | P>|z| | [95% Conf. Interval] |
|--------------|--------|-----------|------|------|----------------------|
| 1._at        | 0.780858 | 0.0052738 | 148.06 | 0.000 | 0.7705216, 0.7911944 |

| 8._at        | 0.9416712 | 0.004694 | 200.61 | 0.000 | 0.9324711, 0.9508712 |
| 9._at        | 0.9537652 | 0.0046115 | 206.82 | 0.000 | 0.9447268, 0.9628035 |
| 10._at       | 0.9637608 | 0.004372 | 220.44 | 0.000 | 0.9551919, 0.9723298 |
| 11._at       | 0.9719159 | 0.0040207 | 241.73 | 0.000 | 0.9640355, 0.9797964 |

Going from no matching to equal matching changes the participation rate from 78% to 91%, and double matching moves participation all the way to 97.2%.
We can also see these results in a graph by using `marginsplot`.

```
marginsplot
```

[R] fracreg — Fractional response regression

[U] 20 Estimation and postestimation commands
**Description**

`frontier` fits stochastic production or cost frontier models; the default is a production frontier model. It provides estimators for the parameters of a linear model with a disturbance that is assumed to be a mixture of two components, which have a strictly nonnegative and symmetric distribution, respectively. `frontier` can fit models in which the nonnegative distribution component (a measurement of inefficiency) is assumed to be from a half-normal, exponential, or truncated-normal distribution. See Kumbhakar and Lovell (2000) for a detailed introduction to frontier analysis.

**Quick start**

Cobb–Douglas production frontier model of `lny1` as a function of `lnx1` and `lnx2`

```
frontier lny1 lnx1 lnx2
```

As above, but use exponential instead of half-normal distribution for the inefficiency term

```
frontier lny1 lnx1 lnx2, distribution(exponential)
```

Include `x3` as an explanatory variable in the idiosyncratic error variance function

```
frontier lny1 lnx1 lnx2, vhet(x3)
```

As above, and include `x4` as an explanatory variable in the technical inefficiency variance function

```
frontier lny1 lnx1 lnx2, vhet(x3) uhet(x4)
```

Conditional mean model with the mean modeled as a linear function of `x3`

```
frontier lny1 lnx1 lnx2, distribution(tnormal) cm(x3)
```

Cost frontier model of `y2` as a function of `lnx1` and `lnx2`

```
frontier y2 lnx1 lnx2, distribution(tnormal) cost
```

* `fweights`, `iweights`, and `pweights` are allowed; see [U] 11.1.6 weight.  
* `collinear` and `coeflegend` do not appear in the dialog box.  
See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.
Options

noconstant; see [R] Estimation options.

distribution(distname) specifies the distribution for the inefficiency term as half-normal (hnormal), exponential, or truncated-normal (tnormal). The default is hnormal.

ufrom(matrix) specifies a $1 \times K$ matrix of untransformed starting values when the distribution is truncated-normal (tnormal). frontier can estimate the parameters of the model by maximizing either the log likelihood or a transformed log likelihood (see Methods and formulas). frontier automatically transforms the starting values before passing them on to the transformed log likelihood. The matrix must have the same number of columns as there are parameters to estimate.

cm(varlist[, noconstant]) may be used only with distribution(tnormal). Here frontier will fit a conditional mean model in which the mean of the truncated-normal distribution is modeled as a linear function of the set of covariates specified in varlist. Specifying noconstant suppresses the constant in the mean function.

constraints(constraints); see [R] Estimation options.

By default, when fitting the truncated-normal model or the conditional mean model, frontier maximizes a transformed log likelihood. When constraints are applied, frontier will maximize the untransformed log likelihood with constraints defined in the untransformed metric.

uhet(varlist[, noconstant]) specifies that the technical inefficiency component is heteroskedastic, with the variance function depending on a linear combination of varlist$_u$. Specifying noconstant suppresses the constant term from the variance function. This option may not be specified with distribution(tnormal).

vhet(varlist[, noconstant]) specifies that the idiosyncratic error component is heteroskedastic, with the variance function depending on a linear combination of varlist$_v$. Specifying noconstant suppresses the constant term from the variance function. This option may not be specified with distribution(tnormal).

cost specifies that frontier fit a cost frontier model.

vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim, opg), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.

vce(robust) and vce(cluster clustvar) may not be specified with distribution(tnormal).

level(#), nocnsreport; see [R] Estimation options.

display_options: noci, nopvalues, noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(#), fvwrapon(style), cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch; see [R] Estimation options.

 maximize_options: difficult, technique(algorithm_spec), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(init_specs); see [R] Maximize. These options are seldom used.

 Setting the optimization type to technique(bhhh) resets the default vcetype to vce(opg).

 The following options are available with frontier but are not shown in the dialog box: collinear, coeflegend; see [R] Estimation options.

 Remarks and examples

 Stochastic production frontier models were introduced by Aigner, Lovell, and Schmidt (1977) and Meeusen and van den Broeck (1977). Since then, stochastic frontier models have become a popular subfield in econometrics. Kumbhakar and Lovell (2000) provide a good introduction.

 frontier fits three stochastic frontier models with distinct parameterizations of the inefficiency term and can fit stochastic production or cost frontier models.

 Let’s review the nature of the stochastic frontier problem. Suppose that a producer has a production function \( f(z_i, \beta) \). In a world without error or inefficiency, the \( i \)th firm would produce

 \[ q_i = f(z_i, \beta) \]

 Stochastic frontier analysis assumes that each firm potentially produces less than it might due to a degree of inefficiency. Specifically,

 \[ q_i = f(z_i, \beta)\xi_i \]

 where \( \xi_i \) is the level of efficiency for firm \( i \); \( \xi_i \) must be in the interval \((0, 1]\). If \( \xi_i = 1 \), the firm is achieving the optimal output with the technology embodied in the production function \( f(z_i, \beta) \). When \( \xi_i < 1 \), the firm is not making the most of the inputs \( z_i \) given the technology embodied in the production function \( f(z_i, \beta) \). Because the output is assumed to be strictly positive (that is, \( q_i > 0 \)), the degree of technical efficiency is assumed to be strictly positive (that is, \( \xi_i > 0 \)).

 Output is also assumed to be subject to random shocks, implying that

 \[ q_i = f(z_i, \beta)\xi_i \exp(v_i) \]

 Taking the natural log of both sides yields

 \[ \ln(q_i) = \ln\{ f(z_i, \beta)\} + \ln(\xi_i) + v_i \]

 Assuming that there are \( k \) inputs and that the production function is linear in logs, defining \( u_i = -\ln(\xi_i) \) yields

 \[ \ln(q_i) = \beta_0 + \sum_{j=1}^{k} \beta_j \ln(z_{ji}) + v_i - u_i \]  

 (1)

 Because \( u_i \) is subtracted from \( \ln(q_i) \), restricting \( u_i \geq 0 \) implies that \( 0 < \xi_i \leq 1 \), as specified above.
Kumbhakar and Lovell (2000) provide a detailed version of the above derivation, and they show that performing an analogous derivation in the dual cost function problem allows us to specify the problem as

\[
\ln(c_i) = \beta_0 + \beta_q \ln(q_i) + \sum_{j=1}^{k} \beta_j \ln(p_{ji}) + v_i + u_i
\]  

(2)

where \( q_i \) is output, \( z_{ji} \) are input quantities, \( c_i \) is cost, and the \( p_{ji} \) are input prices.

Intuitively, the inefficiency effect is required to lower output or raise expenditure, depending on the specification.

- **Technical note**

  The model that \textit{frontier} actually fits is of the form

  \[
y_i = \beta_0 + \sum_{j=1}^{k} \beta_j x_{ji} + v_i - su_i
\]

  where

  \[
s = \begin{cases} 
  1, & \text{for production functions} \\
  -1, & \text{for cost functions}
  \end{cases}
\]

  so, in the context of the discussion above, \( y_i = \ln(q_i) \), and \( x_{ji} = \ln(z_{ji}) \) for a production function; and for a cost function, \( y_i = \ln(c_i) \), and the \( x_{ji} \) are the \( \ln(p_{ji}) \) and \( \ln(q_i) \). You must take the natural logarithm of the data before fitting a stochastic frontier production or cost model. \textit{frontier} performs no transformations on the data.

Different specifications of the \( u_i \) and the \( v_i \) terms give rise to distinct models. \textit{frontier} provides estimators for the parameters of three basic models in which the idiosyncratic component, \( v_i \), is assumed to be independently \( N(0, \sigma_v) \) distributed over the observations. The basic models differ in their specification of the inefficiency term, \( u_i \), as follows:

- **exponential**: the \( u_i \) are independently exponentially distributed with variance \( \sigma_u^2 \)
- **hnormal**: the \( u_i \) are independently half-normally \( N^+(0, \sigma_u^2) \) distributed
- **tnormal**: the \( u_i \) are independently \( N^+(\mu, \sigma_u^2) \) distributed with truncation point at 0

For half-normal or exponential distributions, \textit{frontier} can fit models with heteroskedastic error components, conditional on a set of covariates. For a truncated-normal distribution, \textit{frontier} can also fit a conditional mean model in which the mean is modeled as a linear function of a set of covariates.

- **Example 1: The half-normal and the exponential models**

  For our first example, we demonstrate the half-normal and exponential models by reproducing a study found in Greene (2003, 505), which uses data originally published in Zellner and Revankar (1969). In this study of the transportation-equipment manufacturing industry, observations on value added, capital, and labor are used to estimate a Cobb–Douglas production function. The variable \( \ln v \) is the log-transformed value added, \( \ln k \) is the log-transformed capital, and \( \ln l \) is the log-transformed labor. OLS estimates are compared with those from stochastic frontier models using both the half-normal and exponential distribution for the inefficiency term.

</table>
The parameter estimates and the estimates of the inefficiency terms closely match those published in Greene (2003, 505), but the standard errors of the parameter estimates are estimated differently (see the technical note below).

The output from frontier includes estimates of the standard deviations of the two error components, \( \sigma_v \) and \( \sigma_u \), which are labeled \texttt{sigma,v} and \texttt{sigma,u}, respectively. In the log likelihood, they are parameterized as \( \ln \sigma_v^2 \) and \( \ln \sigma_u^2 \), and these estimates are labeled \texttt{/lnsig2v} and \texttt{/lnsig2u} in the output. frontier also reports two other useful parameterizations. The estimate of the total error variance, \( \sigma_S^2 = \sigma_v^2 + \sigma_u^2 \), is labeled \texttt{sigma2}, and the estimate of the ratio of the standard deviation of the inefficiency component to the standard deviation of the idiosyncratic component, \( \lambda = \sigma_u / \sigma_v \), is labeled \texttt{lambda}.

At the bottom of the output, frontier reports the results of a test that there is no technical inefficiency component in the model. This is a test of the null hypothesis \( H_0 : \sigma_u^2 = 0 \) against the alternative hypotheses \( H_1 : \sigma_u^2 > 0 \). If the null hypothesis is true, the stochastic frontier model reduces to an OLS model with normal errors. However, because the test lies on the boundary of the parameter space of \( \sigma_u^2 \), the standard likelihood-ratio test is not valid, and a one-sided generalized likelihood-ratio test must be constructed; see Gutierrez, Carter, and Drukker (2001). For this example, the output shows \( LR = 0.43 \) with a \( p \)-value of 0.256 for the half-normal model and \( LR = 1.21 \) with a \( p \)-value of 0.135 for the exponential model. There are several possible reasons for the failure to reject the null hypothesis, but the fact that the test is based on an asymptotic distribution and the sample size was 25 is certainly a leading candidate among those possibilities.

### Technical note

frontier maximizes the log-likelihood function of a stochastic frontier model by using the Newton–Raphson method, and the estimated variance–covariance matrix is calculated as the inverse of the negative Hessian (matrix of second partial derivatives); see [R] ml. When comparing the results with those published using other software, be aware of the difference in the optimization methods, which may result in different, yet asymptotically equivalent, variance estimates.

### Example 2: Models with heteroskedasticity

Often the error terms may not have constant variance. frontier allows you to model heteroskedasticity in either error term as a linear function of a set of covariates. The variance of either the technical inefficiency or the idiosyncratic component may be modeled as

\[
\sigma_i^2 = \exp(w_i \delta)
\]

The default constant included in \( w_i \) may be suppressed by appending a \texttt{noconstant} option to the list of covariates. Also, you can simultaneously specify covariates for both \( \sigma_u \) and \( \sigma_v \).

In this example, we use a sample of 756 observations of fictional firms producing a manufactured good by using capital and labor. The firms are hypothesized to use a constant returns-to-scale technology, but the sizes of the firms differ. Believing that this size variation will introduce heteroskedasticity into the idiosyncratic error term, we estimate the parameters of a Cobb–Douglas production function. To do this, we use a conditional heteroskedastic half-normal model, with the size of the firm as an explanatory variable in the variance function for the idiosyncratic error. We also perform a test of the hypothesis that the firms use a constant returns-to-scale technology.

| lnsig2u        |           |           |      |      |                      |
| _cons          | 1.947487  | .1017653  | 19.14| 0.000| 1.748031 2.146943    |
| sigma_u        | 2.647838  | .134729   | 19.14| 0.000| 2.396514 2.925518    |

. test _b[lnlabor] + _b[lncapital] = 1
( 1)  [lnoutput]lnlabor + [lnoutput]lncapital = 1
      chi2(  1) = 0.03
      Prob > chi2 = 0.8622

The output above indicates that the variance of the idiosyncratic error term is a function of firm size. Also, we failed to reject the hypothesis that the firms use a constant returns-to-scale technology.

Technical note

In small samples, the conditional heteroskedastic estimators will lack precision for the variance parameters and may fail to converge altogether.

Example 3: The truncated-normal model

Let’s turn our attention to the truncated-normal model. Once again, we will use fictional data. For this example, we have 1,231 observations on the quantity of output, the total cost of production for each firm, the prices that each firm paid for labor and capital services, and a categorical variable measuring the quality of each firm’s management. After taking the natural logarithm of the costs (lncost), prices (lnp_k and lnp_l), and output (lnout), we fit a stochastic cost frontier model and specify the distribution for the inefficiency term to be truncated normal.

HO: No inefficiency component:  z = 5.595  Prob>=z = 0.000

In the example below, we fit a truncated model and detect a statistically significant inefficiency term in the model. We might question whether the inefficiency term is identically distributed over all firms or whether there might be heterogeneity across firms.  frontier provides an extension to the truncated normal model by allowing the mean of the inefficiency term to be modeled as a linear function of a set of covariates. In our dataset, we have a categorical variable that measures the quality of a firm’s management. We refit the model, including the cm() option, specifying a set of
binary indicator variables representing the different categories of the quality-measurement variable as covariates.

```

The conditional mean model was developed in the context of panel-data estimators, and we can apply frontier’s conditional mean model to panel data.
frontier stores the following in e():

Scalars
- \( e(N) \): number of observations
- \( e(df_m) \): model degrees of freedom
- \( e(k) \): number of parameters
- \( e(k_{eq}) \): number of equations in \( e(b) \)
- \( e(k_{eq\_model}) \): number of equations in overall model test
- \( e(k_{dv}) \): number of dependent variables
- \( e(chi2) \): \( \chi^2 \)
- \( e(ll) \): log likelihood
- \( e(ll_c) \): log likelihood for \( H_0: \sigma_u=0 \)
- \( e(z) \): test for negative skewness of OLS residuals
- \( e(sigma_u) \): standard deviation of technical inefficiency
- \( e(sigma_v) \): standard deviation of \( v_i \)
- \( e(p) \): \( p \)-value for model test
- \( e(chi2_c) \): LR test statistic
- \( e(p_z) \): \( p \)-value for \( z \)
- \( e(rank) \): rank of \( e(V) \)
- \( e(ic) \): number of iterations
- \( e(rc) \): return code
- \( e(converged) \): 1 if converged, 0 otherwise

Macros
- \( e(cmd) \): \texttt{frontier}
- \( e(cmdline) \): command as typed
- \( e(depvar) \): name of dependent variable
- \( e(function) \): production or cost
- \( e(wtype) \): weight type
- \( e(wexp) \): weight expression
- \( e(title) \): title in estimation output
- \( e(chi2type) \): \texttt{Wald}; type of model \( \chi^2 \) test
- \( e(dist) \): distribution assumption for \( u_i \)
- \( e(het) \): heteroskedastic components
- \( e(u_{hetvar}) \): \texttt{varlist} in \texttt{uhet(})
- \( e(v_{hetvar}) \): \texttt{varlist} in \texttt{vhet(}
- \( e(vce) \): \texttt{vcetype} specified in \texttt{vce(}
- \( e(vcetype) \): title used to label Std. Err.
- \( e(opt) \): type of optimization
- \( e(which) \): max or min; whether optimizer is to perform maximization or minimization
- \( e(ml\_method) \): type of \texttt{ml} method
- \( e(user) \): name of likelihood-evaluator program
- \( e(technique) \): maximization technique
- \( e(properties) \): \texttt{b V}
- \( e(predict) \): program used to implement \texttt{predict}
- \( e(asbalanced) \): factor variables \texttt{fvset as asbalanced}
- \( e(asobserved) \): factor variables \texttt{fvset as asobserved}

Matrices
- \( e(b) \): coefficient vector
- \( e(Cns) \): constraints matrix
- \( e(11og) \): iteration log (up to 20 iterations)
- \( e(gradient) \): gradient vector
- \( e(V) \): variance–covariance matrix of the estimators
- \( e(V\_modelbased) \): model-based variance

Functions
- \( e(sample) \): marks estimation sample
Methods and formulas

Consider an equation of the form

$$y_i = x_i \beta + v_i - su_i$$

where $y_i$ is the dependent variable, $x_i$ is a $1 \times k$ vector of observations on the independent variables included as indent covariates, $\beta$ is a $k \times 1$ vector of coefficients, and

$$s = \begin{cases} 1, & \text{for production functions} \\ -1, & \text{for cost functions} \end{cases}$$

The log-likelihood functions are as follows.

Normal/half-normal model:

$$\ln L = \sum_{i=1}^{N} \left\{ \frac{1}{2} \ln \left( \frac{2}{\pi} \right) - \ln \sigma_S + \ln \Phi \left( -\frac{s \epsilon_i \lambda}{\sigma_S} \right) - \frac{\epsilon_i^2}{2\sigma_S^2} \right\}$$

Normal/exponential model:

$$\ln L = \sum_{i=1}^{N} \left\{ -\ln \sigma_u + \frac{\sigma_v^2}{2\sigma_u^2} + \ln \Phi \left( -s \frac{\epsilon_i - \frac{\sigma_u}{\sigma_v}}{\sigma_u} \right) + \frac{s \epsilon_i}{\sigma_u} \right\}$$

Normal/truncated-normal model:

$$\ln L = \sum_{i=1}^{N} \left\{ -\frac{1}{2} \ln (2\pi) - \ln \sigma_S - \ln \Phi \left( \frac{\mu}{\sigma_S \sqrt{\gamma}} \right) \\
+ \ln \Phi \left[ \frac{(1 - \gamma) \mu - s \gamma \epsilon_i}{\{\sigma_S^2 \gamma (1 - \gamma)\}^{1/2}} \right] - \frac{1}{2} \left( \frac{\epsilon_i + s \mu}{\sigma_S} \right)^2 \right\}$$

where $\sigma_S = (\sigma_u^2 + \sigma_v^2)^{1/2}$, $\lambda = \sigma_u / \sigma_v$, $\gamma = \sigma_u^2 / \sigma_S^2$, $\epsilon_i = y_i - x_i \beta$, and $\Phi()$ is the cumulative distribution function of the standard normal distribution.

To obtain estimation for $u_i$, you can use either the mean or the mode of the conditional distribution $f(u_i | \epsilon_i)$.

$$E (u_i \mid \epsilon_i) = \mu_{\ast i} + \sigma_{\ast} \left\{ \frac{\phi(-\mu_{\ast i} / \sigma_{\ast})}{\Phi(\mu_{\ast i} / \sigma_{\ast})} \right\}$$

$$M (u_i \mid \epsilon_i) = \begin{cases} \mu_{\ast i}, & \text{if } \mu_{\ast i} \geq 0 \\ 0, & \text{otherwise} \end{cases}$$

Then the technical efficiency ($s = 1$) or cost efficiency ($s = -1$) will be estimated by

$$E_i = E \{ \exp(-su_i) \mid \epsilon_i \}$$

$$= \left\{ \frac{1 - \Phi \left( s \sigma_{\ast} - \mu_{\ast i} / \sigma_{\ast} \right)}{1 - \Phi \left( -\mu_{\ast i} / \sigma_{\ast} \right)} \right\} \exp \left( -s \mu_{\ast i} + \frac{1}{2} \sigma_{\ast}^2 \right)$$
where $\mu_*$ and $\sigma_*$ are defined for the normal/half-normal model as

$$
\mu_* = -s \epsilon_i \sigma_u^2 / \sigma_S^2 \\
\sigma_* = \sigma_u \sigma_v / \sigma_S 
$$

for the normal/exponential model as

$$
\mu_* = -s \epsilon_i - \sigma_v^2 / \sigma_u \\
\sigma_* = \sigma_v 
$$

and for the normal/truncated-normal model as

$$
\mu_* = -s \epsilon_i \sigma_u^2 + \mu \sigma_v^2 / \sigma_S^2 \\
\sigma_* = \sigma_u \sigma_v / \sigma_S 
$$

In the half-normal and exponential models, when heteroskedasticity is assumed, the standard deviations, $\sigma_u$ or $\sigma_v$, will be replaced in the above equations by

$$
\sigma_i^2 = \exp(w_i \delta) 
$$

where $w$ is the vector of explanatory variables in the variance function.

In the conditional mean model, the mean parameter of the truncated normal distribution, $\mu$, is modeled as a linear combination of the set of covariates, $w$.

$$
\mu = w_i \delta 
$$

Therefore, the log-likelihood function can be rewritten as

$$
\ln L = \sum_{i=1}^{N} \left[ -\frac{1}{2} \ln (2\pi) - \ln \sigma_S - \ln \Phi \left( \frac{w_i \delta}{\sqrt{\sigma_S^2 \gamma}} \right) \\
+ \ln \Phi \left( \frac{(1 - \gamma) w_i \delta - s \gamma \epsilon_i}{\sqrt{\sigma_S^2 \gamma (1 - \gamma)}} \right) - \frac{1}{2} \left( \frac{\epsilon_i + s w_i \delta}{\sigma_S} \right)^2 \right] 
$$

The $z$ test reported in the output of the truncated-normal model is a third-moment test developed by Coelli (1995) as an extension of a test previously developed by Pagan and Hall (1983). Coelli shows that under the null of normally distributed errors, the statistic

$$
z = \frac{m_3}{\left( \frac{6m_3^2}{N} \right)^{1/2}} 
$$

has a standard normal distribution, where $m_3$ is the third moment from the OLS regression. Because the residuals are either negatively skewed (production function) or positively skewed (cost function), a one-sided $p$-value is used.

predict

Description for predict

predict creates a new variable containing predictions such as linear predictions, standard errors, and estimates of technical efficiency.

Menu for predict

Statistics > Postestimation

Syntax for predict

predict [type] newvar [if] [in] [, statistic]
predict [type] { stub* | newvar_{xb} newvar_{u} newvar_{m} } [if] [in], scores

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>xb</td>
<td>linear prediction; the default</td>
</tr>
<tr>
<td>stdp</td>
<td>standard error of the prediction</td>
</tr>
<tr>
<td>u</td>
<td>estimates of minus the natural log of the technical efficiency via $E(u_i</td>
</tr>
<tr>
<td>m</td>
<td>estimates of minus the natural log of the technical efficiency via $M(u_i</td>
</tr>
<tr>
<td>te</td>
<td>estimates of the technical efficiency via $E{\exp(-su_i)</td>
</tr>
</tbody>
</table>

$s = \begin{cases} 1, & \text{for production functions} \\ -1, & \text{for cost functions} \end{cases}$

These statistics are available both in and out of sample; type predict ... if e(sample) ... if wanted only for the estimation sample.

Options for predict

xb, the default, calculates the linear prediction.
stdp calculates the standard error of the linear prediction.
u produces estimates of minus the natural log of the technical efficiency via $E(u_i | \epsilon_i)$.
m produces estimates of minus the natural log of the technical efficiency via $M(u_i | \epsilon_i)$.
te produces estimates of the technical efficiency via $E\{\exp(-su_i) | \epsilon_i\}$.
scores calculates equation-level score variables.

The first new variable will contain $\partial \ln L / \partial (x_i \beta)$.
The second new variable will contain $\partial \ln L / \partial (\ln \text{sig2v})$.
The third new variable will contain $\partial \ln L / \partial (\ln \text{sig2u})$.
scores may not be specified after estimation with option distribution(tnormal).
margins

Description for margins

margins estimates margins of response for linear predictions.

Menu for margins

Statistics > Postestimation

Syntax for margins

margins [marginlist] [, options]
margins [marginlist], predict(statistic ...) [options]

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>xb</td>
<td>linear prediction; the default</td>
</tr>
<tr>
<td>stdp</td>
<td>not allowed with margins</td>
</tr>
<tr>
<td>u</td>
<td>not allowed with margins</td>
</tr>
<tr>

<td>not allowed with margins</td>
</tr>
<tr>
<td>te</td>
<td>not allowed with margins</td>
</tr>
</tbody>
</table>

Statistics not allowed with margins are functions of stochastic quantities other than e(b).

For the full syntax, see [R] margins.

Remarks and examples

➢ Example 1

In example 2 of [R] frontier, we modeled heteroskedasticity by specifying the vhet() option. We would like to compare the predicted efficiency in that case with respect to a model specification without accounting for the presence of heteroskedasticity in the error term. Kumbhakar and Lovell (2000, 117) show that failing to account for heteroskedasticity associated with firm size may lead to bias in the estimation of the technical efficiency. By incorrectly assuming homoskedasticity, the estimates for relatively small firms would be biased upward, while the estimates for relatively large firms would be biased downward. Let’s refit the model and use the te option of predict:
Next we fit the model assuming homoskedasticity and then again predict the technical efficiency with the `te` option of `predict`:

```
frontier lnoutput lnlabor lncapital
(output omitted)
predict te, te
```

The graph below shows the estimates for technical efficiency for the smaller and larger firms. The technical efficiency tends to be smaller for smaller firms when the model specification accounts for the presence of heteroskedasticity, whereas the predictions for the technical efficiency tends to be smaller for larger firms assuming homoskedasticity. These results agree with the theoretical statement in Kumbhakar and Lovell (2000) because the firm size was actually relevant to model heteroskedasticity in the idiosyncratic component of the error term.

> Example 2

We also test in example 2 of [R] frontier whether the firms use constant returns to scale. We can use `lincom` as an alternative to perform an equivalent test based on the normal distribution.

```
use https://www.stata-press.com/data/r16/frontier1, clear
frontier lnoutput lnlabor lncapital, vhet(size)
(output omitted)
lincom _b[lnlabor] + _b[lncapital]-1
( 1) [lnoutput]lnlabor + [lnoutput]lncapital = 1
```

| lnoutput | Coef.  | Std. Err. | z     | P>|z|  | [95% Conf. Interval] |
|----------|--------|-----------|-------|------|---------------------|
| (1)      | 0.1022278 | 0.5888511 | 0.17  | 0.862 | -1.051899 1.256355 |
The $p$-value is exactly the same as the one we obtained with the \texttt{test} command in example 2 of \texttt{[R] frontier}. However, notice that by using \texttt{lincom}, we obtained an estimate of the deviation from the constant returns-to-scale assumption, which is not significantly different from zero in this case.

[\texttt{U}] 20 Estimation and postestimation commands
Description

**fvrevar** creates a variable list that includes equivalent, temporary variables in place of the factor variables, interactions, or time-series–operated variables in *varlist*. The resulting variable list can be used by commands that do not otherwise support factor variables or time-series–operated variables. The resulting list also could be used in a program to speed execution at the cost of using more memory.

Quick start

Create temporary indicator variables for the levels of categorical variable *a* and store names in *r(varlist)*

fvrevar i.a

Create temporary variables corresponding to the levels of *a*, *b*, and their interaction

fvrevar i.a##i.b

As above, and create a temporary variable for the lag of *x* using *tsset* data

fvrevar i.a##i.b L.x

Return the list of unoperated variables (*a*, *b*, and *x*) in *r(varlist)*

fvrevar i.a##i.b L.x, list

Create new variables *a*_1, *a*_2, ..., corresponding to the levels of *a*

fvrevar i.a, stub(a_)

Create new variables *ab*_1, *ab*_2, ..., corresponding to the levels of the interaction between *a* and *b*

fvrevar i.a#i.b, stub(ab_)
Syntax

\[ \text{fvrevar} \left[ \text{varlist} \right] \left[ \text{if} \right] \left[ \text{in} \right] \left[ , \text{substitute ts}\text{only list stub(stub)} \right] \]

You must \text{tsset} your data before using \text{fvrevar} if \text{varlist} contains time-series operators; see \{TS\} \text{tsset}.

Options

\text{substitute} specifies that equivalent, temporary variables be substituted for any factor variables, interactions, or time-series–operated variables in \text{varlist}. \text{substitute} is the default action taken by \text{fvrevar}; you do not need to specify the option.

\text{tsonly} specifies that equivalent, temporary variables be substituted for only the time-series–operated variables in \text{varlist}.

\text{list} specifies that all factor-variable operators and time-series operators be removed from \text{varlist} and the resulting list of base variables be returned in \text{r(varlist)}. No new variables are created with this option.

\text{stub(stub)} specifies that \text{fvrevar} generate named variables instead of temporary variables. The new variables will be named \text{stub#}.

Remarks and examples

\text{fvrevar} might create no new variables, one new variable, or many new variables, depending on the number of factor variables, interactions, and time-series operators appearing in \text{varlist}. Any new variables created are temporary. The new, equivalent varlist is returned in \text{r(varlist)}. The new varlist corresponds one to one with the original \text{varlist}.

Example 1

Typing

\begin{verbatim}
. use https://www.stata-press.com/data/r16/auto2
. fvrevar i.rep78 mpg turn
\end{verbatim}

creates five temporary variables corresponding to the levels of \text{rep78}. No new variables are created for variables \text{mpg} and \text{turn} because they do not contain factor-variable or time-series operators.

The resulting variable list is

\begin{verbatim}
. display "'r(varlist)'"
_000000 _000001 _000002 _000003 _000004 mpg turn
\end{verbatim}

(Your temporary variable names may be different, but that is of no consequence.)

Temporary variables automatically vanish when the program concludes.

Example 2

Suppose we want to create temporary variables for specific levels of a factor variable. To do this, we can use the parenthesis notation of factor-variable syntax.

\begin{verbatim}
. fvrevar i(2,3)bn.rep78 mpg
\end{verbatim}
creates two temporary variables corresponding to levels 2 and 3 of `rep78`. Notice that we specified that neither level 2 nor 3 be set as the base level by using the `bn` notation. If we did not specify `bn`, level 2 would have been treated as the base level.

The resulting variable list is

```
. display "'r(varlist)'"
    __000005 __000002 mpg
```

We can see the results by listing the new variables alongside the original value of `rep78`.

```
. list rep78 'r(varlist)' in 1/5
```

<table>
<thead>
<tr>
<th>rep78</th>
<th>__000005</th>
<th>__000002</th>
<th>mpg</th>
</tr>
</thead>
<tbody>
<tr>
<td>Average</td>
<td>0</td>
<td>1</td>
<td>22</td>
</tr>
<tr>
<td>Average</td>
<td>0</td>
<td>1</td>
<td>17</td>
</tr>
<tr>
<td></td>
<td></td>
<td></td>
<td>.</td>
</tr>
<tr>
<td>Average</td>
<td>0</td>
<td>1</td>
<td>20</td>
</tr>
<tr>
<td>Good</td>
<td>0</td>
<td>0</td>
<td>15</td>
</tr>
</tbody>
</table>

If we had needed only the base-variable names, we could have specified

```
. fvrevar i(2,3)bn.rep78 mpg, list
. display "'r(varlist)'"
```

mpg `rep78`

The order of the list will probably differ from that of the original list; base variables are listed only once.

Example 3

Now let’s assume we have a `varlist` containing both an interaction and time-series–operated variables. If we want to create temporary variables for the entire equivalent `varlist`, we can specify `fvrevar` with no options.

```
. generate t = _n
. tsset t
    time variable: t, 1 to 74
    delta: 1 unit
. fvrevar c.turn#i(2,3).rep78 L.mpg
```

The resulting variable list is

```
. display "'r(varlist)'"
    __000006 __000007 __000008
```

If we want to create temporary variables only for the time-series–operated variables, we can specify the `tsonly` option.

```
. fvrevar c.turn#i(2,3).rep78 L.mpg, tsonly
```
The resulting variable list is

```stata
. display "'r(varlist)'"
2. rep78#c.turn 3. rep78#c.turn __000008
```

Notice that `fvrevar` returned the expanded factor-variable list with the `tsonly` option.

### Technical note

`fvrevar, substitute` avoids creating duplicate variables. Consider

```stata
. fvrevar i.rep78 turn mpg i.rep78
```

`i.rep78` appears twice in the varlist. `fvrevar` will create only one set of new variables for the five levels of `rep78` and will use these new variables once in the resulting `r(varlist)`. Moreover, `fvrevar` will do this even across multiple calls:

```stata
. fvrevar i.rep78 turn mpg
. fvrevar i.rep78
```

`i.rep78` appears in two separate calls. At the first call, `fvrevar` creates five temporary variables corresponding to the five levels of `rep78`. At the second call, `fvrevar` remembers what it has done and uses the same temporary variables for `i.rep78`.

### Stored results

`fvrevar` stores the following in `r()`:

**Macros**
- `r(varlist)` the modified variable list or list of base-variable names

fvset — Declare factor-variable settings

Description

fvset base, fvset design, and fvset clear manage factor-variable settings, which identify the base level and specify how to accumulate statistics over levels. fvset base declares the base level for each specified variable; the default for factor variables without a declared base level is the lowest value. fvset design specifies how the margins command is to accumulate over the levels of a factor variable. fvset clear removes factor-variable settings for each variable in varlist. fvset clear _all removes all factor-variable settings from all variables.

fvset report reports the current factor-variable settings for each variable in varlist. fvset without arguments is a synonym for fvset report.

Quick start

Set the base category of categorical variable a1 to 3
   fvset base 3 a1

Set the base category of a2, a3, and a4 to each variable’s largest observed value
   fvset base last a2 a3 a4

Set the base category of a5 to the most frequent category
   fvset base frequent a5

Set a6 to have no base category
   fvset base none a6

Restore the default base category (first) for a5
   fvset base default a5

Specify that margins should treat a2 as though it is balanced
   fvset design asbalanced a2

Clear factor-variable settings for a2 to a4
   fvset clear a2-a4

List factor-variable settings for all factor variables
   fvset report
Syntax

Declare base settings

```
fvset base base_spec varlist
```

Declare design settings

```
fvset design design_spec varlist
```

Clear the current settings

```
fvset clear varlist
```

Report the current settings

```
fvset report [ varlist ] [, base(base_spec) design(design_spec) ]
```

<table>

<tr>
<td>asobserved</td>
<td>accumulate using observed relative frequencies; the default</td>
</tr>
</tbody>
</table>

Options

`base(base_spec)` restricts `fvset report` to report only the factor-variable settings for variables with the specified `base_spec`.

`design(design_spec)` restricts `fvset report` to report only the factor-variable settings for variables with the specified `design_spec`. 
Remarks and examples

Example 1

Using auto2.dta, we include factor variable i.rep78 in a regression:

```
. use https://www.stata-press.com/data/r16/auto2
(1978 Automobile Data)
. regress mpg i.rep78, baselevels
```

```
Source      | SS      | df | MS       | Number of obs = 69 |
----------- | ------- |----| -------- |------------------- |
Model      | 549.415777 | 4  | 137.353944 | F(4, 64)  = 4.91  |
Residual   | 1790.78712  | 64 | 27.9810488 | Prob > F  = 0.0016 |
            |          |    |          | R-squared  = 0.2348 |
            |          |    |          | Adj R-squared  = 0.1869 |
Total      | 2340.2029 | 68 | 34.4147485 | Root MSE  = 5.2897 |
```

```
mpg    | Coef.  | Std. Err. | t     | P>|t|          | [95% Conf. Interval] |
------- |------- |---------- |------|------------- |--------------------- |
rep78   |       |          |      |             |                     |
  Poor   | 0 (base) |        |      |             |                     |
  Fair   | -1.875 | 4.181884 | -0.45| 0.655       | -10.22927 6.479274  |
  Average| -1.566667 | 3.863059 | -0.41| 0.686       | -9.284014 6.150681  |
  Good   | 0.666667 | 3.942718 | 0.17 | 0.866       | -7.209818 8.543152  |
  Excellent| 6.363636 | 4.066234 | 1.56 | 0.123       | -1.759599 14.48687  |
_cons   | 21 | 3.740391 | 5.61 | 0.000       | 13.52771 28.47229  |
```

We specified the `baselevels` option so that the base level would be included in the output. By default, the first level is the base level. We can change the base level to 2:

```
. fvset base 2 rep78
. regress mpg i.rep78, baselevels
```

```
Source      | SS      | df | MS       | Number of obs = 69 |
----------- | ------- |----| -------- |------------------- |

```
Let’s set `rep78` to have no base level and fit a cell-means regression:

```
.fvset base none rep78
.regress mpg i.rep78, noconstant
```

<table>
<thead>
<tr>

Excellent  27.3636 1.594908 17.16 0.000 24.17744 30.54983
```

**Example 2**

By default, `margins` assumes that factor variables are to be treated as observed and accumulates a margin by using the observed relative frequencies of the factor levels or the sum of the weights if weights have been specified.

```
.regress mpg i.foreign
```

<table>
<thead>
<tr>
<th>Source</th>
<th>SS</th>
<th>df</th>
<th>MS</th>
<th>Number of obs = 74</th>
</tr>
</thead>
<tbody>
<tr>
<td>Model</td>
<td>378.153515</td>
<td>1</td>
<td>378.153515</td>
<td>F(1, 72) = 13.18</td>
</tr>
<tr>
<td>Residual</td>
<td>2065.30594</td>
<td>72</td>
<td>28.6848048</td>
<td>Prob &gt; F = 0.0005</td>
</tr>
<tr>
<td>Total</td>
<td>2443.45946</td>
<td>73</td>
<td>33.4720474</td>
<td>R-squared = 0.1548</td>
</tr>
</tbody>
</table>

```
mpg Coef. Std. Err. t P>|t| [95% Conf. Interval]
--- ----------- -------- ---- -------- -------------------
foreign
Foreign     4.945804 1.362162 3.63 0.001 2.230384 7.661225

Let's set *foreign* to always accumulate using equal relative frequencies:

. fvset design asbalanced foreign
. regress mpg i.foreign

<table>
<thead>
<tr>
<th>Source</th>
<th>SS</th>
<th>df</th>
<th>MS</th>
<th>Number of obs</th>
<th>F(1, 72)</th>

</tr>
</tbody>
</table>

| Coef. | Std. Err. | t | P>|t| | [95% Conf. Interval] |
|-------|-----------|---|--------|----------------|
| foreign | 4.945804 | 1.362162 | 3.63 | 0.001 | 2.230384 | 7.661225 |
| _cons  | 19.82692 | .7427186 | 26.70 | 0.000 | 18.34634 | 21.30751 |

. margins
Adjusted predictions
Model VCE : OLS
Expression : Linear prediction, predict()
at : foreign (asbalanced)

| Marginal Std. Err. | t | P>|t| | [95% Conf. Interval] |
|-------------------|---|--------|----------------|
| _cons             | 22.29983 | .6810811 | 32.74 | 0.000 | 20.94211 | 23.65754 |

Suppose that we issued the *fvset design* command earlier in our session and that we cannot remember which variables we set as *asbalanced*. We can retrieve this information by using the *fvset report* command:

. fvset report, design(asbalanced)

Variable  Base  Design

| foreign | asbalanced |
Technical note

margins is aware of a factor variable’s design setting only through the estimation results it is working with. The design setting is stored by the estimation command; thus changing the design setting between the estimation command and margins will have no effect. For example, the output from the following two calls to margins yields the same results:

```
.fvset clear foreign
.regress mpg i.foreign
```

```
Source | SS     | df | MS
-------|--------|----|------
Model   | 378.153515 | 1  | 378.153515
Residual| 2065.30594  | 72 | 28.6848048
Total   | 2443.45946  | 73 | 33.4720474
```

```
R-squared = 0.1548
Adj R-squared = 0.1430
F(1, 72) = 13.18
Prob > F = 0.0005
Root MSE = 5.3558
```

```

```

Stored results

fvset stores the following in r():

Macros

```
r(varlist) varlist
r(baselist) base setting for each variable in varlist
r(designlist) design setting for each variable in varlist
```
**Description**

GLLAMM stands for generalized linear latent and mixed models, and `gllamm` is a Stata command for fitting such models written by Sophia Rabe-Hesketh (University of California–Berkeley) as part of joint work with Anders Skrondal (Norwegian Institute of Public Health) and Andrew Pickles (King’s College London).

**Remarks and examples**

Generalized linear latent and mixed models are a class of multilevel latent variable models, where a latent variable is a factor or a random effect (intercept or coefficient), or a disturbance (residual). The `gllamm` command for fitting such models is not an official command of Stata; it has been independently developed by highly regarded authors and is itself highly regarded. You can learn more about `gllamm` by visiting [http://www.gllamm.org](http://www.gllamm.org).

`gllamm` is available from the Statistical Software Components (SSC) archive. To install, type

```
.ssc describe gllamm
.ssc install gllamm
```

If you later wish to uninstall `gllamm`, type `ado uninstall gllamm`.

**References**

The references above are restricted to works by the primary authors of `gllamm`. There are many other books and articles that use or discuss `gllamm`; see [http://www.gllamm.org/pub.html](http://www.gllamm.org/pub.html) for a list.

Description

`glm` fits generalized linear models. It can fit models by using either IRLS (maximum quasilikelihood) or Newton–Raphson (maximum likelihood) optimization, which is the default.

See [U] 27 Overview of Stata estimation commands for a description of all of Stata’s estimation commands, several of which fit models that can also be fit using `glm`.

Quick start

Model of y as a function of x when y is a proportion
```
  glm y x, family(binomial)
```

Logit model of y events occurring in 15 trials as a function of x
```
  glm y x, family(binomial 15) link(logit)
```

Probit model of y events as a function of x using grouped data with group sizes n
```
  glm y x, family(binomial n) link(probit)
```

Model of discrete y with user-defined family `myfamily` and link `mylink`
```
  glm y x, family(myfamily) link(mylink)
```

Bootstrap standard errors in a model of y as a function of x with a gamma family and log link
```
  glm y x, family(gamma) link(log) vce(bootstrap)
```

Menu

`family(familyname)` specifies the distribution of `depvar`; `family(gaussian)` is the default.

`link(linkname)` specifies the link function; the default is the canonical link for the `family()` specified (except for `family(nbinomial)`).

`noconstant`, `exposure(varname)`, `offset(varname)`, `constraints(constraints)`; see [R] Estimation options. `constraints(constraints)` is not allowed with `irls`. 

Options

Weights are not allowed with the bootstrap prefix; see [R] bootstrap.

`aweight`s are not allowed with the jackknife prefix; see [R] jackknife.

`vce()`, `vfactor()`, `disp()`, `scale()`, `irls`, `fisher()`, `noheader`, `notable`, `nodisplay`, and weights are not allowed with the `svy` prefix; see [SVY] svy.

`fweight`, `aweight`, `iweight`, and `pweight` are allowed; see [U] 11.1.6 weight.

`noheader`, `notable`, `nodisplay`, `collinear`, and `coeflegend` do not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.
asis forces retention of perfect predictor variables and their associated, perfectly predicted observations and may produce instabilities in maximization; see \( \text{probit} \). This option is allowed only with option family(binomial) with a denominator of 1.

\text{mu}(\text{varname}) \) specifies \text{varname} \ as the initial estimate for the mean of \text{depvar}. This option can be useful with models that experience convergence difficulties, such as family(binomial) models with power or odds-power links. \text{init}(\text{varname}) \ is a synonym.

\text{vce( vcetype )} \ specifies the type of standard error reported, which includes types that are derived from asymptotic theory (\text{opg}, \text{oim}), that are robust to some kinds of misspecification (\text{robust}), that allow for intragroup correlation (\text{cluster clustvar}), and that use bootstrap or jackknife methods (\text{bootstrap}, \text{jackknife}); see \( \text{vce} \) option.

In addition to the standard \text{vcetypes}, \text{glm} allows the following alternatives:

\text{vce(eim)} \ specifies that the EIM estimate of variance be used.

\text{vce(jackknife1)} \ specifies that the one-step jackknife estimate of variance be used.

\text{vce(hac kernel [#])} \ specifies that a heteroskedasticity- and autocorrelation-consistent (HAC) variance estimate be used. HAC refers to the general form for combining weighted matrices to form the variance estimate. There are three kernels built into \text{glm}. \text{kernel} \ is a user-written program or one of

\begin{verbatim}
 nwest | gallant | anderson
\end{verbatim}

\# specifies the number of lags. If \# is not specified, \( N - 2 \) is assumed. If you wish to specify \text{vce(hac ...)}, you must \text{tsset} your data before calling \text{glm}.

\text{vce(unbiased)} \ specifies that the unbiased sandwich estimate of variance be used.

\text{vfactor( # )} \ specifies a scalar by which to multiply the resulting variance matrix. This option allows you to match output with other packages, which may apply degrees of freedom or other small-sample corrections to estimates of variance.

\text{disp( # )} \ multiplies the variance of \text{depvar} by \# and divides the deviance by \#. The resulting distributions are members of the quasilikelihood family. This option is allowed only with option \text{irls}.

\text{scale(x2 | dev | #)} \ overrides the default scale parameter. This option is allowed only with Hessian (information matrix) variance estimates.

By default, \text{scale(1)} is assumed for the discrete distributions (binomial, Poisson, and negative binomial), and \text{scale(x2)} is assumed for the continuous distributions (Gaussian, gamma, and inverse Gaussian).

\text{scale(x2)} \ specifies that the scale parameter be set to the Pearson chi-squared (or generalized chi-squared) statistic divided by the residual degrees of freedom, which is recommended by McCullagh and Nelder (1989) as a good general choice for continuous distributions.

\text{scale(dev)} \ sets the scale parameter to the deviance divided by the residual degrees of freedom. This option provides an alternative to \text{scale(x2)} for continuous distributions and overdispersed or underdispersed discrete distributions. This option is allowed only with option \text{irls}.

\text{scale(#)} \ sets the scale parameter to \#. For example, using \text{scale(1)} in family(gamma) models results in exponential-errors regression. Additional use of link(log) rather than the default link(power -1) for family(gamma) essentially reproduces Stata’s \text{streg, dist(exp) nohr} \ command (see \[ \text{ST} \] \text{streg}) if all the observations are uncensored.
Reporting

level(#) \( \text{; see [R] Estimation options.} \)

eform displays the exponentiated coefficients and corresponding standard errors and confidence intervals. For family(binomial) link(logit) (that is, logistic regression), exponentiation results are odds ratios; for family(nbinomial) link(log) (that is, negative binomial regression) and for family(poisson) link(log) (that is, Poisson regression), exponentiated coefficients are incidence-rate ratios.

nocnsreport; \( \text{see [R] Estimation options.} \)

display\_options: noci, nopvvalues, noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(#), fvwrapon(style), cformat(\%fmt), pformat(\%fmt), sformat(\%fmt), and nolstretch; \( \text{see [R] Estimation options.} \)

Maximization

ml requests that optimization be carried out using Stata’s ml commands and is the default.

irls requests iterated, reweighted least-squares (IRLS) optimization of the deviance instead of Newton–Raphson optimization of the log likelihood. If the iirls option is not specified, the optimization is carried out using Stata’s ml commands, in which case all options of ml maximize are also available.

maximize\_options: difficult, technique(algorithm\_spec), iterate(#), \[no\]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(init\_specs); \( \text{see [R] Maximize.} \) These options are seldom used.

Setting the optimization method to technique(bhhh) resets the default vcetype to vce(opg).

If option iirls is specified, only maximize\_options iterate(), nolog, trace, and ltolerance() are allowed. With iirls specified, the convergence criterion is satisfied when the absolute change in deviance from one iteration to the next is less than or equal to ltolerance(), where ltolerance(1e-6) is the default.

fisher(#) specifies the number of Newton–Raphson steps that should use the Fisher scoring Hessian or EIM before switching to the observed information matrix (OIM). This option is useful only for Newton–Raphson optimization (and not when using iirls).

search specifies that the command search for good starting values. This option is useful only for Newton–Raphson optimization (and not when using iirls).

The following options are available with glm but are not shown in the dialog box:

noheader suppresses the header information from the output. The coefficient table is still displayed.

notable suppresses the table of coefficients from the output. The header information is still displayed.

nodisplay suppresses the output. The iteration log is still displayed.

collinear, coeflegend; \( \text{see [R] Estimation options.} \) collinear is not allowed with iirls.
**General use**

`glm` fits generalized linear models of $y$ with covariates $x$:

$$g\{E(y)\} = x\beta, \quad y \sim F$$

$g(\cdot)$ is called the link function, and $F$ is the distributional family. Substituting various definitions for $g(\cdot)$ and $F$ results in a surprising array of models. For instance, if $y$ is distributed as Gaussian (normal) and $g(\cdot)$ is the identity function, we have

$$E(y) = x\beta, \quad y \sim \text{Normal}$$

or linear regression. If $g(\cdot)$ is the logit function and $y$ is distributed as Bernoulli, we have

$$\logit\{E(y)\} = x\beta, \quad y \sim \text{Bernoulli}$$

or logistic regression. If $g(\cdot)$ is the natural log function and $y$ is distributed as Poisson, we have

$$\ln\{E(y)\} = x\beta, \quad y \sim \text{Poisson}$$

or Poisson regression, also known as the log-linear model. Other combinations are possible.

Although `glm` can be used to perform linear regression (and, in fact, does so by default), this regression should be viewed as an instructional feature; `regress` produces such estimates more quickly, and many postestimation commands are available to explore the adequacy of the fit; see [R] regress and [R] regress postestimation.

In any case, you specify the link function by using the `link()` option and specify the distributional family by using `family()`. The available link functions are

<table>
<thead>
<tr>
<th>Link function</th>
<th><code>glm</code> option</th>
</tr>
</thead>
<tbody>
<tr>
<td>identity</td>
<td><code>link(identity)</code></td>
</tr>
<tr>

<td><code>link(logc)</code></td>
</tr>
</tbody>
</table>

Define $\mu = E(y)$ and $\eta = g(\mu)$, meaning that $g(\cdot)$ maps $E(y)$ to $\eta = x\beta + \text{offset}$. 
Link functions are defined as follows:

- **identity** is defined as $\eta = g(\mu) = \mu$.
- **log** is defined as $\eta = \ln(\mu)$.
- **logit** is defined as $\eta = \ln\{\mu / (1 - \mu)\}$, the natural log of the odds.
- **probit** is defined as $\eta = \Phi^{-1}(\mu)$, where $\Phi^{-1}()$ is the inverse Gaussian cumulative.
- **cloglog** is defined as $\eta = \ln\{\ln(1 - \mu)\}$.
- **opower** is defined as $\eta = \left[\left\{\mu / (1 - \mu)\right\}^n - 1\right] / n$, the power of the odds. The function is generalized so that link(opower 0) is equivalent to link(logit), the natural log of the odds.
- **power** is defined as $\eta = \mu^n$. Specifying link(power 1) is equivalent to specifying link(identity). The power function is generalized so that $\mu^0 \equiv \ln(\mu)$. Thus link(power 0) is equivalent to link(log). Negative powers are, of course, allowed.
- **nbinomial** is defined as $\eta = \ln\{\mu / (\mu + k)\}$, where $k = 1$ if family(nbinomial) is specified, $k = #_k$ if family(nbinomial #_k) is specified, and $k$ is estimated via maximum likelihood if family(nbinomial ml) is specified.

The available distributional families are

<table>
<thead>
<tr>
<th>Family</th>
<th>glm option</th>
</tr>
</thead>
<tbody>
<tr>
<td>Gaussian (normal)</td>
<td>family(gaussian)</td>
</tr>
<tr>
<td>inverse Gaussian</td>

</tr>
<tr>
<td>negative binomial</td>
<td>family(nbinomial)</td>
</tr>
<tr>
<td>gamma</td>
<td>family(gamma)</td>
</tr>
</tbody>
</table>

family(normal) is a synonym for family(gaussian).

The binomial distribution can be specified as 1) family(binomial), 2) family(binomial #_N), or 3) family(binomial varname_N). In case 2, #_N is the value of the binomial denominator $N$, the number of trials. Specifying family(binomial 1) is the same as specifying family(binomial). In case 3, varname_N is the variable containing the binomial denominator, allowing the number of trials to vary across observations.

The negative binomial distribution can be specified as 1) family(nbinomial), 2) family(nbinomial #_k), or 3) family(nbinomial ml). Omitting #_k is equivalent to specifying family(nbinomial 1). In case 3, the value of #_k is estimated via maximum likelihood. The value #_k enters the variance and deviance functions. Typical values range between 0.01 and 2; see the technical note below.

You do not have to specify both family() and link(); the default link() is the canonical link for the specified family() (except for nbinomial):
If you specify both `family()` and `link()`, not all combinations make sense. You may choose from the following combinations:

<table>
<thead>
<tr>
<th>Family</th>
<th>Default link</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>family(gaussian)</code></td>
<td><code>link(identity)</code></td>
</tr>
<tr>
<td><code>family(igaussian)</code></td>
<td><code>link(power -2)</code></td>
</tr>
<tr>
<td><code>family(binominal)</code></td>
<td><code>link(logit)</code></td>
</tr>
<tr>
<td><code>family(poisson)</code></td>
<td><code>link(log)</code></td>
</tr>
<tr>
<td><code>family(nbinomial)</code></td>
<td><code>link(log)</code></td>
</tr>
<tr>
<td><code>family(gamma)</code></td>
<td><code>link(power -1)</code></td>
</tr>
</tbody>
</table>

Some `family()` and `link()` combinations result in models already fit by Stata. These are:

</tbody>
</table>

Notes:

1. The variance factor \( \#_v \) should be set to \( n/(n - k) \), where \( n \) is the number of observations and \( k \) the number of regressors. If the number of regressors is not specified, the estimated standard errors will, as a result, differ by this factor.

2. Because the link is not the canonical link for the binomial family, you must specify the `vce(oim)` option if using `irls` to get equivalent standard errors. If `irls` is used without `vce(oim)`, the regression coefficients will be the same but the standard errors will be only asymptotically equivalent. If no options are specified (`nothing`), `glm` will optimize using Newton–Raphson, making it equivalent to the other Stata command.

   See [R] `cloglog` and [R] `probit` for more details about these commands.

3. Because the canonical link is being used, the standard errors will be equivalent whether the EIM or the OIM estimator of variance is used.
4. Family negative binomial, log-link models—also known as negative binomial regression models—are used for data with an overdispersed Poisson distribution. Although \texttt{glm} can be used to fit such models, using Stata’s maximum likelihood \texttt{nbreg} command is probably better. In the GLM approach, you specify \texttt{family(nbinomial \#k)} and then search for a \#k that results in the deviance-based dispersion being 1. You can also specify \texttt{family(nbinomial ml)} to estimate \#k via maximum likelihood, which will report the same value returned from \texttt{nbreg}. However, \texttt{nbreg} also reports a confidence interval for it; see \texttt{[R] nbreg} and Rogers (1993). Of course, \texttt{glm} allows links other than log, and for those links, including the canonical nbinomial link, you will need to use \texttt{glm}.

5. \texttt{glm} can be used to estimate parameters from exponential regressions, but this method requires specifying \texttt{scale(1)}. However, censoring is not available. Censored exponential regression may be modeled using \texttt{glm} with \texttt{family(poisson)}. The log of the original response is entered into a Poisson model as an offset, whereas the new response is the censor variable. The result of such modeling is identical to the log relative hazard parameterization of \texttt{streg, dist(exp) nohr}. See \texttt{[ST] streg} for details about the \texttt{streg} command.

In general, where there is overlap between a capability of \texttt{glm} and that of some other Stata command, we recommend using the other Stata command. Our recommendation is not because of some inferiority of the GLM approach. Rather, those other commands, by being specialized, provide options and ancillary commands that are missing in the broader \texttt{glm} framework. Nevertheless, \texttt{glm} does produce the same answers where it should.

\textit{Special note.} When equivalence is expected, for some datasets, you may still see very slight differences in the results, most often only in the later digits of the standard errors. When you compare \texttt{glm} output to an equivalent Stata command, these tiny discrepancies arise for many reasons:

\begin{itemize}
  \item \texttt{glm} uses a general methodology for starting values, whereas the equivalent Stata command may be more specialized in its treatment of starting values.
  \item When using a canonical link, \texttt{glm}, \texttt{irls} should be equivalent to the maximum likelihood method of the equivalent Stata command, yet the convergence criterion is different (one is for deviance, the other for log likelihood). These discrepancies are easily resolved by adjusting one convergence criterion to correspond to the other.
  \item When both \texttt{glm} and the equivalent Stata command use Newton–Raphson, small differences may still occur if the Stata command has a different default convergence criterion from that of \texttt{glm}. Adjusting the convergence criterion will resolve the difference. See \texttt{[R] ml} and \texttt{[R] Maximize} for more details.
\end{itemize}

\textbf{Example 1}

In example 1 of \texttt{[R] logistic}, we fit a model based on data from a study of risk factors associated with low birthweight (Hosmer, Lemeshow, and Sturdivant 2013, 24). We can replicate the estimation by using \texttt{glm}:
. use https://www.stata-press.com/data/r16/lbw
(Hosmer & Lemeshow data)
. glm low age lwt i.race smoke ptl ht ui, family(binomial) link(logit)
Iteration 0: log likelihood = -101.0213
Iteration 1: log likelihood = -100.72519
Iteration 2: log likelihood = -100.724
Iteration 3: log likelihood = -100.724

glm, by default, presents coefficient estimates, whereas logistic presents the exponentiated coefficients—the odds ratios. glm’s eform option reports exponentiated coefficients, and glm, like Stata’s other estimation commands, replays results.
. glm, eform

Note: _cons estimates baseline odds.

These results are the same as those reported in example 1 of [R] logistic.

Included in the output header are values for the Akaike (1973) information criterion (AIC) and the Bayesian information criterion (BIC) (Raftery 1995). Both are measures of model fit adjusted for the number of parameters that can be compared across models. In both cases, a smaller value generally indicates a better model fit. AIC is based on the log likelihood and thus is available only when Newton–Raphson optimization is used. BIC is based on the deviance and thus is always available.

Technical note

The values for AIC and BIC reported in the output after glm are different from those reported by estat ic:

. estat ic

Akaike’s information criterion and Bayesian information criterion

<table>
<thead>
<tr>
<th>Model</th>
<th>N</th>
<th>ll(null)</th>
<th>ll(model)</th>
<th>df</th>
<th>AIC</th>
<th>BIC</th>
</tr>
</thead>
<tbody>
<tr>
<td>.</td>
<td>189</td>
<td>-100.724</td>
<td>219.448</td>
<td>9</td>
<td>248.6237</td>
<td></td>
</tr>
</tbody>
</table>

Note: BIC uses $N$ = number of observations. See [R] BIC note.

There are various definitions of these information criteria (IC) in the literature; glm and estat ic use different definitions. glm bases its computation of the BIC on deviance, whereas estat ic uses the likelihood. Both glm and estat ic use the likelihood to compute the AIC; however, the AIC from estat ic is equal to $N$, the number of observations, times the AIC from glm. Refer to Methods and formulas in this entry and [R] estat ic for the references and formulas used by glm and estat ic, respectively, to compute AIC and BIC. Inferences based on comparison of IC values reported by glm
for different GLM models will be equivalent to those based on comparison of IC values reported by \texttt{estat ic} after \texttt{glm}.

\begin{itemize}
  \item Example 2
\end{itemize}

We use data from an early insecticide experiment, given in Pregibon (1980). The variables are \texttt{ldose}, the log dose of insecticide; \texttt{n}, the number of flour beetles subjected to each dose; and \texttt{r}, the number killed.

```
. use https://www.stata-press.com/data/r16/ldose
. list, sep(4)
     ldose  n   r
    1.  1.6907  59  6
    2.  1.7242  60 13
    3.  1.7552  62 18
    4.  1.7842  56 28
    5.  1.8113  63 52
    6.  1.8369  59 53
    7.  1.861   62 61
    8.  1.8839  60 60
```

The aim of the analysis is to estimate a dose–response relationship between \( p \), the proportion killed, and \( X \), the log dose.

As a first attempt, we will formulate the model as a linear logistic regression of \( p \) on \texttt{ldose}; that is, we will take the logit of \( p \) and represent the dose–response curve as a straight line in \( X \):

\[
\ln\left\{\frac{p}{1-p}\right\} = \beta_0 + \beta_1 X
\]

Because the data are grouped, we cannot use Stata’s \texttt{logistic} command to fit the model. Instead, we will fit the model by using \texttt{glm}:

```
. glm r ldose, family(binomial n) link(logit)
  Iteration 0: log likelihood = -18.824848
  Iteration 1: log likelihood = -18.715271
  Iteration 2: log likelihood = -18.715123
  Iteration 3: log likelihood = -18.715123
  Generalized linear models
  Number of obs = 8
  Optimization : ML
  Residual df = 6
  Scale parameter = 1
  Deviance = 11.23220702 (1/df) Deviance = 1.872035
  Pearson = 10.0267936 (1/df) Pearson = 1.671132
  Variance function: V(u) = u*(1-u/n) [Binomial]
  Link function : g(u) = ln(u/(n-u)) [Logit]
  AIC = 5.178781
  Log likelihood = -18.71512262
  BIC = -1.244442

|    r | Coef. | Std. Err. | z | P>|z| | [95% Conf. Interval] |
|-----|-------|-----------|---|-----|-------------------|
| ldose | 34.27034 | 2.912141 | 11.77 | 0.000 | [28.56265, 39.97803] |
| _cons | -60.71747 | 5.180713 | -11.72 | 0.000 | [-70.87149, -50.56346] |
```
We specified `family(binomial n)` meaning that variable `n` contains the denominator.

An alternative model, which gives asymmetric sigmoid curves for `p`, involves the complementary log-log, or clog-log, function:

\[
\ln\left\{ \frac{-\ln(1 - p)}{1 - n} \right\} = \beta_0 + \beta_1 X
\]

We fit this model by using `glm`:

```
    . glm r ldose, family(binomial n) link(cloglog)
```

```
Iteration 0:  log likelihood = -14.883594
Iteration 1:  log likelihood = -14.822264
Iteration 2:  log likelihood = -14.822228
Iteration 3:  log likelihood = -14.822228
```

```
Generalized linear models

                      OIM
        r    Coef.    Std. Err.    z     P>|z|    [95% Conf. Interval]
    ldose      22.04118    1.793089    12.29    0.000    18.52679   25.55557
     _cons     -39.57232    3.229047   -12.26    0.000   -45.90114   -33.24351
```

The complementary log-log model is preferred; the deviance for the logistic model, 11.23, is much higher than the deviance for the clog-log model, 3.45. This change also is evident by comparing log likelihoods, or equivalently, AIC values.

This example also shows the advantage of the `glm` command—we can vary assumptions easily. Note the minor difference in what we typed to obtain the logistic and clog-log models:

```
    . glm r ldose, family(binomial n) link(logit)
    . glm r ldose, family(binomial n) link(cloglog)
```

If we were performing this work for ourselves, we would have typed the commands in a more abbreviated form:

```
    . glm r ldose, f(b n) l(l)
    . glm r ldose, f(b n) l(cl)
```

Technical note

Factor variables may be used with `glm`. Say that, in the example above, we had `ldose`, the log dose of insecticide; `n`, the number of flour beetles subjected to each dose; and `r`, the number killed—all as before—except that now we have results for three different kinds of beetles. Our hypothetical data include `beetle`, which contains the values 1 (“Destructive flour”), 2 (“Red flour”), and 3 (“Mealworm”).

We find strong evidence that the insecticide works differently on the mealworm. We now check whether the curve is merely shifted or also differently sloped:

```
. glm r beetle##c.ldose, family(bin n) link(cloglog)
```

```
Iteration 0:  log likelihood = -67.270188
Iteration 1:  log likelihood = -65.149316
Iteration 2:  log likelihood = -65.147978
Iteration 3:  log likelihood = -65.147978
```

We find that the (complementary log-log) dose–response curve for the mealworm has roughly half the slope of that for the destructive flour beetle.

See [U] 26 Working with categorical data and factor variables; what is said there concerning linear regression is applicable to any GLM model.
Variance estimators

`glm` offers many variance options and gives different types of standard errors when used in various combinations. We highlight some of them here, but for a full explanation, see Hardin and Hilbe (2018).

Example 3

Continuing with our flour beetle data, we rerun the most recently displayed model, this time requesting estimation via `IRLS`.

```
use https://www.stata-press.com/data/r16/beetle
.glm r beetle##c.ldose, f(bin n) l(cloglog) ltol(1e-13) irls
```

Iteration 1:  deviance =  54.41414
Iteration 2:  deviance =  50.19424
Iteration 3:  deviance =  50.16973
(output omitted)

| _cons    | -39.57232| 3.240274  | -12.21| 0.000 | -45.92314 -33.2215 |

Note our use of the `ltol()` option, which, although unrelated to our discussion on variance estimation, was used so that the regression coefficients would match those of the previous Newton–Raphson (NR) fit.

Because `IRLS` uses the EIM for optimization, the variance estimate is also based on EIM. If we want optimization via `IRLS` but the variance estimate based on OIM, we specify `glm, irls vce(oim)`:
This approach is identical to NR except for the convergence path. Because the clog-log link is not the canonical link for the binomial family, EIM and OIM produce different results. Both estimators, however, are asymptotically equivalent.

Going back to NR, we can also specify \textit{vce(robust)} to get the Huber/White/sandwich estimator of variance:

\begin{verbatim}
  . glm r beetle##c.ldose, f(b n) l(cl) vce(robust) noheader nolog
\end{verbatim}

The sandwich estimator gets its name from the form of the calculation—it is the multiplication of three matrices, with the outer two matrices (the “bread”) set to the OIM variance matrix. When \textit{irls} is used along with \textit{vce(robust)}, the EIM variance matrix is instead used as the bread. Using a result from McCullagh and Nelder (1989), Newson (1999) points out that the EIM and OIM variance matrices are equivalent under the canonical link. Thus if \textit{irls} is specified with the canonical link, the resulting variance is labeled “Robust”. When the noncanonical link for the family is used, which is the case in the example below, the EIM and OIM variance matrices differ, so the resulting variance is labeled “Semirobust”.
The outer product of the gradient (OPG) estimate of variance is one that avoids the calculation of second derivatives. It is equivalent to the “middle” part of the sandwich estimate of variance and can be specified by using `glm, vce(opg)`, regardless of whether NR or IRLS optimization is used.

```
. glm r beetle##c.ldose, f(b n) l(1e-15) vce(robust) noheader nolog
```

|          | Coef.    | Std. Err. | z      | P>|z|   | [95% Conf. Interval] |

The OPG estimate of variance is a component of the BHHH (Berndt et al. 1974) optimization technique. This method of optimization is also available with `glm` with the `technique()` option; however, the `technique()` option is not allowed with the `irls` option.

---

**Example 4**

The Newey–West (1987) estimator of variance is a sandwich estimator with the “middle” of the sandwich modified to take into account possible autocorrelation between the observations. These estimators are a generalization of those given by the Stata command `newey` for linear regression. See [TS] `newey` for more details.

For example, consider the dataset given in [TS] `newey`, which has time-series measurements on `usr` and `idle`. We want to perform a linear regression with Newey–West standard errors.
Examining Methods and formulas of [TS] newey, we see that the variance estimate is multiplied by a correction factor of \( n/(n-k) \), where \( k \) is the number of regressors. \texttt{glm, vce(hac ...)} does not make this correction, so to get the same standard errors, we must use the \texttt{vfactor()} option within \texttt{glm} to make the correction manually.

```
. display 30/28
 1.0714286
. tsset time
    time variable:  time, 1 to 30
    delta:  1 unit
. glm usr idle, vce(hac nwest 3) vfactor(1.0714286)
```

The \texttt{glm} command above reproduces the results given in [TS] newey. We may now generalize this output to models other than simple linear regression and to different kernel weights.
. glm usr idle, fam(gamma) link(log) vce(hac gallant 3)

Iteration 0: log likelihood = -61.76593
Iteration 1: log likelihood = -60.963233
Iteration 2: log likelihood = -60.95097

`glm` also offers variance estimators based on the bootstrap (resampling your data with replacement) and the jackknife (refitting the model with each observation left out in succession). Also included is the one-step jackknife estimate, which, instead of performing full reestimation when each observation is omitted, calculates a one-step NR estimate, with the full data regression coefficients as starting values.

See Hardin and Hilbe (2018) for a full discussion of the variance options that go with `glm` and, in particular, of how the different variance estimators are modified when `vce(cluster clustvar)` is specified. Finally, not all variance options are supported with all types of weights. See `help glm` for a current table of the variance options that are supported with the different weights.
User-defined functions

glm may be called with a community-contributed link function, variance (family) function, Newey-West kernel-weight function, or any combination of the three.

Syntax of link functions

```stata
program proglm
    version 16.0
    args todo eta mu return
    if 'todo' == -1 {
        /* Set global macros for output */
        global SGLM_lt "title for link function"
        global SGLM_lf "subtitle showing link definition"
        exit
    }
    if 'todo' == 0 {
        /* set η=g(μ) */
        /* Intermediate calculations go here */
        generate double 'eta' = ...
        exit
    }
    if 'todo' == 1 {
        /* set μ=g⁻¹(η) */
        /* Intermediate calculations go here */
        generate double 'mu' = ...
        exit
    }
    if 'todo' == 2 {
        /* set return = ∂μ/∂η */
        /* Intermediate calculations go here */
        generate double 'return' = ...
        exit
    }
    if 'todo' == 3 {
        /* set return = ∂²μ/∂η² */
        /* Intermediate calculations go here */
        generate double 'return' = ...
        exit
    }
    display as error "Unknown call to glm link function"
    exit 198
end
```
Syntax of variance functions

program proname
    version 16.0
    args todo eta mu return

Example 5

Suppose that we wish to perform Poisson regression with a log-link function. Although this regression is already possible with standard `glm`, we will write our own version for illustrative purposes.

Because we want a log link, \( \eta = g(\mu) = \ln(\mu) \), and for a Poisson family the variance function is \( V(\mu) = \mu \).

The Poisson density is given by

\[
f(y_i) = \frac{e^{-\exp(\mu_i)\varepsilon\mu_i y_i}}{y_i!}
\]

resulting in a log likelihood of

\[
L = \sum_{i=1}^{n} \left\{ -e^{\mu_i} + \mu_i y_i - \ln(y_i!) \right\}
\]

The squared deviance of the \( i \)th observation for the Poisson family is given by

\[
d_i^2 = \begin{cases} 2\mu_i & \text{if } y_i = 0 \\ 2\{y_i \ln(y_i/\hat{\mu}_i) - (y_i - \hat{\mu}_i)\} & \text{otherwise} \end{cases}
\]
We now have enough information to write our own Poisson-log glm module. We create the file mylog.ado, which contains

```stata
program mylog
    version 16.0
    args todo eta mu return
    if `todo' == -1 {
        global SGLM_lt "My Log"        // Titles for output
        global SGLM_lf "ln(u)"
        exit
    }
    if `todo' == 0 {
        gen double `eta' = ln(`mu')     // \eta = \ln(\mu)
        exit
    }
    if `todo' == 1 {
        gen double `mu' = exp(`eta')    // \mu = \exp(\eta)
        exit
    }
    if `todo' == 2 {
        gen double `return' = `mu'      // \partial \mu/\partial \eta = \exp(\eta) = \mu
        exit
    }
    if `todo' == 3 {
        gen double `return' = `mu'      // \partial^2 \mu/\partial \eta^2 = \exp(\eta) = \mu
        exit
    }
    di as error "Unknown call to glm link function"
    exit 198
end
```

and we create the file mypois.ado, which contains

```stata
program mypois
    version 16.0
    args todo eta mu return
    if `todo' == -1 {
        local y "$SGLM_y"
        local touse "'eta'" // 'eta' marks estimation sample here
        capture assert `y'>=0 if `touse'    // check range of y
        if _rc {
            di as error "dependent variable 'y' has negative values"
            exit 499
        }
        global SGLM_vt "My Poisson"        // Titles for output
        global SGLM_vf "u"
        global SGLM_mu "glim_mu 0 ."     // see note 1
        exit
    }
    if `todo' == 0 {
        gen double `eta' = ln(`mu')       // Initialization of \eta; see note 2
        exit
    }
```

if `todo' == 1 {
    gen double `return' = `mu' // \( V(\mu) = \mu \)
    exit
}
if `todo' == 2 { // \( \partial V(\mu)/\partial \mu \)
    gen byte `return' = 1
    exit
}
if `todo' == 3 { // squared deviance, defined above
    local y "$SGLM_y"
    if "`y'" == ""
        local y "$e(depvar)"
    }
    gen double `return' = cond(`y'==0, 2*`mu', /*
        */ 2*(`y'*ln(`y'/'mu')-(`y'-'mu'))) //
    exit
}
if `todo' == 4 { // Anscombe residual; see note 3
    local y "$SGLM_y"
    if "`y'" == ""
        local y "$e(depvar)"
    }
    gen double `return' = 1.5*(`y'^(2/3)-`mu'^(2/3)) / `mu'^(1/6)
    exit
}
if `todo' == 5 { // log likelihood; see note 4
    local y "$SGLM_y"
    if "`y'" == ""
        local y "$e(depvar)"
    }
    gen double `return' = -`mu'+`y'*ln(`mu')-lngamma(`y'+1)
    exit
}
if `todo' == 6 { // adjustment to residual; see note 5
    gen double `return' = 1/(6*sqrt(`mu'))
    exit
}
di as error "Unknown call to glm variance function"
error 198
end

Notes:

1. \texttt{glm\_mu} is a Stata program that will, at each iteration, bring \( \hat{\mu} \) back into its plausible range, should it stray out of it. Here \texttt{glm\_mu} is called with the arguments zero and missing, meaning that zero is the lower bound of \( \hat{\mu} \) and there exists no upper bound—such is the case for Poisson models.

2. Here the initial value of \( \eta \) is easy because we intend to fit this model with our user-defined log link. In general, however, the initialization may need to vary according to the link to obtain convergence. If so, the global macro \texttt{SGLM\_L} is used to determine which link is being utilized.

3. The Anscombe formula is given here because we know it. If we were not interested in Anscombe residuals, we could merely set `return' to missing. Also, the local macro \( y \) is set either to \texttt{SGLM\_y} if it is in current estimation or to \texttt{e(depvar)} if this function is being accessed by \texttt{predict}.

4. If we were not interested in ML estimation, we could omit this code entirely and just leave an exit statement in its place. Similarly, if we were not interested in deviance or IRLS optimization, we could set `return' in the deviance portion of the code (`todo'==3) to missing.
5. This code defines the term to be added to the predicted residuals if the adjusted option is specified. Again, if we were not interested, we could set 'return' to missing.

We can now test our Poisson-log module by running it on the airline data presented in [R] poisson.

```
. use https://www.stata-press.com/data/r16/airline
. list airline injuries n XYZowned
```

(Standard errors scaled using dispersion equal to square root of 1.)

These are precisely the results given in [R] poisson and are those that would have been given had we run glm, family(poisson) link(log). The only minor adjustment we needed to make was to specify the scale(1) option. If scale() is left unspecified, glm assumes scale(1) for discrete distributions and scale(x2) for continuous ones. By default, glm assumes that any user-defined family is continuous because it has no way of checking. Thus we needed to specify scale(1) because our model is discrete.

Because we were careful in defining the squared deviance, we could have fit this model with IRLS. Because log is the canonical link for the Poisson family, we would not only get the same regression coefficients but also the same standard errors.
Example 6

Suppose now that we wish to use our log link (mylog.ado) with glm’s binomial family. This task requires some modification because our current function is not equipped to deal with the binomial denominator, which we are allowed to specify. This denominator is accessible to our link function through the global macro SGLM_m. We now make the modifications and store them in mylog2.ado.

```stata
program mylog2 // <-- changed
    version 16.0
    args todo eta mu return
    if `todo' == -1 {
        global SGLM_lt "My Log, Version 2" // <-- changed
        if "$SGLM_m" == "1" { // <-- changed
            global SGLM lf "ln(u)" // <-- changed
        } // <-- changed
        else global SGLM lf "ln(u/$SGLM_m)" // <-- changed
        exit
    }
    if `todo' == 0 {
        gen double `eta' = ln(`mu'/$SGLM_m) // <-- changed
        exit
    }
    if `todo' == 1 {
        gen double `mu' = $SGLM_m*exp(`eta') // <-- changed
        exit
    }
    if `todo' == 2 {
        gen double `return' = `mu'
        exit
    }
    if `todo' == 3 {
        gen double `return' = `mu'
        exit
    }
    di as error "Unknown call to glm link function"
    exit 198
end
```

We can now run our new log link with glm’s binomial family. Using the flour beetle data from earlier, we have
. use https://www.stata-press.com/data/r16/beetle, clear
. glm r ldose, f(bin n) 1(mylog2) irls

```
Iteration 1:  deviance = 2212.108
Iteration 2:  deviance = 452.9352
Iteration 3:  deviance = 429.95
Iteration 4:  deviance = 429.2745
Iteration 5:  deviance = 429.2192
Iteration 6:  deviance = 429.2082
Iteration 7:  deviance = 429.2061
Iteration 8:  deviance = 429.2057
Iteration 9:  deviance = 429.2056
Iteration 10: deviance = 429.2056
Iteration 11: deviance = 429.2056
Iteration 12: deviance = 429.2056
```

For a more detailed discussion on user-defined functions, and for an example of a user-defined Newey–West kernel weight, see Hardin and Hilbe (2018).

John Ashworth Nelder (1924–2010) was born in Somerset, England. He studied mathematics and statistics at Cambridge and worked as a statistician at the National Vegetable Research Station and then Rothamsted Experimental Station. In retirement, he was actively affiliated with Imperial College London. Nelder was especially well known for his contributions to the theory of linear models and to statistical computing. He was the principal architect of generalized and hierarchical generalized linear models and of the programs GenStat and GLIM.

Robert William Maclagan Wedderburn (1947–1975) was born in Edinburgh and studied mathematics and statistics at Cambridge. At Rothamsted Experimental Station, he developed the theory of generalized linear models with Nelder and originated the concept of quasilikelihood. He died of anaphylactic shock from an insect bite on a canal holiday.

Methods and formulas

This discussion highlights the details of parameter estimation and predicted statistics. For a more detailed treatment, and for information on variance estimation, see Hardin and Hilbe (2018).

glm supports estimation with survey data. For details on VCEs with survey data, see [SVY] Variance estimation.

glm obtains results by IRLS, as described in McCullagh and Nelder (1989), or by maximum likelihood using Newton–Raphson. The implementation here, however, allows user-specified weights, which we denote as \( v_j \) for the \( j \)th observation. Let \( M \) be the number of “observations” ignoring weights. Define

\[
  w_j = \begin{cases} 
    1 & \text{if no weights are specified} \\
    v_j & \text{if fweights or iweights are specified} \\
    Mv_j/(\sum_k v_k) & \text{if aweights or pweights are specified}
  \end{cases}
\]

The number of observations is then \( N = \sum_j w_j \) if fweights are specified and \( N = M \) otherwise. Each IRLS step is performed by regress using \( w_j \) as the weights.

Let \( d_j^2 \) denote the squared deviance residual for the \( j \)th observation:

For the Gaussian family, \( d_j^2 = (y_j - \hat{\mu}_j)^2 \).

For the Bernoulli family (binomial with denominator 1),

\[
  d_j^2 = \begin{cases} 
    -2\ln(1 - \hat{\mu}_j) & \text{if } y_j = 0 \\
    -2\ln(\hat{\mu}_j) & \text{otherwise}
  \end{cases}
\]

For the binomial family with denominator \( m_j \),

\[
  d_j^2 = \begin{cases} 
    2y_j\ln(y_j/\hat{\mu}_j) + 2(m_j - y_j)\ln\{(m_j - y_j)/(m_j - \hat{\mu}_j)\} & \text{if } 0 < y_j < m_j \\
    2m_j \ln\{m_j/(m_j - \hat{\mu}_j)\} & \text{if } y_j = 0 \\
    2y_j\ln(y_j/\hat{\mu}_j) & \text{if } y_j = m_j
  \end{cases}
\]

For the Poisson family,

\[
  d_j^2 = \begin{cases} 
    2\hat{\mu}_j & \text{if } y_j = 0 \\
    2\{y_j\ln(y_j/\hat{\mu}_j) - (y_j - \hat{\mu}_j)\} & \text{otherwise}
  \end{cases}
\]

For the gamma family, \( d_j^2 = -2\{\ln(y_j/\hat{\mu}_j) - (y_j - \hat{\mu}_j)/\hat{\mu}_j\} \).

For the inverse Gaussian, \( d_j^2 = (y_j - \hat{\mu}_j)^2/\hat{\mu}_j^2 y_j \).
For the negative binomial,
\[
d^2_j = \begin{cases} 
\frac{2\ln(1 + k\hat{\mu}_j)}{k} & \text{if } y_j = 0 \\
2y_j\ln(y_j/\hat{\mu}_j) - 2\{(1 + ky_j)/k\ln(1 + ky_j)/(1 + k\hat{\mu}_j)\} & \text{otherwise}
\end{cases}
\]

Let \( \phi = 1 \) if the scale parameter is set to one; otherwise, define \( \phi = \hat{\phi}_0(n - k)/n \), where \( \hat{\phi}_0 \) is the estimated scale parameter and \( k \) is the number of covariates in the model (including intercept).

Let \( \ln L_j \) denote the log likelihood for the \( j \)th observation:

For the Gaussian family,
\[
\ln L_j = -\frac{1}{2} \left\{ \frac{(y_j - \hat{\mu}_j)^2}{\phi} \right\} + \ln(2\pi\phi)
\]

For the binomial family with denominator \( m_j \) (Bernoulli if all \( m_j = 1 \)),
\[
\ln L_j = \phi \times \begin{cases} 
\ln\{\Gamma(m_j + 1)\} - \ln\{\Gamma(y_j + 1)\} - \ln\{\Gamma(m_j - y_j + 1)\} & \text{if } 0 < y_j < m_j \\
(m_j - y_j)\ln(1 - \hat{\mu}_j/m_j) + y_j\ln(\hat{\mu}_j/m_j) & \text{if } y_j = 0 \\
m_j\ln(1 - \hat{\mu}_j/m_j) & \text{if } y_j = m_j
\end{cases}
\]

For the Poisson family,
\[
\ln L_j = \phi [y_j\ln(\hat{\mu}_j) - \hat{\mu}_j - \ln\{\Gamma(y_j + 1)\}]
\]

For the gamma family,
\[
\ln L_j = -y_j/\hat{\mu}_j + \ln(1/\hat{\mu}_j).
\]

For the inverse Gaussian,
\[
\ln L_j = -\frac{1}{2} \left\{ \frac{(y_j - \hat{\mu}_j)^2}{y_j\hat{\mu}_j^2} + 3\ln(y_j) + \ln(2\pi) \right\}
\]

For the negative binomial (let \( m = 1/k \)),
\[
\ln L_j = \phi [\ln\{\Gamma(m + y_j)\} - \ln\{\Gamma(y_j + 1)\} - \ln\{\Gamma(m)\} \\
- m\ln(1 + \hat{\mu}_j/m) + y_j\ln\{\hat{\mu}_j/(\hat{\mu}_j + m)\}]
\]

The overall deviance reported by \texttt{glm} is \( D^2 = \sum_j w_j d^2_j \). The dispersion of the deviance is \( D^2 \) divided by the residual degrees of freedom.

The Akaike information criterion (AIC) and Bayesian information criterion (BIC) are given by
\[
\text{AIC} = \frac{-2\ln L + 2k}{N}
\]
\[
\text{BIC} = D^2 - (N - k)\ln(N)
\]

where \( \ln L = \sum_j w_j \ln L_j \) is the overall log likelihood.
The Pearson deviance reported by \texttt{glm} is $\sum_j w_j r_j^2$. The corresponding Pearson dispersion is the Pearson deviance divided by the residual degrees of freedom. \texttt{glm} also calculates the scaled versions of all of these quantities by dividing by the estimated scale parameter.

Acknowledgments

\texttt{glm} was written by James Hardin of the Arnold School of Public Health at the University of South Carolina and Joseph Hilbe (1944–2017) of Arizona State University, the coauthors of the Stata Press book \textit{Generalized Linear Models and Extensions}. The previous version of this routine was written by Patrick Royston of the MRC Clinical Trials Unit, London, and coauthor of the Stata Press book \textit{Flexible Parametric Survival Analysis Using Stata: Beyond the Cox Model}. The original version of this routine was published in Royston (1994). Royston’s work, in turn, was based on a prior implementation by Joseph Hilbe, first published in Hilbe (1993). Roger Newson wrote an early implementation (Newson 1999) of robust variance estimates for GLM. Parts of this entry are excerpts from Hardin and Hilbe (2018).

* estat ic and lrtest are not appropriate after `glm`, `irls`.
† forecast, hausman, and lrtest are not appropriate with svy estimation results. forecast is also not appropriate with mi estimation results.
predict

Description for predict

predict creates a new variable containing predictions such as expected values, linear predictions, standard errors, residuals, Cook’s distance, diagonals of the “hat” matrix, weighted averages, differences between the observed and fitted outcomes, and equation-level scores.

These statistics are available both in and out of sample; type predict ... if e(sample) ... if wanted only for the estimation sample.

mu, xb, stdp, and score are the only statistics allowed with svy estimation results.
Options for **predict**

- **Main**
  - **mu**, the default, specifies that `predict` calculate the expected value of `y`, equal to $g^{-1}(\mathbf{x} \hat{\beta}) [ng^{-1}(\mathbf{x} \hat{\beta})]$ for the binomial family.
  - **xb** calculates the linear prediction $\eta = \mathbf{x} \hat{\beta}$.
  - **eta** is a synonym for **xb**.
  - **stdp** calculates the standard error of the linear prediction.
  - **anscombe** calculates the Anscombe (1953) residuals to produce residuals that closely follow a normal distribution.
  - **cooks** calculates Cook’s distance, which measures the aggregate change in the estimated coefficients when each observation is left out of the estimation.
  - **deviance** calculates the deviance residuals. Deviance residuals are recommended by McCullagh and Nelder (1989) and by others as having the best properties for examining the goodness of fit of a GLM. They are approximately normally distributed if the model is correct. They may be plotted against the fitted values or against a covariate to inspect the model’s fit. Also see the **pearson** option below.
  - **hat** calculates the diagonals of the “hat” matrix, analogous to linear regression.
  - **likelihood** calculates a weighted average of standardized deviance and standardized Pearson residuals.
  - **pearson** calculates the Pearson residuals. Pearson residuals often have markedly skewed distributions for nonnormal family distributions. Also see the **deviance** option above.
  - **response** calculates the differences between the observed and fitted outcomes.
  - **score** calculates the equation-level score, $\partial \ln L / \partial (\mathbf{x}_j \beta)$.
  - **working** calculates the working residuals, which are response residuals weighted according to the derivative of the link function.

- **Options**
  - **nooffset** is relevant only if you specified `offset(varname)` for **glm**. It modifies the calculations made by `predict` so that they ignore the offset variable; the linear prediction is treated as $\mathbf{x}_j \beta$ rather than as $\mathbf{x}_j \beta + \text{offset}_j$.
  - **adjusted** adjusts the deviance residual to speed up the convergence to the limiting normal distribution. The adjustment deals with adding to the deviance residual a higher-order term that depends on the variance function family. This option is allowed only when **deviance** is specified.
  - **standardized** requests that the residual be multiplied by the factor $(1 - h)^{-1/2}$, where $h$ is the diagonal of the hat matrix. This operation is done to account for the correlation between `depvar` and its predicted value.
  - **studentized** requests that the residual be multiplied by one over the square root of the estimated scale parameter.
  - **modified** requests that the denominator of the residual be modified to be a reasonable estimate of the variance of `depvar`. The base residual is multiplied by the factor $(k/w)^{-1/2}$, where $k$ is either one or the user-specified dispersion parameter and $w$ is the specified weight (or one if left unspecified).
margins

Description for margins

margins estimates margins of response for expected values and linear predictions.

Menu for margins

Statistics > Postestimation

Syntax for margins

margins [marginlist] [, options]

Statistics not allowed with margins are functions of stochastic quantities other than \( e(b) \).

For the full syntax, see [R] margins.

Remarks and examples

Remarks are presented under the following headings:

Predictions
Other postestimation commands
Predictions

Example 1

After glm estimation, predict may be used to obtain various predictions based on the model. In example 2 of [R] glm, we mentioned that the complementary log-log link seemed to fit the data better than the logit link. Now we go back and obtain the fitted values and deviance residuals:

```
. use https://www.stata-press.com/data/r16/ldose
. glm r ldose, family(binomial n) link(logit)
(output omitted)
. predict mu_logit
(option mu assumed; predicted mean r)
. predict dr_logit, deviance
. quietly glm r ldose, f(binomial n) l(cloglog)
. predict mu_cl
(option mu assumed; predicted mean r)
. predict dr_cl, d
. format mu_logit dr_logit mu_cl dr_cl %9.5f
. list r mu_logit dr_logit mu_cl dr_cl, sep(4)
```

<table>
<thead>
<tr>
<th>r</th>
<th>mu_logit</th>
<th>dr_logit</th>
<th>mu_cl</th>
<th>dr_cl</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>6</td>
<td>3.45746</td>
<td>1.28368</td>
<td>5.58945</td>
</tr>
<tr>
<td>2</td>
<td>13</td>
<td>9.84167</td>
<td>1.05969</td>
<td>11.28067</td>
</tr>
<tr>
<td>3</td>
<td>18</td>
<td>22.45139</td>
<td>-1.19611</td>
<td>20.95422</td>
</tr>
<tr>
<td>4</td>
<td>28</td>
<td>33.89761</td>
<td>-1.59412</td>
<td>30.36942</td>
</tr>
<tr>
<td>5</td>
<td>52</td>
<td>50.09584</td>
<td>0.60614</td>
<td>47.77644</td>
</tr>
<tr>
<td>6</td>
<td>53</td>
<td>53.29092</td>
<td>-0.12716</td>
<td>54.14273</td>
</tr>
<tr>
<td>7</td>
<td>61</td>
<td>59.22216</td>
<td>1.25107</td>
<td>61.11331</td>
</tr>
<tr>
<td>8</td>
<td>60</td>
<td>58.74297</td>
<td>1.59398</td>
<td>59.94723</td>
</tr>
</tbody>
</table>

In six of the eight cases, \(|\text{dr\_logit}| > |\text{dr\_cl}|\). The above represents only one of the many available options for predict. See Hardin and Hilbe (2018) for a more in-depth examination.

Other postestimation commands

Technical note

After glm estimation, you may perform any of the postestimation commands that you would perform after any other kind of estimation in Stata; see [U] 20 Estimation and postestimation commands. Below we test the joint significance of all the interaction terms.
. use https://www.stata-press.com/data/r16/beetle, clear
. glm r beetle##c.ldose, family(binomial n) link(cloglog)
   (output omitted)
. testparm i.beetle beetle#c.ldose
   ( 1) [r]2.beetle = 0
   ( 2) [r]3.beetle = 0
   ( 3) [r]2.beetle#c.ldose = 0
   ( 4) [r]3.beetle#c.ldose = 0
   chi2( 4) = 249.69
   Prob > chi2 = 0.0000

If you wanted to print the variance–covariance matrix of the estimators, you would type estat vce.

If you use the linktest postestimation command, you must also specify the family() and link() options; see [R] linktest.

### Methods and formulas

We follow the terminology used in Methods and formulas of [R] glm.

The deviance residual calculated by predict following glm is

\[ r_D^j = \text{sign}(y_j - \hat{\mu}_j) \sqrt{d_j^2} \]

The Pearson residual calculated by predict following glm is

\[ r_P^j = \frac{y_j - \hat{\mu}_j}{\sqrt{V(\hat{\mu}_j)}} \]

where \( V(\hat{\mu}_j) \) is the family-specific variance function.

\[
V(\hat{\mu}_j) = \begin{cases} 
\hat{\mu}_j (1 - \hat{\mu}_j / m_j) & \text{if binomial or Bernoulli (} m_j = 1 \text{)} \\
\hat{\mu}_j^2 & \text{if gamma} \\
1 & \text{if Gaussian} \\
\hat{\mu}_j^3 & \text{if inverse Gaussian} \\
\hat{\mu}_j + k\hat{\mu}_j^2 & \text{if negative binomial} \\
\hat{\mu}_j & \text{if Poisson}
\end{cases}
\]

The response residuals are given by \( r_R^j = y_j - \hat{\mu}_j \). The working residuals are

\[ r_W^j = (y_j - \hat{\mu}_j) \left( \frac{\partial \eta}{\partial \mu} \right)_j \]

and the score residuals are

\[ r_S^j = \frac{y_j - \hat{\mu}_j}{V(\hat{\mu}_j)} \left( \frac{\partial \eta}{\partial \mu} \right)^{-1}_j \]

Define \( \hat{W} = V(\hat{\mu}) \) and \( X \) to be the covariate matrix. \( h_j \), then, is the \( j \)th diagonal of the hat matrix given by

\[ \hat{H} = \hat{W}^{1/2} X (X^T \hat{W} X)^{-1} X^T \hat{W}^{1/2} \]
As a result, the likelihood residuals are given by

\[ r^L_j = \text{sign}(y_j - \hat{\mu}_j) \left\{ h_j (r^P_j)^2 + (1 - h_j)(r^D_j)^2 \right\}^{1/2} \]

where \( r^P_j \) and \( r^D_j \) are the standardized Pearson and standardized deviance residuals, respectively. By standardized, we mean that the residual is divided by \( \{1 - h_j\}^{1/2} \).

Cook’s distance is an overall measure of the change in the regression coefficients caused by omitting the \( i \)th observation from the analysis. Computationally, Cook’s distance is obtained as

\[ C_j = \frac{(r^P_j)^2 h_j}{k(1 - h_j)} \]

where \( k \) is the number of regressors, including the constant.

Anscombe residuals are given by

\[ r^A_j = \frac{A(y_j) - A(\hat{\mu}_j)}{A'(\hat{\mu}_j)} \left\{ V(\hat{\mu}_j) \right\}^{1/2} \]

where

\[ A(\cdot) = \int \frac{d\mu}{V^{1/3}(\mu)} \]

Deviance residuals may be adjusted (predict, adjusted) to make the following correction:

\[ r^{Da}_j = r^D_j + \frac{1}{6} \rho_3(\theta) \]

where \( \rho_3(\theta) \) is a family-specific correction. See Hardin and Hilbe (2018) for the exact forms of \( \rho_3(\theta) \) for each family.

[U] 20 Estimation and postestimation commands
Description

\texttt{gmm} performs generalized method of moments (GMM) estimation. With the interactive version of the command, you enter the residual equation for each moment condition directly into the dialog box or on the command line by using substitutable expressions. The moment-evaluator program version gives you greater flexibility in exchange for increased complexity; with this version, you write a program in an ado-file that calculates the moments based on a vector of parameters passed to it.

\texttt{gmm} can fit both single- and multiple-equation models. It allows moment conditions of the form \( E\{z_i u_i(\beta)\} = 0 \), where \( z_i \) is a vector of instruments, and \( u_i(\beta) \) is an error term, as well as more general moment conditions of the form \( E\{h_i(z_i; \beta)\} = 0 \). \texttt{gmm} works with cross-sectional, time-series, and longitudinal (panel) data.
**Syntax**

**Interactive version**

```
gmm ([reqname_1]:rexp_1) ([reqname_2]:rexp_2)...[if] [in] [weight] [, options]
```

**Moment-evaluator program version**

```
gmm moment_prog [if] [in] [weight], {equations(namelist)|nequations(#)}
```

```
{parameters(namelist)|nparameters(#)} [options] [program_options]
```

`reqname_j` is the `j`th residual equation name,
`rexp_j` is the substitutable expression for the `j`th residual equation, and
`moment_prog` is a moment-evaluator program.

**options**

<table>

**Instruments**

```
instruments([reqlist]:varlist[, noconstant])
```

specify instruments; can be specified more than once

```
xtinstruments([reqlist]:varlist, lags(#_1/#_2))
```

specify panel-style instruments; can be specified more than once

**Weight matrix**

```
wmatrix(wmtype[, independent])
```

specify weight matrix; `wmtype` may be `robust`, `cluster clustvar`, `hac kernel [lags]`, or `unadjusted`

```
center
```

center moments in weight-matrix computation

```
winitial(iwtype[, independent])
```

specify initial weight matrix; `iwtype` may be `unadjusted`, `identity`, `xt xtspec`, or the name of a Stata matrix
SE/Robust
\[ \text{vce(vcetype[, independent])} \]
- \text{vcetype} may be \textbf{robust}, \textbf{cluster clustvar}, \textbf{bootstrap}, \textbf{jackknife}, \textbf{hac kernel lags}, or \textbf{unadjusted}
- \text{quickderivatives} use alternative method of computing numerical derivatives for VCE

Reporting
\[ \text{level(#)} \]
- set confidence level; default is \text{level(95)}
\[ \text{title(string)} \]
- display \textit{string} as title above the table of parameter estimates
\[ \text{title2(string)} \]
- display \textit{string} as subtitle
\[ \text{display_options} \]
- control columns and column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling

Optimization
\[ \text{from(initial_values)} \]
- specify initial values for parameters
\[ \text{† igmmiterate(#)} \]
- specify maximum number of iterations for iterated GMM estimator
\[ \text{‡ igmmeps(#)} \]
- specify \# for iterated GMM parameter convergence criterion; default is \text{igmmeps(1e-6)}
\[ \text{‡ igmmweps(#)} \]
- specify \# for iterated GMM weight-matrix convergence criterion; default is \text{igmmweps(1e-6)}
\[ \text{optimization_options} \]
- control the optimization process; seldom used
\[ \text{coeflegend} \]
- display legend instead of statistics

* You can specify at most one of these options.
† These options may be specified only when \text{igmm} is specified.

\[ \text{program_options} \]
\begin{tabular}{ll}

† \text{nparameters(#)} & specify number of parameters \\
\hline
\end{tabular}

* You may not specify both \textit{hasderivatives} and \textit{haslfderivatives}.
† You must specify \text{equations(namelist)} or \text{nequations(#)}; you may specify both.
‡ You must specify \text{parameters(namelist)} or \text{nparameters(#)}; you may specify both.
rexp_j and dexp_jk may contain factor variables and time-series operators; see [U] 11.4.3 Factor variables and [U] 11.4.4 Time-series varlists.

bootstrap, by, jackknife, rolling, and statsby are allowed; see [U] 11.1.10 Prefix commands.

Weights are not allowed with the bootstrap prefix; see [R] bootstrap.

aweights are not allowed with the jackknife prefix; see [R] jackknife.

aweights, fweights, iweights, and pweights are allowed; see [U] 11.1.6 weight.

coefflegend does not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

rexp_j and dexp_jk are substitutable expressions, that is, Stata expressions that also contain parameters to be estimated. The parameters are enclosed in curly braces and must satisfy the naming requirements for variables; \{beta\} is an example of a parameter. The notation \(\{lcname\: varlist\}\) is allowed for linear combinations of multiple covariates and their parameters. For example, \(\{xb: mpg\ price\ turn\ _cons\}\) defines a linear combination of the variables mpg, price, turn, and _cons (the constant term). See Substitutable expressions under Remarks and examples below.

Options

derivative(\[ reqname \| \# \] / name = dexp_jk) specifies the derivative of residual equation reqname or \# with respect to parameter name. If reqname or \# is not specified, gmm assumes that the derivative applies to the first residual equation.

For a moment condition of the form \(E\{z_{ji}u_{ji}(\beta)\} = 0\), derivative(\(j/\beta_{k} = dexp_jk\)) is to contain a substitutable expression for \(\partial u_{ji}/\partial \beta_{k}\). If you specified \(m\) as the reqname, then for a moment condition of the form \(E\{z_{mi}u_{mi}(\beta)\} = 0\), you can specify derivative(\(m/\beta_{k} = dexp_{mk}\)), where \(m\) is the index of \(m\).

dexp_jk uses the same substitutable expression syntax as is used to specify residual equations. If you declare a linear combination in a residual equation, you provide the derivative for the linear combination; gmm then applies the chain rule for you. See Specifying derivatives under Remarks and examples below for examples.

If you do not specify the derivative() option, gmm calculates derivatives numerically. You must either specify no derivatives or specify a derivative for each of the \(k\) parameters that appears in each of the \(j\) residual equations unless the derivative is identically zero. You cannot specify some analytic derivatives and have gmm compute the rest numerically.

twostep, onestep, and igmm specify which estimator is to be used. You can specify at most one of these options. twostep is the default.

twostep requests the two-step GMM estimator. gmm obtains parameter estimates based on the initial weight matrix, computes a new weight matrix based on those estimates, and then reestimates the parameters based on that weight matrix.

onestep requests the one-step GMM estimator. The parameters are estimated based on an initial weight matrix, and no updating of the weight matrix is performed except when calculating the appropriate variance–covariance (VCE) matrix.

igmm requests the iterative GMM estimator. gmm obtains parameter estimates based on the initial weight matrix, computes a new weight matrix based on those estimates, reestimates the parameters based on that weight matrix, computes a new weight matrix, and so on, to convergence. Convergence is declared when the relative change in the parameter vector is less than igmmweps(), the relative change in the weight matrix is less than igmmweps(), or igmmiterate() iterations have been
completed. Hall (2005, sec. 2.4 and 3.6) mentions that there may be gains to finite-sample efficiency from using the iterative estimator.

`variables(varlist)` specifies the variables in the model. `gmm` ignores observations for which any of these variables has a missing value. If you do not specify `variables()`, then `gmm` assumes all the observations are valid and issues an error message if any residual equations evaluate to missing for any observations at the initial value of the parameter vector.

`nocommonesample` requests that `gmm` not restrict the estimation sample to be the same for all equations. By default, `gmm` will restrict the estimation sample to observations that are available for all equations in the model, mirroring the behavior of other multiple-equation estimators such as `nlsur`, `sureg`, or `reg3`. For certain models, however, different equations can have different numbers of observations. For these models, you should specify `nocommonesample`. See Dynamic panel-data models below for one application of this option. You cannot specify weights if you specify `nocommonesample`.

`instruments([reqlist]: varlist[, noconstant])` specifies a list of instrumental variables to be used. If you specify a single residual equation, then you do not need to specify the equations to which the instruments apply; you can omit the `reqlist` and simply specify `instruments(varlist)`. By default, a constant term is included in `varlist`; to omit the constant term, use the `noconstant` suboption: `instruments(varlist, noconstant)`.

If your model has multiple moment conditions of the form

\[
E\left\{\begin{array}{l}
z_{1i}u_{1i}(\beta) \\
\vdots \\
z_{qi}u_{qi}(\beta)
\end{array}\right\} = 0
\]

then you can specify multiple corresponding residual equations. Then specify the `reqlist` to indicate the residual equations for which the list of variables is to be used as instruments if you do not want that list applied to all the residual equations. For example, you might type

\[
gmm (main:rexp_1) (rexp_2) (rexp_3), instruments(z1 z2) ///
\]

\[
instruments(2: z3) instruments(main 3: z4)
\]

Variables `z1` and `z2` will be used as instruments for all three equations, `z3` will be used as an instrument for the second equation, and `z4` will be used as an instrument for the first and third equations. Notice that we chose to supply a name for the first residual equation but not the second two, identifying each by its equation number.

`varlist` may contain factor variables and time-series operators; see [U] 11.4.3 Factor variables and [U] 11.4.4 Time-series varlists, respectively.

`xtinstruments([reqlist]: varlist, lags(#_1/#_2))` is for use with panel-data models in which the set of available instruments depends on the time period. As with `instruments()`, you can prefix the list of variables with residual equation names or numbers to target instruments to specific equations. Unlike with `instruments()`, a constant term is not included in `varlist`. You must `xtset` your data before using this option; see [XT] xtset.

If you specify

\[
gmm ..., xtinstruments(x, lags(1/.) ...)
\]

then for panel `i` and period `t`, `gmm` uses `x_{i,t-1}, x_{i,t-2}, ..., x_{i1}` as instruments. More generally, specifying `xtinstruments(x, lags(#_1, #_2))` uses `x_{i,t-#_1}, ..., x_{i,t-#_2}` as instruments; setting `#_2 = .` requests all available lags. `#_1` and `#_2` must be zero or positive integers.
gmm automatically excludes observations for which no valid instruments are available. It does, however, include observations for which only a subset of the lags is available. For example, if you request that lags one through three be used, then gmm will include the observations for the second and third time periods even though fewer than three lags are available as instruments.

**Weight matrix**

\[ \text{wmatrix(wmtype[, independent])} \]

specifies the type of weight matrix to be used in conjunction with the two-step and iterated GMM estimators.

Specifying \text{wmatrix(robust)} requests a weight matrix that is appropriate when the errors are independent but not necessarily identically distributed. \text{wmatrix(robust)} is the default.

Specifying \text{wmatrix(cluster clustvar)} requests a weight matrix that accounts for arbitrary correlation among observations within clusters identified by \text{clustvar}.

Specifying \text{wmatrix(hac kernel #)} requests a heteroskedasticity- and autocorrelation-consistent (HAC) weight matrix using the specified kernel (see below) with \# lags. The bandwidth of a kernel is equal to the number of lags plus one.

Specifying \text{wmatrix(hac kernel opt [#])} requests an HAC weight matrix using the specified kernel, and the lag order is selected using Newey and West’s (1994) optimal lag-selection algorithm. \# is an optional tuning parameter that affects the lag order selected; see the discussion in Methods and formulas.

Specifying \text{wmatrix(hac kernel)} requests an HAC weight matrix using the specified kernel and \( N - 2 \) lags, where \( N \) is the sample size.

There are three kernels available for HAC weight matrices, and you can request each one by using the name used by statisticians or the name perhaps more familiar to economists:

- \text{bartlett} or \text{nwest} requests the Bartlett (Newey–West) kernel;
- \text{parzen} or \text{gallant} requests the Parzen (Gallant) kernel; and
- \text{quadraticspectral} or \text{andrews} requests the quadratic spectral (Andrews) kernel.

Specifying \text{wmatrix(unadjusted)} requests a weight matrix that is suitable when the errors are homoskedastic. In some applications, the GMM estimator so constructed is known as the (nonlinear) two-stage least-squares (2SLS) estimator.

Including the \text{independent} suboption creates a weight matrix that assumes moment conditions are independent. This suboption is often used to replicate other models that can be motivated outside the GMM framework, such as the estimation of a system of equations by system-wide 2SLS. This suboption has no effect if only one residual equation is specified.

\text{wmatrix()} has no effect if \text{onestep} is also specified.

\text{center} requests that the sample moments be centered (demeaned) when computing GMM weight matrices. By default, centering is not done.

\[ \text{winitial(iwtype[, independent])} \]

specifies the weight matrix to use to obtain the first-step parameter estimates.

Specifying \text{winitial(unadjusted)} requests a weight matrix that assumes the moment conditions are independent and identically distributed. This matrix is of the form \((Z'Z)^{-1}\), where \(Z\) represents all the instruments specified in the \text{instruments()} option. To avoid a singular weight matrix, you should specify at least \( q - 1 \) moment conditions of the form \( E\{z_{hi}u_{hi}(\beta)\} = 0 \), where \( q \) is the number of moment conditions, or you should specify the \text{independent} suboption.
Including the `independent` suboption creates a weight matrix that assumes moment conditions are independent. Elements of the weight matrix corresponding to covariances between two moment conditions are set equal to zero. This suboption has no effect if only one residual equation is specified.

`winitial(unadjusted)` is the default.

`winitial(identity)` requests that the identity matrix be used.

`winitial(xt xtspec)` is for use with dynamic panel-data models in which one of the residual equations is specified in first-differences form. `xtspec` is a string consisting of the letters “L” and “D”, the length of which is equal to the number of residual equations in the model. You specify “L” for a residual equation if that residual equation is written in levels, and you specify “D” for a residual equation if it is written in first differences; `xtspec` is not case sensitive. When you specify this option, you can specify at most one residual equation in levels and one residual equation in first differences. See the examples listed in `Dynamic panel-data models` under `Remarks and examples` below.

`winitial(matname)` requests that Stata matrix `matname` be used. You cannot specify the `independent` suboption if you specify `winitial(matname)`.

`vce(vcetype[ , independent])` specifies the type of standard error reported, which includes types that are robust to some kinds of misspecification (`robust`), that allow for intragroup correlation (`cluster clustvar`), and that use bootstrap or jackknife methods (`bootstrap`, `jackknife`); see [R] `vce_option`.

`vce(unadjusted)` specifies that an unadjusted (nonrobust) VCE matrix be used; this, along with the `twostep` option, results in the “optimal two-step GMM” estimates often discussed in textbooks.

The default `vcetype` is based on the `wmtype` specified in the `wmatrix()` option. If `wmatrix()` is specified but `vce()` is not, then `vcetype` is set equal to `wmtype`. To override this behavior and obtain an unadjusted (nonrobust) VCE matrix, specify `vce(unadjusted)`.

Specifying `vce(bootstrap)` or `vce(jackknife)` results in standard errors based on the bootstrap or jackknife, respectively. See [R] `vce_option`, [R] `bootstrap`, and [R] `jackknife` for more information on these VCEs.

The syntax for `vcetypes` other than `bootstrap` and `jackknife` is identical to those for `wmatrix()`.

`quickderivatives` requests that an alternative method be used to compute the numerical derivatives for the VCE. This option has no effect if you specify the `derivatives()`, `hasderivatives`, or `haslfderivatives` option.

The VCE depends on a matrix of partial derivatives that `gmm` must compute numerically unless you supply analytic derivatives. This Jacobian matrix will be especially large if your model has many instruments, residual equations, or parameters.

By default, `gmm` computes each element of the Jacobian matrix individually, searching for an optimal step size each time. Although this procedure results in accurate derivatives, it is computationally taxing: `gmm` may have to evaluate the moments of your model five or more times for each element of the Jacobian matrix.

When you specify the `quickderivatives` option, `gmm` computes all derivatives corresponding to a parameter at once, using a fixed step size proportional to the parameter’s value. This method requires just two evaluations of the model’s moments to compute an entire column of the Jacobian matrix and therefore has the most impact when you specify many instruments or residual equations.
Most of the time, the two methods produce virtually identical results, but the quickderivatives method may fail if a residual equation is highly nonlinear or if instruments differ by orders of magnitude. In the rare case where you specify quickderivatives and obtain suspiciously large or small standard errors, try refitting your model without this option.

**Reporting**

level(#); see [R] Estimation options.

title(string) specifies an optional title that will be displayed just above the table of parameter estimates.

title2(string) specifies an optional subtitle that will be displayed between the title specified in title() and the table of parameter estimates. If title2() is specified but title() is not, title2() has the same effect as title().

display_options: noci, nopvalues, noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(#), fvwrapon(style), cformat(%,fmt), pformat(%,fmt), sformat(%,fmt), and nolstretch; see [R] Estimation options.

**Optimization**

from(initial_values) specifies the initial values to begin the estimation. You can specify a parameter name, its initial value, another parameter name, its initial value, and so on, or you can specify a $1 \times k$ matrix, where $k$ is the number of parameters in the model. For example, to initialize alpha to 1.23 and delta to 4.57, you would type

```plaintext
   gmm ..., from(alpha 1.23 delta 4.57) ...
```

or equivalently

```plaintext
   matrix define initval = (1.23, 4.57)
   gmm ..., from(initval) ...
```

Initial values declared in the from() option override any that are declared within substitutable expressions. If you specify a parameter that does not appear in your model, gmm exits with an error message. If you specify a matrix, the values must be in the same order in which the parameters are declared in your model.

igmmiterate(#), igmmeps(#), and igmmweps(#) control the iterative process for the iterative GMM estimator. These options can be specified only if you also specify igmm.

igmmiterate(#) specifies the maximum number of iterations to perform with the iterative GMM estimator. The default is the number set using set maxiter, which is 16,000 by default.

igmmeps(#) specifies the convergence criterion used for successive parameter estimates when the iterative GMM estimator is used. The default is igmmeps(1e-6). Convergence is declared when the relative difference between successive parameter estimates is less than igmmeps() and the relative difference between successive estimates of the weight matrix is less than igmmweps().

igmmweps(#) specifies the convergence criterion used for successive estimates of the weight matrix when the iterative GMM estimator is used. The default is igmmweps(1e-6). Convergence is declared when the relative difference between successive parameter estimates is less than igmmeps() and the relative difference between successive estimates of the weight matrix is less than igmmweps().

optimization_options: technique(), conv_maxiter(), conv_ptol(), conv_vtol(), conv_nrtol(), tracelevel(). technique() specifies the optimization technique to use; gn (the default), nr, dfp, and bfgs are allowed. conv_maxiter() specifies the maximum number
of iterations; \texttt{conv_ptol()}, \texttt{conv_vtol()}, and \texttt{conv_nrtol()} specify the convergence criteria for the parameters, gradient, and scaled Hessian, respectively. \texttt{tracelevel()} allows you to obtain additional details during the iterative process. See \cite{M-5} \texttt{optimize()}.

The following options pertain only to the moment-evaluator program version of \texttt{gmm}.

\begin{itemize}
\item \texttt{Model} \texttt{evaluator_options} refer to any options allowed by your \texttt{moment-prog}.
\item \texttt{hasderivatives} and \texttt{haslfdervatives} indicate that you have written your moment-evaluator program to compute derivatives. You may specify one or the other but not both. If you do not specify either of these options, \texttt{gmm} computes the derivatives numerically.
\item \texttt{hasderivatives} indicates that your moment-evaluator program computes parameter-level derivatives.
\item \texttt{haslfdervatives} indicates that your moment-evaluator program computes equation-level derivatives and is useful only when you specify the parameters of your model using the \texttt{\{lcname:varlist\}} syntax of the \texttt{parameters()} option.
\end{itemize}

See \textit{Details of moment-evaluator programs} below for more information.

\texttt{equations(namelist)} specifies the names of the residual equations in the model. If you specify both \texttt{equations()} and \texttt{nequations()}, the number of names in the former must match the number specified in the latter.

\texttt{nequations(#)} specifies the number of residual equations in the model. If you do not specify names with the \texttt{equations()} option, \texttt{gmm} numbers the residual equations 1, 2, 3, \ldots. If you specify both \texttt{equations()} and \texttt{nequations()}, the number of names in the former must match the number specified in the latter.

\texttt{parameters(namelist)} specifies the names of the parameters in the model. The names of the parameters must comply with the naming conventions of Stata’s variables; see \cite{U} \textit{11.3 Naming conventions}.

Alternatively, you can use parameter equation notation to specify linear combinations of parameters. Each linear combination is of the form \texttt{\{lcname:varlist\}}, where \texttt{varlist} is one or more variable names. Specify the \texttt{system variable} \texttt{\_cons} in \texttt{varlist} to include a constant term. Distinguish between \texttt{\{lcname:varlist\}}, in which \texttt{lcname} identifies the linear combination, and \texttt{(reqname:rexp)}, in which \texttt{reqname} identifies the residual equation. When you use linear-combination syntax, \texttt{gmm} prepends each element of the parameter vector passed to your evaluator program with \texttt{lcname}: to generate unique names.

If you specify both \texttt{parameters()} and \texttt{nparameters()}, the number of names in the former must match the number specified in the latter.

\texttt{nparameters(#)} specifies the number of parameters in the model. If you do not specify names with the \texttt{parameters()} option, \texttt{gmm} names them \texttt{b1}, \texttt{b2}, \ldots, \texttt{b#}. If you specify both \texttt{parameters()} and \texttt{nparameters()}, the number of names in the former must match the number specified in the latter.

The following option is available with \texttt{gmm} but is not shown in the dialog box:

\texttt{coeflegend}; see \cite{R} \textit{Estimation options}. 

Remarks and examples

Remarks are presented under the following headings:

- Introduction
- Substitutable expressions
- The weight matrix and two-step estimation
- Obtaining standard errors
- Factor-variable coefficients in multiple residual functions
- Parameter interpretation using margins
- Exponential (Poisson) regression models
- Specifying derivatives
- Exponential regression models with panel data
- Rational-expectations models
- System estimators
- Dynamic panel-data models
- Details of moment-evaluator programs

Introduction

The GMM estimator is a workhorse of modern econometrics and is discussed in all the leading textbooks, including Cameron and Trivedi (2005, 2010), Davidson and MacKinnon (1993), Greene (2018, 500–534), Ruud (2000), Hayashi (2000), Wooldridge (2010), Hamilton (1994), and Baum (2006). An excellent treatise on GMM with a focus on time-series applications is Hall (2005). The collection of papers by Mátyás (1999) provides both theoretical and applied aspects of GMM. Here we give a brief introduction to the methodology and emphasize how the various options of gmm are used.

The starting point for the GMM estimator is the analogy principle, which says we can estimate a parameter by replacing a population moment condition with its sample analogue. For example, the mean of an independent and identically distributed (i.i.d.) population is defined as the value $\mu$ such that the first (central) population moment is zero; that is, $\mu$ solves $E(y - \mu) = 0$, where $y$ is a random draw from the population. The analogy principle tells us that to obtain an estimate, $\hat{\mu}$, of $\mu$, we replace the population-expectations operator with its sample analogue (Manski 1988; Wooldridge 2010),

$$ E(y - \mu) = 0 \implies \frac{1}{N} \sum_{i=1}^{N} (y_i - \hat{\mu}) = 0 \implies \hat{\mu} = \frac{1}{N} \sum_{i=1}^{N} y_i $$

where $N$ denotes sample size, and $y_i$ represents the $i$th observation of $y$ in our dataset. The estimator $\hat{\mu}$ is known as the method of moments (MM) estimator because we started with a population moment condition and then applied the analogy principle to obtain an estimator that depends on the observed data.

Ordinary least-squares (OLS) regression can also be viewed as an MM estimator. In the model

$$ y = \mathbf{x}'\beta + u $$

we assume that $u$ has mean zero conditional on $\mathbf{x}$: $E(u|\mathbf{x}) = 0$. This conditional expectation implies the unconditional expectation $E(\mathbf{x}u) = 0$ because, with the law of iterated expectations,

$$ E(\mathbf{x}u) = E_{\mathbf{x}} \{ E(\mathbf{x}u|\mathbf{x}) \} = E_{\mathbf{x}} \{ \mathbf{x} E(u|\mathbf{x}) \} = 0 $$

(Using the law of iterated expectations to derive unconditional expectations based on conditional expectations, perhaps motivated by subject theory, is extremely common in GMM estimation.) Continuing, we see that

$$ E(\mathbf{x}u) = E \{ \mathbf{x}(y - \mathbf{x}'\beta) \} = 0 $$
Applying the analogy principle, we obtain
\[
E \{ x(y - x' \beta) \} \rightarrow \frac{1}{N} \sum_{i=1}^{N} x_i (y_i - x'_i \beta) = 0
\]
so that
\[
\hat{\beta} = \left( \sum_i x_i x'_i \right)^{-1} \sum_i x_i y_i
\]
which is just the more familiar formula \( \hat{\beta} = (X'X)^{-1} X'y \) written with summation notation.

In both of the previous examples, the number of parameters we were estimating equaled the number of moment conditions. In the first example, we estimated one parameter, \( \mu \), and had one moment condition \( E(y - \mu) = 0 \). In the second example, the parameter vector \( \beta \) had \( k \) elements, as did the vector of regressors \( x \), yielding \( k \) moment conditions. Ignoring peculiar cases, we see that a model of \( m \) equations in \( m \) unknowns has a unique solution; and because the residual equations in these examples were linear, we could solve for the parameters analytically. If the moment conditions had been nonlinear, we would have had to use numerical techniques to solve for the parameters, but that is not a significant limitation with modern computers.

What if we have more moment conditions than parameters? Say we have \( q \) moment conditions and \( k \) parameters. A model of \( q > k \) equations in \( k \) unknowns does not have a unique solution. Any size-\( k \) subset of the moment conditions would yield a consistent parameter estimate, though the parameter estimate would in general be different depending on which \( k \) moment conditions we used.

For concreteness, let’s return to our regression model,
\[
y = x'\beta + u
\]
Now, however, we no longer wish to assume that \( E(xu) = 0 \); we suspect that the error term \( u \) affects one or more elements of \( x \). Thus, we can no longer use the OLS estimator. Suppose we have a vector \( z \) with the properties that \( E(zu) = 0 \), that the rank of \( E(z'z) \) equals \( q \), and that the rank of \( E(z'x) = k \). The first assumption simply states that \( z \) is not correlated with the error term. The second assumption rules out perfect collinearity among the elements of \( z \). The third assumption, known as the rank condition in econometrics, ensures that \( z \) is sufficiently correlated with \( x \) and that the estimator is feasible. If some elements of \( x \) are not correlated with \( u \), then they should also appear in \( z \).

If \( q < k \), then the rank of \( E(z'x) < k \), which violates the rank condition.

If \( q = k \), then we can use the simpler MM estimator we already discussed; we would obtain what is sometimes called the simple instrumental-variables estimator \( \hat{\beta} = (\sum_i z_i x'_i)^{-1} \sum_i z_i y_i \). The rank condition ensures that \( \sum_i z_i x'_i \) is invertible, at least in the population.

If \( q > k \), the GMM estimator chooses the value, \( \hat{\beta} \), that minimizes a quadratic function of the moment conditions. We could define
\[
\hat{\beta} \equiv \arg \min_{\beta} \left\{ \frac{1}{N} \sum_i z_i u_i(\beta) \right\}' \left\{ \frac{1}{N} \sum_i z_i u_i(\beta) \right\}
\]
where for our linear regression example \( u_i(\beta) = y_i - x'_i \beta \). This estimator tries to make the moment conditions as close to zero as possible. This simple estimator, however, applies equal weight to each of the moment conditions; and as we will see later, we can obtain more efficient estimators by choosing to weight some moment conditions more highly than others.
Consider the quadratic function

$$Q(\beta) = \left\{ \frac{1}{N} \sum_i z_i u_i(\beta) \right\}' W \left\{ \frac{1}{N} \sum_i z_i u_i(\beta) \right\}$$

where $W$ is a symmetric positive-definite matrix known as a weight matrix. Then we define the GMM estimator as

$$\hat{\beta} \equiv \arg \min_{\beta} Q(\beta)$$

Continuing with our regression model example, if we choose

$$W = \left( \frac{1}{N} \sum_i z_i z_i' \right)^{-1}$$

then we obtain

$$\hat{\beta} = \left\{ \left( \frac{1}{N} \sum_i x_i z_i' \right) \left( \frac{1}{N} \sum_i z_i z_i' \right)^{-1} \left( \frac{1}{N} \sum_i z_i x_i' \right) \right\}^{-1} \times \left( \frac{1}{N} \sum_i x_i z_i' \right) \left( \frac{1}{N} \sum_i z_i z_i' \right)^{-1} \left( \frac{1}{N} \sum_i z_i y_i \right)$$

which is the well-known two-stage least-squares (2SLS) estimator. Our choice of weight matrix here was based on the assumption that $u$ was homoskedastic. A feature of GMM estimation is that by selecting different weight matrices, we can obtain estimators that can tolerate heteroskedasticity, clustering, autocorrelation, and other features of $u$. See [R] ivregress for more information about the 2SLS and linear GMM estimators.

Returning to the case where the model is “just identified”, meaning that $q = k$, if we apply the GMM estimator, we will obtain the same estimate, $\hat{\beta}$, regardless of our choice of $W$. Because $q = k$, if a unique solution exists, it will set all the sample moment conditions jointly to zero, so $W$ has no impact on the value of $\beta$ that minimizes the objective function.

We will highlight other features of the GMM estimator and the gmm command as we proceed through examples. First, though, we discuss how to specify moment conditions by using substitutable expressions.

**Substitutable expressions**

To use the interactive version of gmm, you define the moment conditions by using substitutable expressions. Your moment conditions are of the form $E \{ z_i' u_i(\beta) \} = 0$, where $u_i(\beta)$ is a residual expression that depends on the parameter vector $\beta$ as well as variables in your dataset, though we suppress expressing the variables for notational simplicity.

gmm requires you to write a substitutable expression for $u_i(\beta)$. This substitutable expression is the right-hand side of the model written in terms of $u$, or in the language of Stata syntax, a “residual equation”. For example, suppose you want to fit the function $y = f(x; \beta) + u$. In this example, $u_i(\beta) = u = y - f(x; \beta)$, so you would type

```
gmm (y - expression for f(x;\beta)), . . .
```

Note that we are not restricted to models with additive error terms.
In general, there are three rules to follow when defining substitutable expressions:

1. Parameters of the model are bound in curly braces: \( \{b0\}, \{param\}, \text{etc.} \) Parameter names must follow the same conventions as variable names. See \([U]\ 11.3\ Naming\ conventions\).

2. Initial values for parameters are given by including an equal sign and the initial value inside the curly braces: \( \{b0=1\}, \{param=3.571\}, \text{etc.} \)
   
   You can also specify initial values by using the \( \text{from()} \) option. Initial values specified in \( \text{from()} \) override whatever initial values are given within the substitutable expression. If you do not specify an initial value for a parameter, it is initialized to 0.

3. Linear combinations of variables can be included using the notation \( \{lcname:varlist\}: \{xb:\text{mpg price weight}, \{score: w x z\}, \text{etc.} \)
   
   Parameters of linear combinations are initialized to 0.

Substitutable expressions may use any mathematical expression involving scalars and variables. See \([U]\ 13.2\ Operators\) and \([U]\ 13.3\ Functions\) for more information on expressions.

The notation \( \{xb:x1 \ x2 \ x3\} \) tells \texttt{gmm} that you want a linear combination of the variables \( x1, x2, \text{and} x3 \). We named this linear combination \( xb \), so \texttt{gmm} will name the three parameters \( xb:x1, xb:x2, \text{and} xb:x3 \), which corresponds to the three variables \( x1, x2, \text{and} x3 \) in the \( xb \) equation. Specify \%cons to include a constant term in a linear combination. Factor variables and time-series operators are allowed; see \([U]\ 11.4.3\ Factor\ variables\) and \([U]\ 11.4.4\ Time-Series\ varlists\).

Once we have declared the variables in the linear combination \( xb \), we can refer to the linear combination in our substitutable expression by using the notation \( xb: \). The colon is not optional; it tells \texttt{gmm} that you are referring to a previously declared linear combination, not an individual parameter. This shorthand notation is also handy when specifying derivatives, as we will show later.

Example 1: OLS regression

In \textit{Introduction}, we stated that OLS is an MM estimator. Say that we want to fit the model

\[
\text{mpg} = \beta_0 + \beta_1 \text{weight} + \beta_2 \text{length} + u
\]

where \( u \) is an i.i.d. error term. Recall that the moment condition for OLS regression is \( E(xu) = 0 \), where \( x \), the list of instruments, is the same as the list of regressors in the model. Writing this in the form required for a \texttt{gmm} substitutable expression, we have

\[
u = \text{mpg} - \beta_0 - \beta_1 \text{weight} - \beta_2 \text{length}\]

The right-hand side of the equation is the substitutable expression that we will provide to \texttt{gmm}. We give \( \beta_0, \beta_1, \text{and} \beta_2 \) the parameter names \( b0, b1, \text{and} b2 \) and enclose them in curly braces. Because linear combinations declared in substitutable expressions do not include a constant term by default, we include our own \( (b0) \). We specify the regressors, \texttt{weight} and \texttt{length}, with their respective parameters and also in the \texttt{instruments()}\ option. \texttt{gmm} includes a constant term in the instrument list by default, so we do not need to add an additional term there. Thus, our command is
. use https://www.stata-press.com/data/r16/auto
(1978 Automobile Data)
. gmm (mpg - {b1}*weight - {b2}*length - {b0}), instruments(weight length)

Step 1
Iteration 0:  GMM criterion Q(b) = 475.4138
Iteration 1:  GMM criterion Q(b) = 2.696e-20
Iteration 2:  GMM criterion Q(b) = 3.329e-27

Step 2
Iteration 0:  GMM criterion Q(b) = 5.109e-28
Iteration 1:  GMM criterion Q(b) = 7.237e-32

note: model is exactly identified

GMM estimation
Number of parameters = 3
Number of moments = 3
Initial weight matrix: Unadjusted Number of obs = 74
GMM weight matrix: Robust

|        | Coef.  | Std. Err. | z      | P>|z|   | [95% Conf. Interval] |
|--------|--------|-----------|--------|-------|---------------------|
| /b1    | -.0038515 | .0019472  | -1.98  | 0.048 | -.0076678 to -.0000351 |
| /b2    | -.0795935 | .0677528  | -1.17  | 0.240 | -.2123866 to .0531996 |
| /b0    | 47.88487  | 7.50599   | 6.38   | 0.000 | 33.1734 to 62.59634  |

Instruments for equation 1: weight length _cons

Because the number of moments equals the number of parameters we are estimating, the model is said to be “just identified” or “exactly identified”. Therefore, the choice of weight matrix has no impact on the solution to (1), and the criterion function $Q(\beta)$ achieves its minimum value at 0.

The OLS estimator is a one-step GMM estimator, but we did not bother to specify the onestep option, because the model is just identified. Doing a second step of GMM estimation affects neither the point estimates nor the standard errors, so to keep the syntax as simple as possible, we did not include the onestep option. The first step of estimation resulted in $Q(\beta) = 0$ as expected, and the second step of estimation did not change the minimized value of $Q(\beta)$. ($4 \times 10^{-27}$ and $3 \times 10^{-31}$ are both 0 for all practical purposes.)

When you do not specify either the wmatrix() or the vce() option, gmm reports heteroskedasticity-robust standard errors. The parameter estimates reported here match those that we would obtain from the command

. regress mpg weight length, vce(robust)

The standard errors reported by that regress command would be larger than those reported by gmm by a factor of $\sqrt{74/71}$ because regress makes a small-sample adjustment to the estimated variance matrix while gmm does not. Likewise, if we had specified the vce(unadjusted) option with our gmm command, then our standard errors would differ by a factor of $\sqrt{74/71}$ from those reported by regress without the vce(robust) option.

We could have submitted our substitutable expression using the notation for linear combinations of parameters. If we select xb as the name of our parameter equation, we could type

. gmm (mpg - {xb: weight length _cons}), instruments(weight length)

and obtain identical results. With this syntax, instead of having parameters b1, b2, and b0, we would have parameters xb:weight, xb:length, and xb:_cons. Note that _cons allows you to include a constant in a linear combination, so this time, we do not have to specify a separate parameter from our varlist.
Factor variables and time-series operated variables are allowed in the linear combinations. For example,

```
.regress mpg i.foreign i.foreign#c.weight, vce(robust)
```

produces the same results as

```
.gmm (mpg - {xb:i.foreign i.foreign#c.weight _cons}),
> instruments(i.foreign i.foreign#c.weight)
```

See [U] 11.4.3 Factor variables and [U] 11.4.4 Time-series varlists for an introduction to factor variables and time-series operators. See example 4 for an example of factor-variable syntax with `gmm`. See example 16 for an example using time-series operated variables.

### Example 2: Instrumental-variables regression

In Introduction, we mentioned that 2SLS can be viewed as a GMM estimator. In example 1 of [R] ivregress, we fit by a 2SLS model of rental rates (`rent`) as a function of the value of owner-occupied housing (`hsngval`) and the percentage of the population living in urban areas (`pcturban`):

\[
rent = \beta_0 + \beta_1 hsngval + \beta_2 pcturban + u
\]

We argued that random shocks that affect rental rates likely also affect housing values, so we treated `hsngval` as an endogenous variable. As additional instruments, we used family income, `faminc`, and three regional dummies (`reg2`–`reg4`).

To replicate the results of `ivregress 2sls` by using `gmm`, we type

```
.use https://www.stata-press.com/data/r16/hsng2, clear
(1980 Census housing data)
.gmm (rent - {xb:hsngval pcturban _cons}),
> instruments(pcturban faminc reg2-reg4) vce(unadjusted) onestep
```

```
Step 1
Iteration 0: GMM criterion Q(b) = 56115.03
Iteration 1: GMM criterion Q(b) = 110.91583
Iteration 2: GMM criterion Q(b) = 110.91583
GMM estimation
Number of parameters = 3
Number of moments = 6

Instruments for equation 1: pcturban faminc reg2 reg3 reg4 _cons
```

We specified `vce(unadjusted)` so that we would obtain an unadjusted VCE matrix and our standard errors would match those reported in [R] ivregress.

Note how we specified the `instruments()` option. In Introduction, we mentioned that the moment conditions for the 2SLS estimator are \(E(zu) = 0\), and we mentioned that if some elements of \(x\) (the regressors) are not endogenous, then they should also appear in \(z\). In this model, we assume the regressor `pcturban` is exogenous, so we included it in the list of instrumental variables. Commands like `ivregress`, `ivprobit`, and `ivtobit` accept standard `varlists`, so they can deduce the exogenous regressors in the model. Because `gmm` accepts arbitrary functions in the form of substitutable expressions, it has no way of discerning the exogenous variables of the model on its own.
Also notice that we specified the onestep option. The 2SLS estimator is a one-step GMM estimator that is based on a weight matrix that assumes the error terms are i.i.d. Unlike the previous example, this example had more instruments than parameters, so the minimized value of $Q(\beta)$ is nonzero. We discuss the weight matrix and its relationship to two-step estimation next.

**The weight matrix and two-step estimation**

Recall our definition of the GMM estimator given in (1). The estimator, $\hat{\beta}$, depends on the choice of the weight matrix, $W$. Under relatively mild assumptions, our estimator, $\hat{\beta}$, is consistent regardless of the choice of $W$, so how are we to decide what $W$ to use? The most common solution is to use the two-step estimator, which we now describe.

A key result in Hansen’s (1982) seminal paper is that if we denote by $S$ the covariance matrix of the moment conditions, then the optimal (in a way we make precise later) GMM estimator is the one that uses a weight matrix equal to the inverse of the moment covariance matrix. That is, if we let $S = \text{Cov}(zu)$, then we want to use $W = S^{-1}$. But how do we obtain $S$ in the first place?

If we assume that the errors are i.i.d., then

$$\text{Cov}(zu) = E(u^2zz') = \sigma^2E(zz')$$

where $\sigma^2$ is the variance of $u$. Because $\sigma^2$ is a positive scalar, we can ignore it when solving (1). Thus we compute

$$\hat{W}_1 = \left( \frac{1}{N} \sum_i z_i z_i' \right)^{-1}$$

which does not depend on any unknown model parameters. (Notice that $\hat{W}_1$ is the same weight matrix used in 2SLS.) Given $\hat{W}_1$, we can solve (1) to obtain an initial estimate, say, $\hat{\beta}_1$.

Our estimate, $\hat{\beta}_1$, is consistent, so by Slutsky’s theorem, the sample residuals $\hat{u}$ computed at this value of $\beta$ will also be consistent. Using virtually the same arguments used to justify the Huber/Eicker/White heteroskedasticity-robust VCE, if we assume that the residuals are independent though not identically distributed, we can estimate $S$ as

$$\hat{S} = \frac{1}{N} \sum_i \hat{u}_i^2 z_i z_i'$$

Then, in the second step, we re-solve (1), using $\hat{W}_2 = \hat{S}^{-1}$, which yields the two-step GMM estimate $\hat{\beta}_2$. If the residuals exhibit clustering, you can specify `wmatrix(cluster varname)` so that `gmm` computes a weight matrix that does not assume the $u_i$’s are independent within clusters identified by `varname`. You can specify `wmatrix(hac ...)` to obtain weight matrices that are suitable for when the $u_i$’s exhibit autocorrelation as well as heteroskedasticity.

We could take the point estimates from the second round of estimation and use them to compute yet another weight matrix, $\hat{W}_3$, say, re-solve (1) yet again, and so on, stopping when the parameters or weight matrix do not change much from one iteration to the next. This procedure is known as the iterative GMM estimator and is obtained with the `igmm` option. Asymptotically, the two-step and iterative GMM estimators have the same distribution. However, Hall (2005, 90) suggests that the iterative estimator may have better finite-sample properties.
Instead of computing $\hat{W}_1$ as in (2), we could simply choose $\hat{W}_1 = I$, the identity matrix. The initial estimate, $\hat{\beta}_1$, would still be consistent. You can request this behavior by specifying the \texttt{winitial(identity)} option. However, if you specify all of your moment conditions of the form $E(zu) = 0$, we recommend using the default \texttt{winitial(unadjusted)} instead; the rescaling of the moment conditions implied by using a homoskedastic initial weight matrix makes the numerical routines used to solve (1) more stable.

If you fit a model with more than one of the moment conditions of the form $E\{h(z; \beta)\} = 0$, then you must use \texttt{winitial(identity)} or \texttt{winitial(unadjusted, independent)}. With moment conditions of that form, you do not specify a list of instruments, and \texttt{gmm} cannot evaluate (2)—the matrix expression in parentheses would necessarily be singular, so it cannot be inverted.

### Example 3: Two-step linear GMM estimator

From the previous discussion and the comments in \textit{Introduction}, we see that the linear 2SLS estimator is a one-step GMM estimator where we use the weight matrix defined in (2) that assumes the errors are i.i.d. If we use the 2SLS estimate of $\beta$ to obtain the sample residuals, compute a new weight matrix based on those residuals, and then do a second step of GMM estimation, we obtain the linear two-step GMM estimator as implemented by \texttt{ivregress gmm}.

In example 3 of \cite{R} \texttt{ivregress}, we fit the model of rental rates as discussed in example 2 above. We now allow the residuals to be heteroskedastic, though we will maintain our assumption that they are independent. We type

\begin{verbatim}
. gmm (rent - {xb:hsngval pcturban _cons}), instruments(pcturban faminc reg2-reg4)
\end{verbatim}

\begin{verbatim}
Step 1
Iteration 0:  GMM criterion Q(b) = 56115.03
Iteration 1:  GMM criterion Q(b) = 110.91583
Iteration 2:  GMM criterion Q(b) = 110.91583
Step 2
Iteration 0:  GMM criterion Q(b) = .2406087
Iteration 1:  GMM criterion Q(b) = .13672801
Iteration 2:  GMM criterion Q(b) = .13672801
\end{verbatim}

\begin{verbatim}
GMM estimation
Number of parameters =  3
Number of moments  =  6
Initial weight matrix: Unadjusted       Number of obs  =  50
GMM weight matrix:      Robust
\end{verbatim}

Instruments for equation 1: pcturban faminc reg2 reg3 reg4 _cons
\end{verbatim}

By default, \texttt{gmm} computes a heteroskedasticity-robust weight matrix before the second step of estimation, though we could have specified \texttt{wmatrix(robust)} if we wanted to be explicit. Because we did not specify the \texttt{vce()} option, \texttt{gmm} used a heteroskedasticity-robust one. Our results match those in example 3 of \cite{R} \texttt{ivregress}. Moreover, the only substantive difference between this example and example 2 is that here we did not specify the \texttt{onestep} option, so we obtain the two-step estimates.
Obtaining standard errors

This section is a bit more theoretical and can be skipped on first reading. However, the information is sufficiently important that you should return to this section at some point.

So far in our discussion, we have focused on point estimation without much mention of how we obtain the standard errors of the estimates. We also mentioned that if we choose $W$ to be the inverse of the covariance matrix of the moment conditions, then we obtain the “optimal” GMM estimator. We elaborate those points now.

Using mostly standard statistical arguments, we can show that for the GMM estimator defined in (1), the variance of $\hat{\beta}$ is given by

$$\text{Var}(\hat{\beta}) = \frac{1}{N} \left\{ \mathbf{G}(\hat{\beta})' \mathbf{W} \mathbf{G}(\hat{\beta}) \right\}^{-1} \mathbf{G}(\hat{\beta})' \mathbf{W} \mathbf{S} \mathbf{W} \mathbf{G}(\hat{\beta}) \left\{ \mathbf{G}(\hat{\beta})' \mathbf{W} \mathbf{G}(\hat{\beta}) \right\}^{-1}$$  \hspace{1cm} (3)

where

$$\mathbf{G}(\hat{\beta}) = \frac{1}{N} \sum_i \mathbf{z}_i \frac{\partial u_i}{\partial \beta} \bigg|_{\beta = \hat{\beta}} \quad \text{or} \quad \mathbf{G}(\hat{\beta}) = \frac{1}{N} \sum_i \frac{\partial \mathbf{h}_i}{\partial \beta} \bigg|_{\beta = \hat{\beta}}$$

as the case may be and $\mathbf{S} = E(\mathbf{z}uu' \mathbf{z}')$.

Assuming the vce(unadjusted) option is not specified, gmm reports standard errors based on the robust variance matrix defined in (3). For the two-step estimator, $\mathbf{W}$ is the weight matrix requested with the wmatrix() option, and it is calculated based on the residuals obtained after the first estimation step. The second-step point estimates and residuals are obtained, and $\mathbf{S}$ is calculated based on the specification of the vce() option. For the iterated estimator, $\mathbf{W}$ is calculated based on the second-to-last round of estimation, while $\mathbf{S}$ is based on the residuals obtained after the last round of estimation. Computation of the covariance matrix for the one-step estimator is, perhaps surprisingly, more involved; we discuss the covariance matrix with the one-step estimator in the technical note at the end of this section.

If the model is exactly identified, the matrix $\mathbf{G}(\hat{\beta})$ is square, and (3) simplifies to the following:

$$\text{Var}(\hat{\beta}) = \frac{1}{N} \mathbf{G}(\hat{\beta})^{-1} \mathbf{S} (\mathbf{G}(\hat{\beta})')^{-1}$$

If we choose the weight matrix to be the inverse of the covariance matrix of the moment conditions so that $\mathbf{W} = \mathbf{S}^{-1}$, then (3) simplifies substantially:

$$\text{Var}(\hat{\beta}) = \frac{1}{N} \left\{ \mathbf{G}(\hat{\beta})' \mathbf{W} \mathbf{G}(\hat{\beta}) \right\}^{-1}$$  \hspace{1cm} (4)

The GMM estimator constructed using this choice of weight matrix along with the covariance matrix in (4) is known as the “optimal” GMM estimator. One can show that if in fact $\mathbf{W} = \mathbf{S}^{-1}$, then the variance in (4) is smaller than the variance in (3) of any other GMM estimator based on the same moment conditions but with a different choice of weight matrix. Thus the optimal GMM estimator is also known as the efficient GMM estimator because it has the smallest variance of any estimator based on the given moment conditions.

To obtain standard errors from gmm based on the optimal GMM estimator, you specify the vce(unadjusted) option. We call that VCE unadjusted because we do not recompute the residuals after estimation to obtain the matrix $\mathbf{S}$ required in (3) or allow for the fact that those residuals may not be i.i.d. Some statistical packages by default report standard errors based on (4) and offer standard errors based on (3) only as an option or not at all. While the optimal GMM estimator is theoretically appealing, Cameron and Trivedi (2005, 177) suggest that in finite samples, it need not perform better than the GMM estimator that uses (3) to obtain standard errors.
Technical note

Computing the covariance matrix of the parameters after using the one-step estimator is actually a bit more complex than after using the two-step or iterative estimator. We can illustrate most of the intricacies by using linear regression with moment conditions of the form \( E\{x(y - x'\beta)\} = 0 \).

If you specify \texttt{winitial(unadjusted)} and \texttt{vce(unadjusted)}, then the initial weight matrix will be computed as

\[
\hat{W}_1 = \left( \frac{1}{N} \sum_i x_i x_i' \right)^{-1}
\]

Moreover, for linear regression, we can show that

\[
\mathbb{G}(\hat{\beta}) = \frac{1}{N} \sum_i x_i x_i'
\]

so that (4) becomes

\[
\text{Var}\left(\hat{\beta}\right) = \frac{1}{N} \left\{ \left( \frac{1}{N} \sum_i x_i x_i' \right) \left( \frac{1}{N} \sum_i x_i x_i' \right)^{-1} \left( \frac{1}{N} \sum_i x_i x_i' \right) \right\}^{-1}
\]

\[
= \left( \sum_i x_i x_i' \right)^{-1}
\]

\[
= (X'X)^{-1}
\]

However, we know that the nonrobust covariance matrix for the OLS estimator is actually \( \hat{\sigma}^2 (X'X)^{-1} \). What is missing from (6) is the scalar \( \hat{\sigma}^2 \), the estimated variance of the residuals. When you use the one-step estimator and specify \texttt{winitial(unadjusted)}, the weight matrix (5) does not include the \( \hat{\sigma}^2 \) term because \texttt{gmm} does not have a consistent estimate of \( \beta \) from which it can then estimate \( \sigma^2 \). The point estimates are still correct because multiplying the weight matrix by a scalar factor does not affect the solution to the minimization problem.

To circumvent this issue, if you specify \texttt{winitial(unadjusted)} and \texttt{vce(unadjusted)}, \texttt{gmm} uses the estimated \( \hat{\beta} \) (which is consistent) to obtain a new unadjusted weight matrix that does include the term \( \hat{\sigma}^2 \) so that evaluating (4) will yield correct standard errors.

If you use the two-step or iterated GMM estimator, this extra effort is not needed to obtain standard errors because the first-step (and subsequent steps') estimate of \( \beta \) is consistent and can be used to estimate \( \sigma^2 \) or some other weight matrix based on the \texttt{wmatrix()} option. Straightforward algebra shows that this extra effort is also not needed if you request any type of adjusted (robust) covariance matrix with the one-step estimator.

A similar issue arises when you specify \texttt{winitial(identity)} and \texttt{vce(unadjusted)} with the one-step estimator. Again the solution is to compute an unadjusted weight matrix after obtaining \( \hat{\beta} \) so that (4) provides the correct standard errors.

We have illustrated the problem and solution using a single-equation linear model. However, the problem arises whenever you use the one-step estimator with an unadjusted VCE, regardless of the number of equations, and \texttt{gmm} handles all the details automatically. Computation of Hansen’s \( J \) statistic presents an identical issue, and \texttt{gmm} takes care of that as well.
If you supply your own initial weight matrix by using `winitial(matname)`, then the standard errors (as well as the $J$ statistic reported by `estat overid`) are based on that weight matrix. You should verify that the weight matrix you provide will yield appropriate statistics.

**Factor-variable coefficients in multiple residual functions**

The long example in this section uses `gmm` to replicate the results produced by `regress` with factor variables and `margins`. It illustrates how to refer to the coefficients on factor variables in linear combinations in subsequent residual functions. The example also shows how to use `gmm` to address the two-step estimation problem, or the inconsistency of standard errors produced by two-step estimators that depend on previously estimated parameters.

Example 4: Means of linear combinations of factor variables

The mean of a variable when everyone in a population receives a given treatment level is known as a potential-outcome mean. We use `regress` and `margins` to estimate the potential-outcome means of a mother's smoking behavior while pregnant on the birthweight of her baby after controlling for the mother's age and an indicator for whether the mother had a prenatal visit in the first trimester. We use an extract of data from Cattaneo (2010) in which `bweight` is the baby's birthweight in grams, `mbsmoke` is a binary variable indicating whether a mother smoked while pregnant, `mage` is the mother's age, and `prenatal1` is a binary variable indicating whether the mother had a prenatal visit in the first trimester.

We use `regress` to estimate the regression coefficients.

```stata
. use https://www.stata-press.com/data/r16/cattaneo2
. regress bweight ibn.mbsmoke ibn.mbsmoke#(c.mage i.prenatal1), noconstant vce(robust)
Linear regression                     Number of obs = 4,642
                                      F(6, 4636) = 27751.75
                                      Prob > F    = 0.0000
                                      R-squared  = 0.9726
                                      Root MSE   = 565.08

smoker    |          |              |     |         |                            |
          | 64.61752 |    39.72317   1.63| 0.104| -13.25879 - 142.4938       |
prenatal1 |          |              |     |         |                            |
nonsmoker |          |              |     |         |                            |
          |          |              |     |         |                            |
smoker#   |          |              |     |         |                            |
          |          |              |     |         |                            |
  Yes     |          |              |     |         |                            |
          |          |              |     |         |                            |
We used factor variables to interact `mbsmoke` with the other covariates to allow for separate coefficients for smoking and nonsmoking mothers.
The postestimation command margins uses the estimated regression coefficients to estimate the potential-outcome means of bweight, first assuming that no mother smoked and then assuming that all mothers smoked.

```
.margins i.mbsmoke, vce(unconditional)
```

|                  | Unconditional | Std. Err. | t   | P>|t| | [95% Conf. Interval] |
|------------------|---------------|-----------|-----|-----|---------------------|
| mbsmoke          |               |           |     |     |                     |
| nonsmoker        | 3407.506      | 9.34694   | 364.56 | 0.000 | 3389.181 3425.83    |
| smoker           | 3138.23       | 21.20463  | 148.00 | 0.000 | 3096.659 3179.801   |
```

Note that the standard errors for the estimated means account for the estimation error in the estimated coefficients used to compute them.

Before using gmm to simultaneously estimate the regression coefficients and the potential-outcome means, we demonstrate the equivalence of point estimates from gmm and regress and illustrate the two-step estimation problem. First, we use gmm to estimate just the regression coefficients. Note that we specify the factor variables in the linear combination xb: and in the instrument list.

```
.gmm (eq1: bweight - {xb:ibn.mbsmoke ibn.mbsmoke#(c.mage i.prenatal1)}),
> instruments(eq1: ibn.mbsmoke ibn.mbsmoke#(c.mage i.prenatal1), noconstant)
> coeflegend onestep
```

Step 1
Iteration 0:  GMM criterion Q(b) = 11316945
Iteration 1:  GMM criterion Q(b) = 7.143e-19
Iteration 2:  GMM criterion Q(b) = 2.051e-26
```

GMM estimation
Number of parameters = 6
Number of moments = 6
Initial weight matrix: Unadjusted
```

```

We specified the coeflegend option to learn the names of the coefficients on the factor variables in the linear combination. As expected, the point estimates are the same as those reported by regress.
Next, we illustrate the effect of the two-step estimation problem if we calculate the potential-outcome means by hand. We can calculate the mean when no mothers smoke by accessing these coefficients and then estimate the standard errors in the estimated means:

```
. generate mean0 = _b[xb:0.mbsmoke] + _b[xb:0.mbsmoke#c.mage]*mage > + _b[xb:0.mbsmoke#1.prenatal1]*prenatal1
. mean mean0
Mean estimation
Number of obs = 4,642

<table>
<thead>
<tr>
<th>Mean</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>mean0</td>
<td>3407.506</td>
<td>1.085503</td>
</tr>
</tbody>
</table>
```

The estimated potential-outcome mean for no mothers smoking is the same as that reported by `margins`, but the standard error is much smaller because `mean` ignores the estimation error in the coefficients. This underscores the importance of accounting for the estimation error when estimating the standard errors.

Now we use `gmm` to estimate the coefficients and the potential-outcome means simultaneously.

```
. gmm (eq1: bweight - {xb:ibn.mbsmoke ibn.mbsmoke#(c.mage i.prenatal1)}) > (eq2: {xb:0.mbsmoke} + {xb:0bn.mbsmoke#c.mage}*mage > + {xb:0.mbsmoke#1.prenatal1}*1.prenatal1 - {m0}) > (eq3: {xb:1.mbsmoke} + {xb:1.mbsmoke#c.mage}*mage > + {xb:1.mbsmoke#1.prenatal1}*1.prenatal1 - {m1}), > instruments(eq1: ibn.mbsmoke ibn.mbsmoke#(c.mage i.prenatal1), > noconstant) > instruments(eq2 eq3:) winitial(identity) onestep
Step 1
Iteration 0: GMM criterion Q(b) = 5.819e+09
Iteration 1: GMM criterion Q(b) = 3.108e-13
Iteration 2: GMM criterion Q(b) = 1.010e-22

```
This output has five noteworthy features.

1. We specify three different residual equations. The first, eq1:, defines the moment conditions for the regression using the covariates as instruments; eq2: is the moment condition for the potential outcome when no mothers smoke; and eq3: is the moment condition for the potential outcome when all mothers smoke.

2. In eq2: and eq3:, we refer to the individual coefficients on the factor variables in the linear combination xb: by enclosing their names in curly braces.

3. The option instruments() is repeatable. We first specify that the covariates in the regression are the instruments for the residual equation eq1: and then specify that only the unit variable, also known as the constant, is an instrument for each of eq2: and eq3:.

4. The point estimates and the standard errors match those reported by regress and margins, after accounting for the small-sample adjustment performed by regress.

5. Although the point estimates match, the standard errors reported by gmm are much larger than those reported by mean because gmm takes into account that the regression coefficients are estimated.

Parameter interpretation using margins

In the last section, we demonstrated how to use gmm to estimate potential-outcome means in a linear regression model jointly with the coefficients of the models. However, you can also estimate the potential-outcome mean, or any other predictive margins, by using the margins command after gmm. Using margins after gmm can allow more flexibility in the predictive margins that we estimate and is also more convenient. See Obtaining margins of responses in [R] margins for more information about predictive margins.

Example 5: Predicting treatment effects after estimation

In example 4, we used gmm to estimate potential-outcome means of a mother’s smoking behavior on her baby’s birthweight (in grams) after controlling for age and whether she had a prenatal visit in the first trimester. Here we demonstrate how to use margins after gmm to estimate the potential-outcome means.
First, we load the data and reestimate the regression coefficients.

```
. use https://www.stata-press.com/data/r16/cattaneo2

| smoker          | 3138.23      | 21.19321   | 148.08| 0.000 | 3096.692             | 3179.768                |
```

Our point estimates of the potential-outcome means exactly match those that appear as \m0 and \m1
```
in example 4. However, the standard errors are slightly higher because gmm and margins use different
```
values in the denominator for the formula for the robust covariance matrix. gmm uses \N while margins
```
uses $N - 1$, so the standard errors differ by a factor of $\sqrt{\frac{N}{(N - 1)}} = \sqrt{\frac{4,642}{4,641}} \approx 1.0002$. More details about the calculation of the standard errors are provided in *Marginal predictions with unconditional standard errors* in the Methods and formulas.

In addition to potential-outcome means, we can use margins to estimate the average treatment effect (ATE) of the mother’s smoking behavior on birthweight. We use the contrast operator `r.` to instruct margins to difference the potential-outcome means and estimate a treatment effect. We specify the `contrast(nowald)` option to suppress the Wald test that margins displays by default for contrasts.

```
. margins r.mbsmoke, vce(unconditional) contrast(nowald)

Contrasts of predictive margins                      Number of obs = 4,642
Expression : Linear prediction, predict()
--------------------------------------------------------------

Unconditional                     [95% Conf. Interval]
Contrast Std. Err.                
mbsmoke (smoker vs nonsmoker)     -269.2759  23.16069   -314.67   -223.8818

```

The ATE of $-269.28$ is interpreted as the difference between the average birthweight if all mothers in the population smoked and the average birthweight if all mothers in the population did not smoke. The average birthweight if all mothers were to smoke would be $269.28$ grams less than if they did not smoke.

> \textbf{Example 6: Exponential regression}

Cameron and Trivedi (2010, 323) fit a model of the number of doctor visits based on whether the patient has private insurance, whether the patient has a chronic disease, gender, and income. Here we fit that model by using \texttt{gmm}. To allow for potential excess dispersion, we will obtain a robust VCE matrix, which is the default for \texttt{gmm} anyway. We type

```

Instruments for equation 1: private chronic female income _cons

Our point estimates agree with those reported by Cameron and Trivedi (2010) to at least six significant digits; the small discrepancies are attributable to different optimization techniques and convergence criteria being used by gmm and poisson. The standard errors differ by a factor of $\sqrt{\frac{4412}{4411}}$ because gmm uses $N$ in the denominator of the formula for the robust covariance matrix, while the robust covariance matrix estimator used by poisson uses $N - 1$.

Technical note

That the GMM and maximum likelihood estimators of the exponential regression model coincide is not a general property of these two classes of estimators. The maximum likelihood estimator solves the score equations

$$
\frac{1}{N} \sum_{i=1}^{N} \frac{\partial \ln \ell_i}{\partial \beta} = 0
$$

where $\ell_i$ is the likelihood for the $i$th observation. These score equations can be viewed as the sample analogues of the population moment conditions

$$
E \left( \frac{\partial \ln \ell_i}{\partial \beta} \right) = 0
$$

establishing that maximum likelihood estimators represent a subset of the class of GMM estimators.

For the Poisson model,

$$
\ln \ell_i = -\exp(x_i^\prime \beta) + y_i x_i^\prime \beta - \ln y_i!
$$
so the score equations are

\[ \frac{1}{N} \sum_{i=1}^{N} x_i \left\{ y_i - \exp(x'_i \beta) \right\} = 0 \]

which are just the sample moment conditions implied by (8) that we used in the previous example. That is why our results using gmm match Cameron and Trivedi’s (2010) results using poisson.

On the other hand, an intuitive set of moment conditions to consider for GMM estimation of a probit model is

\[ E[x\{y - \Phi(x' \beta)\}] = 0 \]

where \( \Phi() \) is the standard normal cumulative distribution function. Differentiating the likelihood function for the maximum-likelihood probit estimator, we can show that the corresponding score equations are

\[ \frac{1}{N} \sum_{i=1}^{N} \left[ x_i \left\{ y_i \phi(x'_i \beta) \Phi(x'_i \beta) - (1 - y_i) \phi(x'_i \beta) \frac{1}{1 - \Phi(x'_i \beta)} \right\} \right] = 0 \]

where \( \phi() \) is the standard normal density function. These two moment conditions are not equivalent, so the maximum likelihood and GMM probit estimators are distinct.

Example 7: Comparison of GMM and maximum likelihood

Using the automobile dataset, we fit a probit model of foreign on gear_ratio, length, and headroom using first the score equations and then the intuitive set of GMM equations. We type

```
. gmm (foreign*normalden({xb:gear_ratio length headroom _cons})/normal({xb:}) - (1-foreign)*normalden({xb:})/(1-normal({xb:}))),
   instruments(gear_ratio length headroom) onestep

legend: b/se
The coefficients on gear ratio and length are close for the two estimators. The GMM estimate of the coefficient on headroom is twice that of the maximum likelihood estimate, though the relatively large standard errors imply that this difference is not significant. You can verify that the coefficients in the column marked “ml” match those you would obtain with probit. We have not discussed the differences among standard errors based on the various GMM and maximum-likelihood covariance matrix estimators to avoid tedious algebra. However, you can verify that the robust covariance matrix after one-step GMM estimation differs by only a finite-sample adjustment factor of \( (N/N - 1) \) from the robust covariance matrix reported by probit. Both the maximum likelihood and GMM probit estimators require the normality assumption, and the maximum likelihood estimator is efficient if that normality assumption is correct; therefore, in this example, there is no reason to prefer the GMM estimator.

We can modify (8) easily to allow for endogenous regressors. Suppose that \( x_j \) is endogenous in the sense that \( E(u|x_j) \neq 0 \). Then (8) is no longer a valid moment condition. However, suppose we have some variables other than \( x \) such that \( E(u|z) = 0 \). We can instead use the moment conditions

\[
E(zu) = E[z\{y - \exp(x'\beta)\}] = 0
\]

As usual, if some elements of \( x \) are exogenous, then they should appear in \( z \) as well.

Example 8: Exponential regression with endogenous regressors

Returning to the model discussed in example 6, we treat income as endogenous; unobservable factors that determine a person’s income may also affect the number of times a person visits a doctor. We use a person’s age and race as instruments. These are valid instruments if we believe that age and race influence a person’s income but do not have a direct impact on the number of doctor visits. (Whether this belief is justified is another matter; we test that belief in \[R\] gmm postestimation.) Because we have more instruments (seven) than parameters (five), we have an overidentified model. Therefore, the choice of weight matrix does matter. We will use the default two-step GMM estimator. In the first step, we will use a weight matrix that assumes the errors are i.i.d. In the second step, we will use a weight matrix that assumes heteroskedasticity. When you specify twostep, these are the defaults for the first- and second-step weight matrices, so we do not have to use the winitial() or wmatrix() options. We will again obtain a robust VCE, which is also the default. We type

```
. use https://www.stata-press.com/data/r16/docvisits
. gmm (docvis - exp({xb:private chronic female income _cons})),
>    > instruments(private chronic female age black hispanic) twostep
```

Instruments for equation 1: private chronic female age black hispanic _cons

Once we control for the endogeneity of income, we find that its coefficient has quadrupled in size. Additionally, access to private insurance has less of an impact on the number of doctor visits and gender has more of an impact.

Technical note

Although you may be tempted to try, you cannot, as you can in a Poisson model, replace \( x \) in the moment conditions for the probit (or logit) model with a vector of instruments, \( z \), if you have endogenous regressors. See Wilde (2008).

Mullahy (1997) considers a slightly more complicated version of the exponential regression model that incorporates nonadditive unobserved heterogeneity. His model can be written as

\[ y_i = \exp(x'_i \beta) \eta_i + \epsilon_i \]

where \( \eta_i > 0 \) is an unobserved heterogeneity term that may be correlated with \( x_i \). One result from his article is that instead of using the additive moment condition (8), we can use the multiplicative moment condition

\[
E \left\{ z \frac{y - \exp(x' \beta)}{\exp(x' \beta)} \right\} = E [z \{y \exp(-x' \beta) - 1\}] = 0
\]

Windmeijer and Santos Silva (1997) discuss the use of additive versus multiplicative moment conditions with endogenous regressors and note that a set of instruments that satisfies the additive moment conditions will not also satisfy the multiplicative moment conditions. They remark that the decision about which to use is an empirical issue that can at least partially be settled by using the test of overidentifying restrictions that is implemented by \texttt{estat overid} after \texttt{gmm} to see whether the instruments for a given model are valid. See [R] \texttt{gmm postestimation} for information on the test of overidentifying restrictions.
Specifying derivatives

By default, \texttt{gmm} calculates derivatives numerically, and the method used produces accurate results for the vast majority of applications. However, if you refit the same model repeatedly or else have the derivatives available, then \texttt{gmm} will run more quickly if you supply it with analytic derivatives.

When you use the interactive version of \texttt{gmm}, you specify derivatives using substitutable expressions in much the same way you specify the residual equations. There are three rules you must follow:

1. As with the substitutable expressions that define residual equations, you bind parameters of the model in curly braces: \{b0\}, \{param\}, etc.

2. You must specify a derivative for each parameter that appears in each residual equation. If a parameter does not appear in a residual equation, then you do not specify a derivative for that parameter in that residual equation.

3. If you declare a linear combination in an equation, then you specify a derivative with respect to that linear combination. \texttt{gmm} applies the chain rule to obtain the derivatives with respect to the individual parameters encompassed by that linear combination.

We illustrate with several examples.

\textbf{Example 9: Derivatives for a single-equation model}

Consider a simple exponential regression model with one exogenous regressor and a constant term. We have

\[ u_i = y_i - \exp(\beta_0 + \beta_1 x_i) \]

Now

\[ \frac{\partial u_i}{\partial \beta_0} = -\exp(\beta_0 + \beta_1 x_i) \quad \text{and} \quad \frac{\partial u_i}{\partial \beta_1} = -x_i \exp(\beta_0 + \beta_1 x_i) \]

In Stata, we type

\begin{verbatim}
  . gmm (docvis - exp({b0} + {b1}*income)), instruments(income)
  > deriv(/b0 = -1*exp({b0} + {b1}*income))
  > deriv(/b1 = -1*income*exp({b0}+{b1}*income)) onestep
  
  Step 1
  Iteration 0:  GMM criterion Q(b) = 9.1548611
  Iteration 1:  GMM criterion Q(b) = 3.5146131
  Iteration 2:  GMM criterion Q(b) = .01344695
  Iteration 3:  GMM criterion Q(b) = 3.690e-06
  Iteration 4:  GMM criterion Q(b) = 4.606e-13
  Iteration 5:  GMM criterion Q(b) = 1.502e-26
  
  note: model is exactly identified

  GMM estimation
  Number of parameters = 2

  Instruments for equation 1: income _cons
\end{verbatim}
Notice how we specified the `derivative()` option for each parameter. We simply specified a slash, the name of the parameter, an equal sign, then a substitutable expression that represents the derivative. Because our model has only one residual equation, we do not need to specify equation numbers in the `derivative()` options.

When you specify a linear combination of variables, your derivative should be with respect to the entire linear combination. For example, say we have the residual equation

\[ u_i = y - \exp(x_i'\beta + \beta_0) \]

for which we would type

```
gmm (y - exp({xb: x1 x2 x3} + {b0}) ...
```

Then, in addition to the derivative \( \partial u_i / \partial \beta_0 \), we are to compute and specify

\[ \frac{\partial u_i}{\partial x_i'\beta} = -\exp(x_i'\beta + \beta_0) \]

Using the chain rule, \( \partial u_i / \partial \beta_j = \partial u_i / \partial (x_i'\beta) \times \partial (x_i'\beta) / \partial \beta_j = -x_{ij}\exp(x_i'\beta + \beta_0) \). Stata does this last calculation automatically. It knows the variables in the linear combination, so all it needs is the derivative of the residual equation with respect to the linear combination. This allows you to change the variables in your linear combination without having to change the derivatives.

**Example 10: Derivatives with a linear combination**

We refit the model described in the example illustrating exponential regression with endogenous regressors, now providing analytic derivatives. We type
. gmm (docvis - exp({xb:private chronic female income _cons})),
> instruments(private chronic female age black hispanic)
> derivative(/xb = -1*exp({xb:}))

Instruments for equation 1: private chronic female age black hispanic _cons

In the first derivative() option, we specified the name of the linear combination, xb, instead of an individual parameter’s name. We already declared the variables of our linear combination in the substitutable expression for the residual equation, so in our substitutable expressions for the derivatives, we can use the shorthand notation {xb:} to refer to it.

Our point estimates are identical to those we obtained earlier. The standard errors and confidence intervals differ by only trivial amounts.

Exponential regression models with panel data

In addition to supporting cross-sectional and time-series data, gmm also works with panel-data models. Here we illustrate gmm’s panel-data capabilities by expanding our discussion of exponential regression models to allow for panel data. This also provides us the opportunity to demonstrate the moment-evaluator program version of gmm. Our discussion is based on Blundell, Griffith, and Windmeijer (2002). Also see Wooldridge (1999) for further discussion of nonlinear panel-data models.

First, we expand (7) for panel data. With individual heterogeneity term \( \eta_i \), we have

\[
E(y_{it} | x_{it}, \eta_i) = \exp(x'_{it}\beta + \eta_i) = \mu_{it}\nu_i
\]

where \( \mu_{it} = \exp(x'_{it}\beta) \) and \( \nu_i = \exp(\eta_i) \). Note that there is no constant term in this model, because its effect cannot be disentangled from \( \nu_i \). With an additive idiosyncratic error term, we have the regression model

\[
y_{it} = \mu_{it}\nu_i + \epsilon_{it}
\]
We do not impose the assumption \( E(x_{it} \eta_i) = 0 \), so \( \eta_i \) can be considered a fixed effect in the sense that it may be correlated with the regressors.

As discussed by Blundell, Griffith, and Windmeijer (2002), if \( x_{it} \) is strictly exogenous, meaning \( E(x_{it} \epsilon_{is}) = 0 \) for all \( t \) and \( s \), then we can estimate the parameters of the model by using the sample moment conditions

\[
\sum_i \sum_t x_{it} \left( y_{it} - \mu_{it} \frac{\overline{y}_i}{\overline{\mu}_i} \right) = 0
\]

where \( \overline{y}_i \) and \( \overline{\mu}_i \) are the means of \( y_{it} \) and \( \mu_{it} \) for panel \( i \), respectively. Because \( \overline{\mu}_i \) depends on the parameters of the model, it must be recomputed each time \texttt{gmm} needs to evaluate the residual equation. Therefore, we cannot use the substitutable expression version of \texttt{gmm}. Instead, we must use the moment-evaluator program version.

The moment-evaluator program version of \texttt{gmm} functions much like the function-evaluator program versions of \texttt{nl} and \texttt{nlsur}. The program you write is passed one or more variables to be filled in with the residuals evaluated at the parameter values specified in an option passed to your program. For the fixed-effects Poisson model with strictly exogenous regressors, our first crack at a function-evaluator program is

```stata
program gmm_poi
    version 16.0
    syntax varlist if, at(name)
    quietly {
        tempvar mu mubar ybar
        generate double `mu' = exp(`x1'*`at'[1,1] + `x2'*`at'[1,2] + `x3'*`at'[1,3]) 'if'
        egen double `mubar' = mean(`mu') 'if', by(id)
        egen double `ybar' = mean(y) 'if', by(id)
        replace `varlist' = y - `mu'*/`ybar'/`mubar' 'if'
    }
end
```

You can save your program in an ado-file named \texttt{name.ado}, where \texttt{name} is the name you use for your program; here we would save the program in the ado-file \texttt{gmm_poi.ado}. Alternatively, if you are working from within a do-file, you can simply define the program before calling \texttt{gmm}. The \texttt{syntax} statement declares we are expecting to receive a \texttt{varlist} that will contain the names of variables whose values we are to replace with the values of the residual equations and an \texttt{if} expression that will mark the estimation sample; because our model has one residual equation, \texttt{varlist} will consist of one variable. \texttt{at(\textit{name})} is a required option to our program, and it will contain the name of a matrix containing the parameter values at which we are to evaluate the residual equation. All moment-evaluator programs must accept the \texttt{varlist}, \texttt{if} condition, and \texttt{at(\textit{name})} option.

The first part of our program computes \( \mu_{it} \). In the model we will fit shortly, we have three regressors, named \( x_1 \), \( x_2 \), and \( x_3 \). The \texttt{at(\textit{name})} vector will have three elements, one for each of those variables. Notice that we included \texttt{if\textit{\texttt{\textrangle}}}\texttt{\textit{\textrangle}} at the end of each statement that affects variables to restrict the computations to the relevant estimation sample. The two \texttt{egen} statements compute \( \overline{\mu}_i \) and \( \overline{y}_i \); in the example dataset we will use shortly, the panel variable is named \( \texttt{id} \), and for simplicity, we hardcoded that variable into our program as well. Finally, we compute the residual equation, which is the portion of (9) bound in parentheses.
Example 11: Panel Poisson with strictly exogenous regressors

To fit our model, we type

```
. use https://www.stata-press.com/data/r16/poisson1
. gmm gmm_poi, nequations(1) parameters(b1 b2 b3)
> instruments(x1 x2 x3, noconstant) vce(cluster id) onestep
```

Instruments for equation 1: x1 x2 x3

All three of our regressors are strictly exogenous, so they can serve as their own regressors. There is no constant term in the model (it would be unidentified), so we exclude a constant term from our list of instruments. We have one residual equation as indicated by nequations(1), and we have three parameters, named b1, b2, and b3. The order in which you declare parameters in the parameters() option determines the order in which they appear in the ‘at’ vector in the moment-evaluator program. We specified vce(cluster id) to obtain standard errors that allow for correlation among observations within each panel.

```

The program we just wrote is sufficient to fit the model to the poisson1 dataset, but if we want to fit that model to other datasets, we need to change the variable names and perhaps account for having a different number of parameters as well. Despite those limitations, if you just want to fit a single model, that program is adequate.

Next we take advantage of the ability to specify full equation names in the parameters() option and rewrite our evaluator program so that we can more easily change the variables in our model. This approach is particularly useful if some of the residual equations are linear in the parameters because then we can use matrix score (see [P] matrix score) to evaluate those moments.
Our new evaluator program is

```stata
program gmm_poieq
    version 16.0
    syntax varlist if, at(name)
    quietly {
        tempvar mu mubar ybar
        matrix score double 'mu' = 'at' 'if', eq(#1)
        replace 'mu' = exp('mu')
        egen double 'mubar' = mean('mu') 'if', by(id)
        egen double 'ybar' = mean(y) 'if', by(id)
        replace 'varlist' = y - 'mu'*'ybar'/mubar 'if'
    }
end
```

Rather than using `generate` to compute the temporary variable `mu`, we used `matrix score` to obtain the linear combination $x_i\beta$ and then called `replace` to compute $\exp(x_i\beta)$.

### Example 12: Panel Poisson using matrix score

To fit our model, we type

```stata
use https://www.stata-press.com/data/r16/poisson1
gmm gmm_poieq, nequations(1) parameters({y:x1 x2 x3})
> instruments(x1 x2 x3, noconstant) vce(cluster id) onestep
```

GMM estimation

Instruments for equation 1: x1 x2 x3

Instead of specifying simple parameter names in the `parameters()` option, we specified a linear combination name and the variables associated with that combination. We named our linear combination $y$, but you could use any valid Stata name. When we use this syntax, the rows of the coefficient table are grouped by the equation names.

Say we wanted to refit our model using just $x_1$ and $x_3$ as regressors. We do not need to make any changes to `gmm_poieq`. We just change the specification of the `parameters()` option:

```stata
use https://www.stata-press.com/data/r16/poisson1
gmm gmm_poieq, nequations(1) parameters({y:x1 y:x3})
> instruments(x1 x3, noconstant) vce(cluster id) onestep
```
In this evaluator program, we have still hardcoded the name of the dependent variable. The next two examples include methods to tackle that shortcoming.

---

### Technical note

Say we specify the `parameters()` option like this:

```
  . gmm ..., parameters({y1:x1 x2 _cons} {y2:_cons} {y3:x1 _cons})
```

Then the ‘at’ vector passed to our program will have the following column names attached to it:

```
  ‘at’[1,6]  
  y1: y1: y1: y2: y3: y3:  
  x1 x2 _cons _cons x1 _cons
```

Typing

```
  . matrix score double eq1 = ‘at’, eq(#1)
```

is equivalent to typing

```
  . generate double eq1 = x1*‘at’[1,1] + x2*‘at’[1,2] + ‘at’[1,3]
```

with one important difference. If we change some of the variables in the `parameters()` option when we call `gmm`, `matrix score` will compute the correct linear combination. If we were to use the `generate` statement instead, then every time we wanted to change the variables in our model, we would have to modify that statement as well.

The command

```
  . matrix score double alpha = ‘at’, eq(#2) scalar
```

is equivalent to

```
  . scalar alpha = ‘at’[1,4]
```

Thus, even if you specify linear combination and variable names in the `parameters()` option, you can still have scalar parameters in your model.

---

When past values of the idiosyncratic error term affect the value of a regressor, we say that regressor is predetermined. When one or more regressors are predetermined, sample moment condition (8) is no longer valid. However, Chamberlain (1992) shows that a simple alternative is to consider moment conditions of the form

\[
\sum_i \sum_{t=2}^T x_{i,t-1} \left( y_{i,t-1} - \mu_{i,t-1} \frac{y_{it}}{\mu_{it}} \right) = 0
\]  

Also see Wooldridge (1997) and Windmeijer (2000) for other moment conditions that can be used with predetermined regressors.

### Example 13: Panel Poisson with predetermined regressors

Here we refit the previous model, treating all the regressors as predetermined and using the moment conditions in (10). Our moment-evaluator program is
To compute the residual equation, we used lag-operator notation so that Stata properly handles gaps in our panel dataset. We also made our program accept an additional option that we will use to pass in the dependent variable. When we specify this option in our `gmm` statement, it will get passed to our evaluator program because `gmm` will not recognize the option as one of its own. Equation (10) shows that we are to use the first lags of the regressors as instruments, so we type

```
. gmm gmm_poipre, mylhs(y) nequations(1) vce(cluster id) onestep
   > parameters({y:x1 x2 x3}) instruments(L.(x1 x2 x3), noconstant)
```

Here, like earlier with strictly exogenous regressors, the number of instruments equals the number of parameters, so there is no gain to using the two-step or iterated estimator. However, if you do have more instruments than parameters, you will most likely want to use one of those other estimators instead.

The note at the top of the output is given because we have 45 panels in our dataset. Our residual equation includes lagged terms and therefore cannot be evaluated for the first time period within each panel. Notes like this can be ignored once you know why they occurred. If you receive a note that you were not expecting, you should first investigate the cause of the note before trusting the results.

Instead of making our program accept the `mylhs()` option, we could have used Stata’s `coleq` macro function to determine the dependent variable based on the column names attached to the ‘at’ vector; see `[P] macro`. Then we could refit our model with a different dependent variable by changing the `lcnam`e used in the `parameters()` option. In the next example, we take this approach.
In the previous example, we used \( x_{i,t-1} \) as instruments. A more efficient GMM estimator would also use \( x_{i,t-2}, x_{i,t-3}, \ldots, x_{i,1} \) as instruments in period \( t \) as well. \texttt{gmm}'s \texttt{xtinstruments()} option allows you to specify instrument lists that grow as \( t \) increases. Later, we discuss the \texttt{xtinstruments()} option in detail in the context of linear dynamic panel-data models.

When a regressor is contemporaneously correlated with the idiosyncratic error term, we say that regressor is endogenous. Windmeijer (2000) shows that we can use the moment condition

\[
\sum_i \sum_{t=3}^T \left( y_{it} - \mu_{it} \right) \left( y_{i,t-1} - \mu_{i,t-1} \right)
\]

Here we use the second lag of the endogenous regressor as an instrument. If a variable is strictly exogenous, it can of course serve as its own instrument.

**Example 14: Panel Poisson with endogenous regressors**

Here we refit the model, treating \( x_3 \) as endogenous and \( x_1 \) and \( x_2 \) as strictly exogenous. Our moment-evaluator program is

```stata
program gmm_poiend
    version 16.0
    syntax varlist if, at(name)
    quietly {
        tempvar mu
        matrix score double 'mu' = 'at' 'if', eq(#1)
        replace 'mu' = exp('mu')
        local mylhs : coleq 'at'
        local mylhs : word 1 of 'mylhs'
        replace 'varlist' = 'mylhs'/mu - L.'mylhs'/L.'mu' 'if'
    }
end
```
Now we call `gmm` using `x1`, `x2`, and `L2.x3` as instruments:

```stata
use https://www.stata-press.com/data/r16/poisson2
gmm gmm_poiend, nequations(1) vce(cluster id) onestep
> parameters(y:x1 y:x2 y:x3) instruments(x1 x2 L2.x3, noconstant)
```

The note at the top of the output is given because we have 500 panels in our dataset. As in the previous example, our residual equation includes lagged terms and therefore cannot be evaluated for the first time period within each panel. Instead of using just \( x_{i,t-2} \) as an instrument, we could use all further lags of \( x_{i,t} \) as instruments as well.

### Rational-expectations models

Macroeconomic models typically assume that agents’ expectations about the future are formed rationally. By rational expectations, we mean that agents use all information available when forming their forecasts, so the forecast error is uncorrelated with the information available when the forecast was made. Say that at time \( t \), people make a forecast, \( \hat{y}_{t+1} \), of variable \( y \) in the next period. If \( \Omega_t \) denotes all available information at time \( t \), then rational expectations implies that

\[
E \{ (\hat{y}_{t+1} - y_{t+1}) | \Omega_t \} = 0.
\]

If \( \Omega_t \) denotes observable variables such as interest rates or prices, then this conditional expectation can serve as the basis of a moment condition for GMM estimation.

#### Example 15: Fitting a Euler equation

In a well-known article, Hansen and Singleton (1982) consider a model of portfolio decision making and discuss parameter estimation using GMM. We will consider a simple example with one asset in which the agent can invest. A consumer wants to maximize the present value of his or her lifetime utility derived from buying a good. On the one hand, the consumer is impatient, so he or she would rather buy today than wait until tomorrow. On the other hand, by buying less today, the consumer can invest more money, earning more interest that can be used to buy more of the good tomorrow. Thus there is a tradeoff between having cake today or sacrificing a bit today to have more cake tomorrow.
If we assume a specific form for the agent’s utility function, known as the constant relative-risk aversion utility function, we can show that the Euler equation is

$$E \left[ z_t \left\{ 1 - \beta (1 + r_{t+1}) \left( \frac{c_{t+1}}{c_t} \right)^{-\gamma} \right\} \right] = 0$$

where $\beta$ and $\gamma$ are the parameters to estimate, $r_t$ is the return to the financial asset, and $c_t$ is consumption in period $t$. $\beta$ measures the agent’s discount factor. If $\beta$ is near 1, the agent is patient and is more willing to forgo consumption this period. If $\beta$ is close to 0, the agent is less patient and prefers to consume more now. The parameter $\gamma$ characterizes the agent’s utility function. If $\gamma = 0$, the utility function is linear. As $\gamma$ tends toward 1, the utility function tends toward $u = \log(c)$.

We have data on three-month Treasury bills ($r_t$) and consumption expenditures ($c_t$). As instruments, we will use lagged rates of return and past growth rates of consumption. We will use the two-step estimator and a weight matrix that allows for heteroskedasticity and autocorrelation up to four lags with the Bartlett kernel. In Stata, we type

```
. use https://www.stata-press.com/data/r16/cr
. generate cgrowth = c / L.c
(1 missing value generated)
. gmm (1 - {b=1}*(1+F.r)*(F.c/c)^(-1*{gamma=1})),
>    inst(L.r L2.r cgrowth L.cgrowth) wmat(hac nw 4) twostep
note: 1 missing value returned for equation 1 at initial values
```

```
Step 1
Iteration 0:  GMM criterion Q(b) =  .00226482
Iteration 1:  GMM criterion Q(b) =  .00054369
Iteration 2:  GMM criterion Q(b) =  .00053904
Iteration 3:  GMM criterion Q(b) =  .00053904
Step 2
Iteration 0:  GMM criterion Q(b) =  .0600729
Iteration 1:  GMM criterion Q(b) =  .0596369
Iteration 2:  GMM criterion Q(b) =  .0596369

HAC standard errors based on Bartlett kernel with 4 lags.  
Instruments for equation 1: L.r L2.r cgrowth L.cgrowth _cons

The note at the top of the output is given because the forward operator in our substitutable expression says that residuals cannot be computed for the last observation. In addition, two observations are omitted because the L2.r instrument has missing values in the first two time periods. Therefore, of the 242 observations in our dataset, 239 are used to fit the model. Our estimate of $\beta$ is near 1, in line with expectations and published results. However, our estimate of $\gamma$ implies risk-loving behavior and therefore a poorly specified model.

Also notice our use of the forward operator to refer to the values of $r$ and $c$ one period ahead; time-series operators are allowed in substitutable expressions as long as you have previously tsset (see [TS] tsset) your data. See [U] 13.10 Time-series operators for more information on time-series operators.
System estimators

In many economic models, two or more variables are determined jointly through a system of simultaneous equations. Indeed, some of the earliest work in econometrics, including that of the Cowles Commission, was centered around estimation of the parameters of simultaneous equations. The 2SLS and IV estimators we have already discussed are used in some circumstances to estimate such parameters. Here we focus on the joint estimation of all the parameters of systems of equations, and we begin with the well-known three-stage least-squares (3SLS) estimator.

Recall that the 2SLS estimator is based on the moment conditions $E(zu) = 0$. The 2SLS estimator can be used to estimate the parameters of one equation of a system of structural equations. Moreover, with the 2SLS estimator, we do not even need to specify the structural relationship among all the endogenous variables; we need to specify only the equation on which interest focuses and simply assume reduced-form relationships among the endogenous regressors of the equation of interest and the exogenous variables of the model. If we are willing to specify the complete system of structural equations, then assuming our model is correctly specified, by estimating all the equations jointly, we can obtain estimates that are more efficient than equation-by-equation 2SLS.

In [R] **reg3**, we fit a simple two-equation macroeconomic model,

\[
\begin{align*}
\text{consump} &= \beta_0 + \beta_1 \text{wagepriv} + \beta_2 \text{wagegovt} + \epsilon_1 \\
\text{wagepriv} &= \beta_3 + \beta_4 \text{consump} + \beta_5 \text{govt} + \beta_6 \text{capital1} + \epsilon_2
\end{align*}
\]  

(11)

(12)

where consump represents aggregate consumption; wagepriv and wagegovt are total wages paid by the private and government sectors, respectively; govt is government spending; and capital1 is the previous period’s capital stock. We are not willing to assume that $\epsilon_1$ and $\epsilon_2$ are independent, so we must treat both consump and wagepriv as endogenous. Suppose that a random shock makes $\epsilon_2$ positive. Then by (12), wagepriv will be higher than it otherwise would. Moreover, $\epsilon_1$ will be either higher or lower, depending on the correlation between it and $\epsilon_2$. The shock to $\epsilon_2$ has made both wagepriv and $\epsilon_1$ move, which implies that in (11), wagepriv is an endogenous regressor. A similar argument shows that consump is an endogenous regressor in the second equation. In our model, wagegovt, govt, and capital1 are all exogenous variables.

Let $z_1$ and $z_2$ denote the instruments for the first and second equations, respectively; we will discuss what comprises them shortly. We have two sets of moment conditions:

\[
E \left\{ \begin{array}{c} z_1 (\text{consump} - \beta_0 - \beta_1 \text{wagepriv} - \beta_2 \text{wagegovt}) \\ z_2 (\text{wagepriv} - \beta_3 - \beta_4 \text{consump} - \beta_5 \text{govt} - \beta_6 \text{capital1}) \end{array} \right\} = 0
\]  

(13)

One of the defining characteristics of 3SLS is that the errors are homoskedastic conditional on the instrumental variables. Using this assumption, we have

\[
E \left[ \begin{array}{c} z_1' \epsilon_1 \\ z_2' \epsilon_2 \end{array} \right] = \begin{bmatrix} \sigma_{11} E(z_1' z_1') & \sigma_{12} E(z_1' z_2') \\ \sigma_{21} E(z_2' z_1') & \sigma_{22} E(z_2' z_2') \end{bmatrix}
\]  

(14)

where $\sigma_{ij} = \text{cov} (\epsilon_i, \epsilon_j)$. Let $\Sigma$ denote the $2 \times 2$ matrix with typical element $\sigma_{ij}$.

The second defining characteristic of the 3SLS estimator is that it uses all the exogenous variables as instruments for all equations; here $z_1 = z_2 = (\text{wagegovt}, \text{govt}, \text{capital1}, 1)$, where the 1 indicates a constant term. From our discussion on the weight matrix and two-step estimation, we want to use the sample analogue of the matrix inverse of the right-hand side of (14) as our weight matrix.

To implement the 3SLS estimator, we apparently need to know $\Sigma$ or at least have a consistent estimator of it. The solution is to fit (11) and (12) by 2SLS, use the sample residuals $\hat{\epsilon}_1$ and $\hat{\epsilon}_2$ to estimate $\Sigma$, then estimate the parameters of (13) via GMM by using the weight matrix just discussed.
Example 16: 3SLS estimation

3SLS is easier to do using gmm than it sounds. The 3SLS estimator is a two-step GMM estimator. In the first step, we do the equivalent of 2SLS on each equation, and then we compute a weight matrix based on (14). Finally, we perform a second step of GMM with this weight matrix.

In Stata, we type

```
. use https://www.stata-press.com/data/r16/klein, clear
. gmm (eq1: consump - {xb: wagepriv wagegovt _cons})
    > (eq2: wagepriv - {xc: consump govt capital1 _cons}),
    > instruments(eq1: wagegovt govt capital1)
    > instruments(eq2: wagegovt govt capital1)
    > winitial(unadjusted, independent) wmatrix(unadjusted) twostep
```

Step 1
Iteration 0:  GMM criterion Q(b) = 4195.4487
Iteration 1:  GMM criterion Q(b) = .22175631
Iteration 2:  GMM criterion Q(b) = .22175631 (backed up)

Step 2
Iteration 0:  GMM criterion Q(b) = .09716589
Iteration 1:  GMM criterion Q(b) = .07028208
Iteration 2:  GMM criterion Q(b) = .07028208

GMM estimation
Number of parameters =  7
Number of moments =  8
Initial weight matrix: Unadjusted
GMM weight matrix: Unadjusted

Instruments for equation eq1: wagegovt govt capital1 _cons
Instruments for equation eq2: wagegovt govt capital1 _cons

The independent suboption of the winitial() option tells gmm to assume that the residuals are independent across moment conditions; this suboption sets $\sigma_{21} = \sigma_{12} = 0$ in (14). Assuming both homoskedasticity and cross-equation independence is equivalent to fitting the two equations of our model independently by 2SLS. The wmatrix() option controls how the weight matrix is computed on the basis of the first-step parameter estimates before the second step of estimation; here we request a weight matrix that assumes conditional homoskedasticity but that does not impose the cross-equation independence like the initial weight matrix we used. In this example, we also illustrated how to name residual equations and how equation names can be used in the instruments() option. Our results are identical to those in [R] reg3.

We could have specified our instruments with the syntax

```
instruments(wagegovt govt capital1)
```

because gmm uses the variables listed in the instruments() option for all equations unless you specify which equations the list of instruments is to be used with. However, we wanted to emphasize
that the same instruments are being used for both equations; in a moment, we will discuss an estimator that does not use the same instruments in all equations.

In the previous example, if we omit the `twostep` option, the resulting coefficients will be equivalent to equation-by-equation 2SLS, which Wooldridge (2010, 216) calls the “system 2SLS estimator”. Eliminating the `twostep` option makes the `wmatrix()` option irrelevant, so that option can be eliminated as well.

So far, we have developed the traditional 3SLS estimator. Wooldridge (2010, chap. 8) discusses the “GMM 3SLS” estimator, which extends the traditional 3SLS estimator by allowing for heteroskedasticity and different instruments for different equations.

Generalizing (14) to an arbitrary number of equations, we have

\[
\mathbb{E} (Z'\epsilon \epsilon' Z) = \mathbb{E} (Z'\Sigma Z)
\]

where

\[
Z = \begin{bmatrix}
z_1 & 0 & \cdots & 0 \\
0 & z_2 & \cdots & 0 \\
\vdots & \vdots & \ddots & \vdots \\
0 & 0 & \cdots & z_m
\end{bmatrix}
\]

and \(\Sigma\) is now \(m \times m\). Equation (15) is the multivariate analogue of a homoskedasticity assumption; for each equation, the error variance is constant for all observations, as is the covariance between any two equations’ errors.

We can relax this homoskedasticity assumption by considering different weight matrices. For example, if we continue to assume that observations are independent but not necessarily identically distributed, then by specifying `wmatrix(robust)`, we would obtain a weight matrix that allows for heteroskedasticity:

\[
\hat{W} = \frac{1}{N} \sum_i Z_i' \hat{\epsilon}_i \hat{\epsilon}_i' Z_i
\]

This is the weight matrix in Wooldridge’s (2010, 218) Procedure 8.1, “GMM with Optimal Weighting Matrix”. By default, `gmm` would report standard errors based on his covariance matrix (8.27); specifying `vce(unadjusted)` would provide the optimal GMM standard errors. If you have multiple observations for each individual or firm in your dataset, you could specify `wmatrix(cluster id)`, where `id` identifies individuals or firms. This would allow arbitrary within-individual correlation, though it does not account for an individual-specific fixed or random effect. In both cases, we would continue to use `winitial(unadjusted, independent)` so that the first-step estimates are the system 2SLS estimates.

Wooldridge (2010, sec. 9.6) discusses instances where it is necessary to use different instruments in different equations. The GMM 3SLS estimator with different instruments in different equations but with conditional homoskedasticity is what Hayashi (2000, 275) calls the “full-information instrumental variables efficient” (FIVE) estimator. Implementing the FIVE estimator is easy with `gmm`. For example, say we have a two-equation system where `kids`, `age`, `income`, and `education` are all valid instruments for the first equation but where `education` is not a valid instrument for the second equation. Then our syntax would take the form

\[
\text{gmm } (\text{rexp}_1) \ (\text{rexp}_2), \ \text{instruments(1:kids age income education)} \\
\text{instruments(2:kids age income)}
\]
The following syntax is equivalent:

```
gmm (rexp1) (rexp2), instruments(kids age income) instruments(1:education)
```

Because we did not specify a list of equations in the second example’s first `instruments()` option, those variables are used as instruments in both equations. You can use whichever syntax you prefer. The first requires a bit more typing but is arguably more transparent.

If all the regressors in the model are exogenous, then the traditional 3SLS estimator is the seemingly unrelated regression (SUR) estimator. Here you would specify all the regressors as instruments.

**Dynamic panel-data models**

Commands in Stata that work with panel data expect the data to be in the “long” format, meaning that each row of the dataset consists of one subobservation that is a member of a logical observation (represented by the panel identifier variable). See [D] `reshape` for a discussion of the long versus “wide” data forms. `gmm` is no exception in this respect when used with panel data. From a theoretical perspective, however, it is sometimes easier to view GMM estimators for panel data as system estimators in which we have $N$ observations on a system of $T$ equations, where $N$ and $T$ are the number of observations and panels, respectively, rather than a single-equation estimator with $NT$ observations. Usually, each of the $T$ equations will in fact be the same, though we will want to specify different instruments for each of these equations.

In a dynamic panel-data model, lagged values of the dependent variable are included as regressors. Here we consider a simple model with one lag of the dependent variable $y$ as a regressor and a vector of strictly exogenous regressors, $x_{it}$:

$$y_{it} = \rho y_{i,t-1} + x_{it}'\beta + u_i + \epsilon_{it} \quad (16)$$

$u_i$ can be either a fixed- or a random-effect term in the sense that we do not require $x_{it}$ to be independent of it. Even with the assumption that $\epsilon_{it}$ is i.i.d., the presence of both $y_{i,t-1}$ and $u_i$ in (16) renders both the standard fixed- and random-effects estimators to be inconsistent because of the well-known Nickell (1981) bias.OLS regression of $y_{it}$ on $y_{i,t-1}$ and $x_{it}$ also produces inconsistent estimates because $y_{i,t-1}$ will be correlated with the error term.

**Technical note**

Stata has the `xtabond`, `xtdpd`, and `xtdpdsys` commands (see [XT] `xtabond`, [XT] `xtdpd`, and [XT] `xtdpdsys`) to fit equations like (16); for everyday use, those commands are preferred because they offer features such as Windmeijer (2005) bias-corrected standard errors to account for the bias of traditional two-step GMM standard errors seen in dynamic panel-data models and, being linear estimators, only require you to specify variable names instead of complete equations. However, using `gmm` has several pedagogical advantages, including the ability to tie those model-specific commands into a more general framework, a clear illustration of how certain types of instrument matrices for panel-data models are formed, and demonstrations of several advanced features of `gmm`.

First-differencing (16) removes the panel-specific $u_i$ term:

$$y_{it} - y_{i,t-1} = \rho(y_{i,t-1} - y_{i,t-2}) + (x_{it} - x_{i,t-1})'\beta + (\epsilon_{it} - \epsilon_{i,t-1}) \quad (17)$$
However, now \((y_{i,t} - y_{i,t-1}) - (y_{i,t-1} - y_{i,t-2})\) is correlated with \((\epsilon_{it} - \epsilon_{i,t-1})\). Thus we need an instrument that is correlated with the former but not the latter. The lagged variables in (17) mean that the equation is not estimable for \(t < 3\), so consider when \(t = 3\). We have

\[
y_{i3} - y_{i2} = \rho(y_{i2} - y_{i1}) + (x_{i3} - x_{i2})'\beta + (\epsilon_{i3} - \epsilon_{i2})
\]  

(18)

In the Arellano–Bond (1991) estimator, lagged levels of the dependent variable are used as instruments. With our assumption that the \(\epsilon_{it}\) are i.i.d., (16) intimates that \(y_{i1}\) can serve as an instrumental variable when we fit (18).

Next consider (17) when \(t = 4\). We have

\[
y_{i4} - y_{i3} = \rho(y_{i3} - y_{i2}) + (x_{i4} - x_{i3})'\beta + (\epsilon_{i4} - \epsilon_{i3})
\]

where \(y_i = (y_{i3}, \ldots, y_{iT})\) and \(y_i^L = (y_{i2}, \ldots, y_{iT-1})\), \(y_i^{LL} = (y_{i1}, \ldots, y_{iT-2})\), and \(X_i, X_i^L, \epsilon_i, \epsilon_i^L\) are defined analogously. Let \(Z\) denote the full matrix of instruments for panel \(i\), including the variables specified in both the instruments() and xtinstruments() options; the exact structure is detailed in Methods and formulas.

By assumption, \(\epsilon_{it}\) is i.i.d., so the first difference \((\epsilon_{it} - \epsilon_{i,t-1})\) is necessarily autocorrelated with correlation \(-0.5\). Therefore, we should not use a weight matrix that assumes the errors are independent. For dynamic panel-data models, we can show that the appropriate initial weight matrix is

\[
\hat{W} = \left(\frac{1}{N} \sum_i Z_i' H_D Z_i \right)^{-1}
\]

where

\[
H_D = \begin{bmatrix}
  1 & -0.5 & 0 & \ldots & 0 & 0 \\
-0.5 & 1 & -0.5 & \ldots & 0 & 0 \\
  \vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\
0 & 0 & 0 & \ldots & 1 & -0.5 \\
0 & 0 & 0 & \ldots & -0.5 & 1 \\
\end{bmatrix}
\]

We can obtain this initial weight matrix by specifying winitial(xt D). The letter D indicates that the equation we are estimating is specified in first differences.
Example 17: Arellano–Bond estimator

Say we want to fit the model

\[ n_{it} = \rho n_{i,t-1} + \beta_1 w_{it} + \beta_2 w_{i,t-1} + \beta_3 k_{it} + \beta_4 k_{i,t-1} + u_i + \epsilon_{it} \]  

(19)

where we assume that \( w_{it} \) and \( k_{it} \) are strictly exogenous. First-differencing, our residual equation is

\[ \epsilon^*_it = (\epsilon_{it} - \epsilon_{i,t-1}) = n_{it} - n_{i,t-1} - \rho(n_{i,t-1} - n_{i,t-2}) - \beta_1(w_{it} - w_{i,t-1}) - \beta_2(w_{i,t-1} - w_{i,t-2}) - \beta_3(k_{it} - k_{i,t-1}) - \beta_4(k_{i,t-1} - k_{i,t-2}) \]  

(20)

In Stata, we type

```
. use https://www.stata-press.com/data/r16/abdata
. gmm (D.n - {rho}*LD.n - {xb:D.w LD.w D.k LD.k}),
> xtinstruments(n, lags(2/)) instruments(D.w LD.w D.k LD.k, noconstant)
> deriv(/rho = -1*LD.n) deriv(/xb = -1) winitial(xt D) onestep
```

**Step 1**

Iteration 0:  GMM criterion Q(b) = .0011455
Iteration 1:  GMM criterion Q(b) = .00009103
Iteration 2:  GMM criterion Q(b) = .00009103

**GMM estimation**

|           | Robust Coef. | Std. Err. | z    | P>|z| | [95% Conf. Interval] |

Instruments for equation 1:

XT-style: L(2/).n
Standard: D.w LD.w D.k LD.k

Because \( w \) and \( k \) are strictly exogenous, we specified their variants that appear in (20) in the `instruments()` option; because there is no constant term in the model, we specified `noconstant` to omit the constant from the instrument list.

We specified `xtinstruments(n, lags(2/))` to tell gmm what instruments to use for the lagged dependent variable included as a regressor in (19). On the basis of our previous discussion, lags two and higher of \( n_{it} \) can serve as instruments. The `lags(2/)` suboption tells gmm that the first available instrument for \( n_{it} \) is the lag-two value \( n_{i,t-2} \). The “.” tells gmm to use all further lags of \( n_{it} \) as instruments as well. The instrument matrices in dynamic panel-data models can become large if the dataset has many time periods per panel. In those cases, you could specify, for example, `lags(2/4)` to use just lags two through four instead of using all available lags.

Our results are identical to those we would obtain using `xtabond` with the syntax

```
xtabond n L(0/1).w L(0/1).k, lags(1) noconstant vce(robust)
```
If we had left off the `vce(robust)` option in our call to `xtabond`, we would have had to specify `vce(unadjusted)` in our call to `gmm` to obtain the same standard errors.

Technical note

`gmm` automatically excludes observations for which there are no valid observations for the panel-style instruments. However, it keeps in the estimation sample those observations for which fewer than the maximum number of instruments you requested are available. For example, if you specify the `lags(2/4)` suboption, you have requested three instruments, but `gmm` will keep observations even if only one or two instruments are available.

Example 18: Two-step Arellano–Bond estimator

Here we refit the model from example 17, using the two-step GMM estimator.

```stata
. gmm (D.n - {rho}*LD.n - {xb:D.w LD.w D.k LD.k}),
   > xtinstruments(n, lags(2/.) )
   > instruments(D.w LD.w D.k LD.k, noconstant)
   > deriv(/rho = -1*LD.n) deriv(/xb = -1)
   > winitial(xt D) 
   > wmatrix(robust)
   > vce(unadjusted)
```

```
Step 1
Iteration 0: GMM criterion Q(b) = .0011455
Iteration 1: GMM criterion Q(b) = .00009103
Iteration 2: GMM criterion Q(b) = .00009103

Step 2
Iteration 0: GMM criterion Q(b) = .44107941
Iteration 1: GMM criterion Q(b) = .4236729
Iteration 2: GMM criterion Q(b) = .4236729 (backed up)
```

```

Our results match those you would obtain with the command

```
xtabond n L(0/1).(w k), lags(1) noconstant twostep
```
If we had specified `vce(robust)` in our call to `gmm`, we would have obtained the traditional sandwich-based robust covariance matrix, but our standard errors would not match those we would obtain by specifying `vce(robust)` with the `xtabond` command. The `xtabond`, `xtdpd`, and `xtdpdsys` commands implement a bias-corrected robust VCE for the two-step GMM dynamic panel-data estimator. Traditional VCEs computed after the two-step dynamic panel-data estimator have been shown to exhibit often-severe bias; see Windmeijer (2005).

Neither of the two dynamic panel-data examples (17 and 18) we have fit so far include a constant term. When a constant term is included, the dynamic panel-data estimator is in fact a two-equation system estimator. For notational simplicity, consider a simple model containing just a constant term and one lag of the dependent variable:

$$y_{it} = \alpha + \rho y_{i,t-1} + u_i + \epsilon_{it}$$

First-differencing to remove the $u_i$ term, we have

$$y_{it} - y_{i,t-1} = \rho(y_{i,t-1} - y_{i,t-2}) + (\epsilon_{it} - \epsilon_{i,t-1}) \quad (21)$$

This has also eliminated the constant term. If we assume $E(u_i) = 0$, which is reasonable if a constant term is included in the model, then we can recover $\alpha$ by including the moment condition

$$y_{it} = \alpha + \rho y_{i,t-1} + \epsilon'_{it} \quad (22)$$

where $\epsilon'_{it} = u_i + \epsilon_{it}$. The parameter $\rho$ continues to be identified by (21), so the only instrument we use with (22) is a constant term. As before, the error term $(\epsilon_{i,t} - \epsilon_{i,t-1})$ is necessarily autocorrelated with correlation coefficient $-0.5$, though the error term $\epsilon'_{it}$ is white noise. Therefore, our initial weight matrix should be

$$\hat{W} = \left( \frac{1}{N} \sum_i Z'_i H Z_i \right)^{-1}$$

where

$$H = \begin{bmatrix} H_D & 0 \\ 0 & I \end{bmatrix}$$

and $I$ is a conformable identity matrix.

One complication arises concerning the relevant estimation sample. Looking at (21), we apparently lose the first two observations from each panel because of the presence of $y_{i,t-2}$, but in (22), we need to sacrifice only one observation for $y_{i,t-1}$. For most multiple-equation models, we need to use the same estimation sample for all equations. However, in dynamic panel-data models, we can use more observations to fit the equation in level form [(22) here] than the equation in first differences [equation (21)]. To request this behavior, we specify the `nocommonesample` option to `gmm`. That option tells `gmm` to use as many observations as possible for each equation, ignoring the loss of observations due to lagging or differencing.
Example 19: Arellano–Bond estimator with constant term

Here we fit the model

$$n_{it} = \alpha + \rho n_{i,t-1} + u_i + \epsilon_{it}$$

Without specifying derivatives, our command would be

```stata
.gmm (D.n - {rho}*LD.n) (n - {alpha} - {rho}*L.n),
> xtinstruments(1: n, lags(2/)) instruments(1:, noconstant) onestep
> winitial(xt DL) vce(unadj) nocommonesample
```

We would specify `winitial(xt DL)` to obtain the required initial weight matrix. The notation `DL` indicates that our first residual equation is in first differences and that the second residual equation is in levels (not first-differenced). We exclude a constant in the instrument list for the first equation because first-differencing removed the constant term. Because we do not specify the `instruments()` option for the second residual equation, a constant is used by default.

This example also provides us the opportunity to illustrate how to specify derivatives for multiple-equation GMM models. Within the `derivative()` option, instead of specifying just the parameter name, now you must specify the equation name or number, a slash, and the parameter name to which the derivative applies. In Stata, we type

```stata
.gmm (D.n - {rho}*LD.n) (n - {alpha} - {rho}*L.n),
> xtinstruments(1: n, lags(2/)) instruments(1:, noconstant)
> derivative(1/rho = -1*LD.n) derivative(2/alpha = -1)
> derivative(2/rho = -1*L.n) winitial(xt DL) vce(unadj) nocommonesample onestep
```

```stata
Step 1
Iteration 0:  GMM criterion Q(b) = 0.09894466
Iteration 1:  GMM criterion Q(b) = 0.00023508
Iteration 2:  GMM criterion Q(b) = 0.00023508
```

* Number of observations for equation 1: 751
Number of observations for equation 2: 891

Instruments for equation 1:
  XT-style: L(2/).n
Instruments for equation 2:
  Standard: _cons

These results are identical to those we would obtain by typing

```stata
xtabond n, lags(1)
```

Because we specified `nocommonesample`, `gmm` did not report the number of observations used in the header of the output. In this dataset, there are in fact 1,031 observations on 140 panels. In the second equation, the presence of the lagged value of $n$ reduces the sample size for that equation to $1031 - 140 = 891$. In the first equation, we lose the first two observations per panel because of lagging and differencing, which leads to 751 usable observations. These tallies are listed after the coefficient table in the output.
Technical note

Specifying

\texttt{xtinstruments(x1 x2 x3, lags(1/3))}

differs from

\texttt{instruments(L(1/3).(x1 x2 x3))}

in how observations are excluded from the estimation sample. When you use the latter syntax, \texttt{gmm} must exclude the first three observations from each panel when computing the residual equation: you requested that three lags of each regressor be used as instruments, so the first residual that could be interacted with those instruments is the one for \( t = 4 \). On the other hand, when you use \texttt{xtinstruments()}, you are telling \texttt{gmm} that you would like to use up to the first three lags of \( x_1 \), \( x_2 \), and \( x_3 \) as instruments but that using just one lag is acceptable. Because most panel datasets have a relatively modest number of observations per panel, dynamic instrument lists are typically used so that the number of usable observations is maximized. Dynamic instrument lists also accommodate the fact that there are more valid instruments for later time periods than earlier time periods.

Specifying panel-style instruments using the \texttt{xtinstruments()} option also affects how the standard instruments specified in the \texttt{instruments()} option are treated. To illustrate, we will suppose that we have a balanced panel dataset with \( T = 5 \) observations per panel and that we specify

\texttt{gmm ... , xtinstruments(w, lags(1/2)) instruments(x)}

We will lose the first observation because we need at least one lag of \( w \) to serve as an instrument. Our instrument matrix for panel \( i \) will therefore be

\[
Z_i = \begin{bmatrix}
w_{i1} & 0 & 0 & 0 \\
0 & w_{i1} & 0 & 0 \\
0 & w_{i2} & 0 & 0 \\
0 & 0 & w_{i2} & 0 \\
0 & 0 & w_{i3} & 0 \\
0 & 0 & 0 & w_{i3} \\
0 & 0 & 0 & w_{i4} \\
x_{i2} & x_{i3} & x_{i4} & x_{i5} \\
1 & 1 & 1 & 1
\end{bmatrix}
\]

(23)

The vector of ones in the final row represents the constant term implied by the \texttt{instruments()} option. Because we lost the first observation, the residual vector \( u_i \) will be \( 4 \times 1 \). Thus our moment conditions for the \( i \)th panel can be written in matrix notation as

\[
E\{Z_i u_i(\beta)\} = E \left\{ Z_i \begin{bmatrix} u_{i2}(\beta) \\ u_{i3}(\beta) \\ u_{i4}(\beta) \\ u_{i5}(\beta) \end{bmatrix} \right\} = 0
\]

The moment conditions corresponding to the final two rows of (23) say that

\[
E \left\{ \sum_{t=2}^{T=4} x_{it} u_{it}(\beta) \right\} = 0 \quad \text{and} \quad E \left\{ \sum_{t=2}^{T=4} u_{it}(\beta) \right\} = 0
\]
Because we specified panel-style instruments with the `xtinstruments()` option, `gmm` no longer uses moment conditions for strictly exogenous variables of the form \( E\{x_{it}u_{it}(\beta)\} = 0 \) for each \( t \). Instead, the moment conditions now stipulate that the average (over \( t \)) of \( x_{it}u_{it}(\beta) \) has expectation zero. This corresponds to the approach proposed by Arellano and Bond (1991, 280) and others.

When you request panel-style instruments with the `xtinstruments()` option, the number of instruments in the \( Z_i \) matrix increases quadratically in the number of periods. The dynamic panel-data estimators we have discussed in this section are designed for datasets that contain a large number of panels and a modest number of time periods. When the number of time periods is large, estimators that use standard (non-panel-style) instruments are more appropriate.

We have focused on the Arellano–Bond dynamic panel-data estimator because of its relative simplicity. `gmm` can additionally fit any models that can be formulated using the `xtdpd` and `xtdpdsys` commands; see `[XT] xtdpd` and `[XT] xtdpdsys`. The key is to determine the appropriate instruments to use for the level and difference equations. You may find it useful to fit a version of your model with those commands to determine what instruments and XT-style instruments to use. We conclude this section with an example using the Arellano–Bover/Blundell–Bond estimator.

**Example 20: Arellano–Bover/Blundell–Bond estimator**

We fit a small model that includes one lag of the dependent variable \( n \) as a regressor as well as the contemporaneous and first lag of \( w \), which we assume are strictly exogenous. We could fit our model with `xtdpdsys` by using the syntax

```
xtdpdsys n L(0/1).w, lags(1) twostep
```
When we apply virtually all the syntax issues we have discussed so far, the equivalent `gmm` command is

```
. gmm (n - {rho}*L.n - {w}*w - {lagw}*L.w - {c})
> (D.n - {rho}*LD.n - {w}*D.w - {lagw}*LD.w),
> xtinst(1: D.n, lags(1/1)) xtinst(2: n, lags(2/2))
> inst(2: D.w LD.w, noconstant)
> deriv(1/rho = -1*L.n) deriv(1/w = -1*w)
> deriv(1/lagw = -1*L.w) deriv(1/c = -1)
> deriv(2/rho = -1*LD.n) deriv(2/w = -1*D.w)
> deriv(2/lagw = -1*LD.w)
> winit(xt LD) wmatrix(robust) vce(unadjusted) nocommonesample
```

Details of moment-evaluator programs

In examples 10, 11, 12, 13, and 14, we used moment-evaluator programs to evaluate moment conditions that could not be specified using the interactive version of `gmm`. In example 13, we also showed how to pass additional information to an evaluator program. Here we discuss how to make moment-evaluator programs provide derivatives and accept weights.

The complete specification for a moment-evaluator program’s syntax statement is

```
syntax varlist if [weight], at(name) options [derivatives(varlist)]
```

The macro ‘`varlist`’ contains the list of variables that we are to fill in with the values of our residual equations. The macro ‘`if`’ represents an if condition that restricts the estimation sample. The macro ‘`at`’ represents a vector containing the parameter values at which we are to evaluate our
residual equations. **options** represent other options that you specify in your call to `gmm` and want to have passed to your moment-evaluator programs. In example 13, we included the `mylhs()` option so that we could pass the name of the dependent variable to our evaluator program.

Two new elements of the **syntax** statement allow for weights and derivatives. **weight** specifies the types of weights your program allows. The interactive version of `gmm` allows for `fweights`, `aweight`, and `pweight`. However, unless you explicitly allow your moment evaluator program to accept weights, you cannot specify weights in your call to `gmm` with the moment-evaluator program version.

The **derivatives()** option is used to pass to your program a set of variables that you are to fill in with the derivatives of your residual equations with respect to the parameters.

To indicate that your program can calculate derivatives, you specify either the `hasderivatives` or the `haslfderivatives` option to `gmm`. The `hasderivatives` option indicates that your program calculates parameter-level derivatives; that method requires more work but can be applied to any GMM problem. The `haslfderivatives` option requires less work but can be used only when the model’s residual equations satisfy certain restrictions and when you use the `{lname:varlist}` syntax with the `parameters()` option.

We first consider how to write the derivative computation logic to work with the `hasderivatives` option and provide an example; then we do the same for the `haslfderivatives` option.

Say that you specify $k$ parameters in the `nparameters()` or `parameters()` option and $q$ equations in the `nequations()` or `equations()` option and that you specify `hasderivatives`. Then ‘derivatives’ will contain $k \times q$ variables. The first $k$ variables are for the derivatives of the first residual equation with respect to the $k$ parameters, the second $k$ variables are for the derivatives of the second residual equation, and so on.

> **Example 21:** Specifying derivatives with simple parameter names

To focus on how to specify derivatives, we return to the simple moment-evaluator program we used in example 11, in which we had three regressors, and extend it to supply derivatives. The residual equation corresponding to moment condition (9) is

\[ u_{it}(\beta) = y_{it} - \mu_{it} \overline{y}_i \]

where $\mu_{it}$, $\overline{\mu}_i$, and $\overline{y}_i$ were defined previously. Now

\[ \frac{\partial}{\partial \beta_j} u_{it}(\beta) = -\mu_{it} \frac{\overline{y}_i}{\overline{\mu}_i} \left( x_{it}^{(j)} \frac{1}{T} \sum_{l=1}^{T} x_{it}^{(l)} \mu_{it} \right) \quad (24) \]

where $x_{it}^{(j)}$ represents the $j$th element of $x_{it}$.
Our moment-evaluator program is

```stata
program gmm_poideriv
version 16.0
syntax varlist if, at(name) [derivatives(varlist)]
quietly {
// Calculate residuals as before
tempvar mu mubar ybar
generate double `mu' = exp(x1*'at'[1,1] + x2*'at'[1,2] + x3*'at'[1,3]) 'if'
egen double `mubar' = mean(`mu') 'if', by(id)
egen double `ybar' = mean(y) 'if', by(id)
replace `varlist' = y - `mu'*`ybar'/`mubar' 'if'
// Did -gmm- request derivatives?
if "'derivatives'" == "" {
    exit // no, so we are done
}
// Calculate derivatives
// We need the panel means of x1*mu, x2*mu, and x3*mu
tempvar work x1mubar x2mubar x3mubar
generate double `work' = x1*'mu' 'if'
egen double `x1mubar' = mean(`work') 'if', by(id)
replace `work' = x2*'mu' 'if'
egen double `x2mubar' = mean(`work') 'if', by(id)
replace `work' = x3*'mu' 'if'
egen double `x3mubar' = mean(`work') 'if', by(id)
local d1: word 1 of `derivatives'
local d2: word 2 of `derivatives'
local d3: word 3 of `derivatives'
replace `d1' = -1*'mu'*`ybar'/`mubar'^2*(x1*'mubar' - `x1mubar')
replace `d2' = -1*'mu'*`ybar'/`mubar'^2*(x2*'mubar' - `x2mubar')
replace `d3' = -1*'mu'*`ybar'/`mubar'^2*(x3*'mubar' - `x3mubar')
}
end
```

The derivatives() option is made optional in the syntax statement by placing it in square brackets. If gmm needs to evaluate your residual equations but does not need derivatives at that time, then the derivatives() option will be empty. In our program, we check to see whether that is the case and, if so, exit without calculating derivatives. As is often the case with [R] ml as well, the portion of our program devoted to derivatives is longer than the code to compute the objective function.

The first part of our derivative code computes the term

\[ \frac{1}{T} \sum_{l=1}^{T} x_{it}^{(j)} \mu_{il} \]  

for \( x_{it}^{(j)} = x_1, x_2, \text{and} \ x_3 \). The `derivatives' macro contains three variable names corresponding to the three parameters of the `at' matrix. We extract those names into local macros `d1', `d2', and `d3' and then fill in the variables those macros represent with the derivatives shown in (24).
With our program written, we fit our model by typing

```
. use https://www.stata-press.com/data/r16/poisson1, clear
. gmm gmm_poi, nequations(1) parameters(b1 b2 b3)
> instruments(x1 x2 x3, noconstant) vce(cluster id) onestep hasderivatives
```

Instruments for equation 1: x1 x2 x3

Our results are identical to those in example 11. Another way to verify that our program calculates derivatives correctly would be to type

```
. gmm gmm_poi, nequations(1) parameters(b1 b2 b3)
> instruments(x1 x2 x3, noconstant) vce(cluster id) onestep
```

Without the hasderivatives or haslfderivatives option, \texttt{gmm} will not request derivatives from your program, even if it contains code to compute them. If you have trouble obtaining convergence with the hasderivatives or haslfderivatives option but do not have trouble without specifying one of them, then you need to recheck your derivatives.

After example 11, we remarked that the evaluator program would have to be changed to accommodate different regressors. We then showed how you can specify parameters using the syntax \{\texttt{lcname} : \texttt{varlist}\} and then use \texttt{matrix score} to compute linear combinations of variables. To specify derivatives when you specify parameters using this notation, ensure that your residual equations satisfy the “linear-form restriction” analogous to the restrictions of linear-form evaluators used by \texttt{ml}. See \texttt{[R ml]} and Gould, Pitblado, and Poi (2010) for more information about linear-form evaluators.

A GMM residual equation satisfies the linear-form restriction if the equation can be written in terms of a single observation in the dataset and if the equation for observation \(i\) does not depend on any observations \(j \neq i\). Cross-sectional models satisfy the linear-form restriction. Time-series models satisfy the linear-form restriction only when no lags or leads are used.

Panel-data models often do not satisfy the linear-form restriction. For example, recall moment condition (9) for a panel Poisson model. That residual equation included panel-level mean terms \(\bar{y}_i\) and \(\bar{\mu}_i\), so the residual equation for an individual observation depends on all the observations in the same panel.

When a residual equation does not satisfy the linear-form restriction, neither will its derivatives. To apply the chain rule, we need a way to multiply the \texttt{lcname}-level derivative by each of the variables...
in the equation to obtain parameter-level derivatives. In (24), for example, there is no way to factor out each \( x_{it}^{(j)} \) variable and obtain an \( lclineame \)-level derivative that we then multiply by each of the \( x_{it}^{(j)} \) s.

Suppose we do have a model with \( q = 2 \) moment conditions, both of which do satisfy the linear-form restriction, and we specify the \texttt{parameters()} option like this:

\begin{verbatim}
  . gmm ..., parameters({eq1:x1 x2 _cons} {eq2:_cons} {eq3:x1 x2 _cons})
\end{verbatim}

We have specified \( n = 3 \) \textit{lclnames} in the \texttt{parameters()} option: \texttt{eq1}, \texttt{eq2}, and \texttt{eq3}. When we specify the \texttt{haslderivative} option, \texttt{gmm} will pass \( n \times q = 3 \times 2 = 6 \) variables in the \texttt{derivatives()} option. The first three variables are to be filled with

\[
\frac{\partial}{\partial \texttt{eq1}} u_{1i}(\beta) \quad \frac{\partial}{\partial \texttt{eq2}} u_{1i}(\beta) \quad \text{and} \quad \frac{\partial}{\partial \texttt{eq3}} u_{1i}(\beta)
\]

where \( u_{1i}(\beta) \) is the \( i \)th observation for the first moment equation. Then the second three variables are to be filled with

\[
\frac{\partial}{\partial \texttt{eq1}} u_{2i}(\beta) \quad \frac{\partial}{\partial \texttt{eq2}} u_{2i}(\beta) \quad \text{and} \quad \frac{\partial}{\partial \texttt{eq3}} u_{2i}(\beta)
\]

where \( u_{2i}(\beta) \) is the second moment equation. In this example, we filled in a total of six variables with derivatives. If we instead used the \texttt{hasderivative} option, we would have filled \( k \times q = 7 \times 2 = 14 \) variables; moreover, if we wanted to change the number of variables in our model, we would have modified our evaluator program.

\section*{Example 22: Specifying derivatives with linear-form residual equations}

In examples 9 and 10, we showed how to specify derivatives with an exponential regression model when using the interactive version of \texttt{gmm}. Here we show how to write a moment-evaluator program for the exponential regression model, including derivatives.

The residual equation for observation \( i \) is

\[ u_i = y_i - \exp(x_i'\beta) \]

where \( x_i \) may include a constant term. The derivative with respect to the linear combination \( x_i'\beta \) is

\[
\frac{\partial u_i}{\partial x_i'\beta} = -\exp(x_i'\beta)
\]

To verify this residual equation satisfies the linear-form restriction, we see that for the \( j \)th element of \( \beta \), we have

\[
\frac{\partial u_i}{\partial \beta_j} = -x_{ij} \exp(x_i'\beta) = \frac{\partial u_i}{\partial x_i'\beta} \times x_{ij}
\]

so that given \( \partial u_i/\partial x_i'\beta \), \texttt{gmm} can apply the chain rule to obtain the derivatives with respect to the individual parameters.
Our moment-evaluator program is

```
program gmm_poideriv2
  version 16.0
  syntax varlist if, at(name) [derivatives(varlist)]
  quietly {
    tempvar mu
    matrix score double 'mu' = 'at' 'if', eq(#1)
    replace 'mu' = exp('mu')
    local depvar : coleq 'at'
    local depvar : word 1 of 'depvar'
    replace 'varlist' = 'depvar' - 'mu' 'if'
    // Did -gmm- request derivatives?
    if "'derivatives'" == "" {
      exit // no, so we are done
    }
    // Calculate derivatives
    // The derivatives macro only has one variable
    // for this model.
    replace 'derivatives' = -1*'mu' 'if'
  }
end
```

To fit our model of doctor visits treating `income` as an endogenous regressor, we type

Instruments for equation 1: private chronic female age black hispanic _cons

Our results match those shown in example 10.
We can change the variables in our model just by changing the `parameters()` and `instruments()` options; we do not need to make any changes to the moment-evaluator program, because we used linear-form derivatives.

Depending on your model, allowing your moment-evaluator program to accept weights may be as easy as modifying the `syntax` command to allow them, or it may require significantly more work. If your program uses only commands such as `generate` and `replace`, then just modifying the `syntax` command is all you need to do; `gmm` takes care of applying the weights to the observation-level residuals when computing the sample moments, derivatives, and weight matrices. On the other hand, if your moment-evaluator program computes residuals using statistics that depend on multiple observations, then you must apply the weights passed to your program when computing those statistics.

In our examples of panel Poisson with strictly exogenous regressors (11 and 21), we used the statistics $\mu_i$ and $\bar{y}_i$ when computing the residuals. If we are to allow weights with our moment-evaluator program, then we must incorporate those weights when computing $\mu_i$ and $\bar{y}_i$. Moreover, looking at the derivative in (24), we see that the term highlighted in (25) is in fact a sample mean, so we must incorporate weights when computing it.

Example 23: Panel Poisson with derivatives and weights

Here we modify the program in example 21 to accept frequency weights. One complication arises: we had been using `egen` to compute $\mu_i$ and $\bar{y}_i$. `egen` does not accept weights, so we must compute $\mu_i$ and $\bar{y}_i$ ourselves, incorporating any weights the user may specify. Our program is

```
program gmm_poiderivfw
version 16.0
syntax varlist if [fweight/], at(name) [derivatives(varlist)]
quietly {
if "'exp'" == "" { // no weights
    local exp 1 // weight each observation equally
}
// Calculate residuals as before
tempvar mu mubar ybar sumwt
generate double 'mu' = exp(x1*'at'[1,1] + x2*'at'[1,2] + x3*'at'[1,3]) 'if'
bysort id: generate double 'sumwt' = sum('exp')
by id: generate double 'mubar' = sum('mu'*'exp') / 'sumwt'[\_N]
by id: replace 'mubar' = 'mubar'[_N] / 'sumwt'[_N]
by id: replace 'ybar' = 'ybar'[_N] / 'sumwt'[_N]
replace 'varlist' = y - 'mu'*'ybar'/'mubar' 'if'
// Did -gmm- request derivatives?
if "'derivatives'" == "" {
    exit // no, so we are done
}
// Calculate derivatives
// We need the panel means of x1*mu, x2*mu, and x3*mu
tempvar work x1mubar x2mubar x3mubar
generate double 'work' = x1*'mu' 'if'
by id: generate double 'x1mubar' = sum('work'*'exp') / 'sumwt'[_N]
by id: replace 'x1mubar' = 'x1mubar'[_N] / 'sumwt'[_N]
replace 'work' = x2*'mu' 'if'
by id: generate double 'x2mubar' = sum('work'*'exp') / 'sumwt'[_N]
by id: replace 'x2mubar' = 'x2mubar'[_N] / 'sumwt'[_N]
replace 'work' = x3*'mu' 'if'
by id: generate double 'x3mubar' = sum('work'*'exp') / 'sumwt'[_N]
by id: replace 'x3mubar' = 'x3mubar'[_N] / 'sumwt'[_N]
```
Our syntax command now indicates that fweights are allowed. The first part of our code looks at the macro ‘exp’. If it is empty, then the user did not specify weights in their call to \texttt{gmm}; and we set the macro equal to 1 so that we weight each observation equally. After we compute $\mu$, we calculate $\mu_i$ and $y_i$, taking into account weights. To compute frequency-weighted means for each panel, we just multiply each observation by its respective weight, sum over all observations in the panel, then divide by the sum of the weights for the panel. (See [U] 20.24 Weighted estimation for information on how to handle aweights and pweights.) We use the same procedure to compute the frequency-weighted variant of expression (25) in the derivative calculations. To use our program, we type:

\begin{verbatim}
use https://www.stata-press.com/data/r16/poissonwts
.gmm gmm_poiderivfw [fw=fwt], nequations(1) parameters(b1 b2 b3)>
> instruments(x1 x2 x3, noconstant) vce(cluster id) onestep hasderivatives
\end{verbatim}

Step 1
Iteration 0:  GMM criterion Q(b) =  49.8292
Iteration 1:  GMM criterion Q(b) =  0.11136736
Iteration 2:  GMM criterion Q(b) =  0.00008519
Iteration 3:  GMM criterion Q(b) =  7.110e-11
Iteration 4:  GMM criterion Q(b) =  5.596e-23

\textit{note: model is exactly identified}

Instruments for equation 1: x1 x2 x3

Testing whether our program works correctly with frequency weights is easy. A frequency-weighted dataset is just a compact form of a larger dataset in which identical observations are omitted and a frequency-weight variable is included to tell us how many times each observation in the smaller dataset appears in the larger dataset. Therefore, we can expand our smaller dataset by the frequency-weight variable and then refit our model without specifying frequency weights. If we obtain the same results, our program works correctly. When we type:

\begin{verbatim}
.expand fwt
.gmm gmm_poiderivfw, nequations(1) parameters(b1 b2 b3)>
> instruments(x1 x2 x3, noconstant) vce(cluster id) onestep
\end{verbatim}

we obtain the same results as before.
 Stored results

`gmm` stores the following in `e()`:

Scalars

- `e(N)` number of observations
- `e(k)` number of parameters
- `e(k_eq)` number of equations in `e(b)`
- `e(k_eq_model)` number of equations in overall model test
- `e(k_aux)` number of auxiliary parameters
- `e(n_moments)` number of moments
- `e(n_eq)` number of equations in moment-evaluator program
- `e(Q)` criterion function
- `e(J)` Hansen $J \chi^2$ statistic
- `e(J_df)` $J$ statistic degrees of freedom
- `e(k_i)` number of parameters in equation $i$
- `e(has_xtinst)` 1 if panel-style instruments specified, 0 otherwise
- `e(N_clust)` number of clusters
- `e(type)` 1 if interactive version, 2 if moment-evaluator program version
- `e(rank)` rank of `e(V)`
- `e(ic)` number of iterations used by iterative GMM estimator
- `e(converged)` 1 if converged, 0 otherwise

Macros

- `e(cmd)` `gmm`
- `e(cmdline)` command as typed
- `e(title)` title specified in `title()`
- `e(title_2)` title specified in `title2()`
- `e(clustvar)` name of cluster variable
- `e(inst_i)` equation $i$ instruments
- `e(eqnames)` equation names
- `e(winit)` initial weight matrix used
- `e(winitname)` name of user-supplied initial weight matrix
- `e(estimator)` `onestep`, `twostep`, or `igmm`
- `e(rhs)` variables specified in `variables()`
- `e(params_i)` equation $i$ parameters
- `e(wmatrix)` `wmtype` specified in `wmatrix()`
- `e(vce)` `vcetype` specified in `vce()`
- `e(vcetype)` title used to label Std. Err.
- `e(properties)` `b V`
- `e(estat_cmd)` program used to implement `estat`
- `e(predict)` program used to implement `predict`
- `e(marginsok)` predictions allowed by `margins`
- `e(marginsnotok)` predictions disallowed by `margins`
- `e(marginsprop)` signals to the `margins` command
- `e(asbalanced)` factor variables `fvset` as `asbalanced`
- `e(asobserved)` factor variables `fvset` as `asobserved`

Matrices

- `e(b)` coefficient vector
- `e(init)` initial values of the estimators
- `e(Wuser)` user-supplied initial weight matrix
- `e(W)` weight matrix used for final round of estimation
- `e(S)` moment covariance matrix used in robust VCE computations
- `e(G)` averages of derivatives of moment conditions
- `e(N_byequation)` number of observations per equation, if `nocommonesample` specified
- `e(V)` variance–covariance matrix
- `e(V_modelbased)` model-based variance
Methods and formulas

Let $q$ denote the number of moment conditions. For observation $i$, $i = 1, \ldots, N$, write the $j$th moment equation as $z_{ij}u_{ij}(\beta_j)$ for $j = 1, \ldots, q$. $z_{ij}$ is a $1 \times m_j$ vector, where $m_j$ is the number of instruments specified for equation $j$. Let $m = m_1 + \cdots + m_q$.

Our notation can incorporate moment conditions of the form $h_{ij}(w_{ij}; \beta_j)$ with instruments $w_{ij}$ by defining $z_{ij} = 1$ and $u_{ij}(\beta_j) = h_{ij}(w_{ij}; \beta_j)$, so except when necessary, we do not distinguish between the two types of moment conditions. We could instead use notation so that all our moment conditions are of the form $z_{ij}u_{ij}(\beta_j)$, or we could adopt notation that explicitly combines both forms of moment equations. However, because moment conditions of the form $z_{ij}u_{ij}(\beta_j)$ are arguably more common, we use that notation.

Let $\beta$ denote a $k \times 1$ vector of parameters, consisting of all the unique parameters of $\beta_1, \ldots, \beta_q$. Then we can stack the moment conditions and write them more compactly as $Z_i' u_i(\beta)$, where

$$Z_i = \begin{bmatrix} z_{i1} & 0 & \cdots & 0 \\ 0 & z_{i2} & \cdots & 0 \\ \vdots & \vdots & \ddots & \vdots \\ 0 & 0 & \cdots & z_{iq} \end{bmatrix} \quad \text{and} \quad u_i(\beta) = \begin{bmatrix} u_{i1}(\beta_1) \\ u_{i2}(\beta_2) \\ \vdots \\ u_{iq}(\beta_q) \end{bmatrix}$$

The GMM estimator $\hat{\beta}$ is the value of $\beta$ that minimizes

$$Q(\beta) = \left\{ N^{-1} \sum_{i=1}^{N} Z_i' u_i(\beta) \right\}' W \left\{ N^{-1} \sum_{i=1}^{N} Z_i' u_i(\beta) \right\}$$

(A1)

for $q \times q$ weight matrix $W$.

By default, gmm minimizes (A1) using the Gauss–Newton method. See Hayashi (2000, 498) for a derivation. This technique is typically faster than quasi-Newton methods and does not require second-order derivatives.

Methods and formulas are presented under the following headings:

- Initial weight matrix
- Weight matrix
- Variance–covariance matrix
- Hansen’s $J$ statistic
- Panel-style instruments
- Marginal predictions with unconditional standard errors

Initial weight matrix

If you specify winitial(unadjusted), then we create matrix $\Lambda$ with typical submatrix

$$\Lambda_{rs} = N^{-1} \sum_{i=1}^{N} z_{is}' z_{is}$$
for \( r = 1, \ldots, q \) and \( s = 1, \ldots, q \). If you include the independent suboption, then we set \( \Lambda_{rs} = 0 \) for \( r \neq s \). The weight matrix \( W \) equals \( \Lambda^{-1} \).

If you specify winitial(identity), then we set \( W = I_q \).

If you specify winitial(xt xtspec), then you must specify one or two items in xtspec, one for each equation. gmm allows you to specify at most two moment equations when you specify winitial(xt xtspec), one in first-differences, and one in levels. We create the block-diagonal matrix \( H \) with typical block \( H_j \). If the \( j \)th element of xtspec is “L”, then \( H_j \) is the identity matrix of suitable dimension. If the \( j \)th element of xtspec is “D”, then

\[
H_j = \begin{bmatrix}
1 & -0.5 & 0 & \ldots & 0 & 0 \\
-0.5 & 1 & -0.5 & \ldots & 0 & 0 \\
\vdots & \vdots & \vdots & \ddots & \vdots & \vdots \\
0 & 0 & 0 & \ldots & 1 & -0.5 \\
0 & 0 & 0 & \ldots & -0.5 & 1 \\
\end{bmatrix}
\]

Then

\[
\Lambda_H = N_g^{-1} \sum_{g=1}^{N_G} Z'_g H Z_g
\]

where \( g \) indexes panels in the dataset, \( N_G \) is the number of panels, \( Z_g \) is the full instrument matrix for panel \( g \), and \( W = \Lambda_H^{-1} \). See Panel-style instruments below for a discussion of how \( Z_g \) is formed.

If you specify winitial(matname), then we set \( W \) equal to Stata matrix matname.

Weight matrix

Specification of the weight matrix applies only to the two-step and iterative estimators. When you use the onestep option, the wmatrix() option is ignored.

We first evaluate (A1) using the initial weight matrix described above and then compute \( u_i(\hat{\beta}) \). In all cases, \( W = \Lambda^{-1} \). If you specify wmatrix(unadjusted), then we create \( \Lambda \) to have typical submatrix

\[
\Lambda_{rs} = \sigma_{rs} N^{-1} \sum_{i=1}^{N} z'_{ir} z_{is}
\]

where

\[
\sigma_{rs} = N^{-1} \sum_{i=1}^{N} u_{ir}(\hat{\beta}) u_{is}(\hat{\beta})
\]

and \( r \) and \( s \) index moment equations. For all types of weight matrices, if the independent suboption is specified, then \( \Lambda_{rs} = 0 \) for \( r \neq s \), where \( \Lambda_{rs} \) measures the covariance between moment conditions for equations \( r \) and \( s \).

If you specify wmatrix(robust), then

\[
\Lambda = N^{-1} \sum_{i=1}^{N} Z_i u_i(\hat{\beta}) u'_i(\hat{\beta}) Z'_i
\]
If you specify \texttt{wmatrix(cluster clustvar)}, then
\[
\Lambda = N^{-1} \sum_{c=1}^{c=N_C} q_c q_c'
\]
where \(c\) indexes clusters, \(N_C\) is the number of clusters, and
\[
q_c = \sum_{i \in c} Z_i u_i(\hat{\beta})
\]

If you specify \texttt{wmatrix(hac kernel \{\#\})}, then
\[
\Lambda = N^{-1} \sum_{i=1}^{N} Z_i u_i(\hat{\beta}) u_i(\hat{\beta})' Z_i' +
\]
\[
N^{-1} \sum_{l=1}^{l=n-1} \sum_{i=l+1}^{N} K(l, m) \left\{ Z_i u_i(\hat{\beta}) u_{i-l}(\hat{\beta}) Z_{i-l}' + Z_{i-l} u_{i-l}(\hat{\beta}) u_{i-l}' Z_i' \right\}
\]
where \(m = \#\) if \# is specified and \(m = N - 2\) otherwise. Define \(z = l/(m + 1)\). If \textit{kernel} is bartlett or nwest, then
\[
K(l, m) = \begin{cases} 1 - z & 0 \leq z \leq 1 \\ 0 & \text{otherwise} \end{cases}
\]
If \textit{kernel} is parzen or gallant, then
\[
K(l, m) = \begin{cases} 1 - 6z^2 + 6z^3 & 0 \leq z \leq 0.5 \\ 2(1 - z)^3 & 0.5 < z \leq 1 \\ 0 & \text{otherwise} \end{cases}
\]
If \textit{kernel} is quadraticspectral or andrews, then
\[
K(l, m) = \begin{cases} 1 & z = 0 \\ 3\{\sin(\theta)/\theta - \cos(\theta)\}/\theta^2 & \text{otherwise} \end{cases}
\]
where \(\theta = 6\pi z/5\).

If \texttt{wmatrix(hac kernel opt)} is specified, then \texttt{gmm} uses Newey and West’s (1994) automatic lag-selection algorithm, which proceeds as follows. Define \(h\) to be an \(m \times 1\) vector of ones. Note that this definition of \(h\) is slightly different from the one used by \texttt{ivregress}. There the element of \(h\) corresponding to the constant term equals 0, effectively ignoring the effect of the constant in determining the optimal lag length. Here we include the effect of the constant term. Now define
\[
f_i = \{Z_i' u_i(\beta)\}' h
\]
\[
\hat{s}_j = N^{-1} \sum_{i=j+1}^{N} f_i f_{i-j} \quad j = 0, \ldots, m^*
\]
\[
\hat{s}^{(q)} = 2 \sum_{j=1}^{j=m^*} \hat{s}_j j^q
\]
\[
\hat{s}^{(0)} = \hat{s}_0 + 2 \sum_{j=1}^{j=m^*} \hat{s}_j
\]
\[
\hat{\gamma} = c_\gamma \left\{ \frac{\hat{s}^{(q)}}{\hat{s}^{(0)}} \right\}^{1/(2q+1)}
\]
\[
m = \hat{\gamma} N^{1/(2q+1)}
\]
where \( q, m^*, \) and \( c_\gamma \) depend on the kernel specified:

<table>
<thead>
<tr>
<th>Kernel</th>
<th>( q )</th>
<th>( m^* )</th>
<th>( c_\gamma )</th>
</tr>
</thead>
<tbody>
<tr>
<td>Bartlett/Newey–West</td>
<td>1</td>
<td>( \text{int}\left{20(T/100)^{2/9}\right} )</td>
<td>1.1447</td>
</tr>
<tr>
<td>Parzen/Gallant</td>
<td>2</td>
<td>( \text{int}\left{20(T/100)^{4/25}\right} )</td>
<td>2.6614</td>
</tr>
<tr>
<td>Quadratic spectral/Andrews</td>
<td>2</td>
<td>( \text{int}\left{20(T/100)^{2/25}\right} )</td>
<td>1.3221</td>
</tr>
</tbody>
</table>

Here \( \text{int}(x) \) denotes the integer obtained by truncating \( x \) toward zero. For the Bartlett and Parzen kernels, the optimal lag is \( \min\{\text{int}(m), m^*\} \). For the quadratic spectral kernel, the optimal lag is \( \min\{m, m^*\} \).

If \( \text{wmatrix(hac kernel opt #)} \) is specified, then \( \text{gmm} \) uses \( # \) instead of 20 in the definition of \( m^* \) above to select the optimal lag.

**Variance–covariance matrix**

If you specify \( \text{vce(unadjusted)} \), then the VCE matrix is computed as

\[
\text{Var}(\hat{\beta}) = N^{-1} \left\{ \mathbf{G}(\hat{\beta})' \mathbf{W} \mathbf{G}(\hat{\beta}) \right\}^{-1}
\]

(A2)

where

\[
\mathbf{G}(\hat{\beta}) = N^{-1} \sum_{i=1}^{N} \mathbf{Z}_i' \frac{\partial \mathbf{u}_i(\beta)}{\partial \beta'} \bigg|_{\beta=\hat{\beta}}
\]

(A3)

For the two-step and iterated estimators, we use the weight matrix \( \mathbf{W} \) that was used to compute the final-round estimate \( \hat{\beta} \).

When you do not specify analytic derivatives, \( \text{gmm} \) must compute the Jacobian matrix (A3) numerically. By default, \( \text{gmm} \) computes each element of the matrix individually by using the Mata \texttt{deriv()} function; see [M-5] \texttt{deriv()}. This procedure results in accurate derivatives but can be slow if your model has many instruments or parameters.

When you specify the \texttt{quickderivatives} option, \( \text{gmm} \) computes all derivatives corresponding to parameter \( \beta_j, j = 1, \ldots, q \), at once, using two-sided derivatives with a step size of \( |\beta_j|\epsilon^{1/3} \), where \( \epsilon \) is the machine precision of a double precision number (approximately \( 2.22045 \times 10^{-16} \)). This method requires just two evaluations of the model’s moments to compute an entire column of (A3) and therefore has the most impact when you specify many instruments or moment equations so that (A3) has many rows.

For the one-step estimator, how the unadjusted VCE is computed depends on the type of initial weight matrix requested and the form of the moment equations. If you specify two or more moment equations of the form \( h_{ij}(\mathbf{w}_{ij}; \beta_j) \), then \( \text{gmm} \) issues a note and computes a heteroskedasticity-robust VCE because here the matrix \( \mathbf{Z}'\mathbf{Z} \) is necessarily singular; moreover, here you must use the identity matrix as the initial weight matrix. Otherwise, if you specify \( \text{winitial(unadjusted)} \) or \( \text{winitial(identity)} \), then \( \text{gmm} \) first computes an unadjusted weight matrix based on \( \hat{\beta} \) before evaluating (A2). If you specify \( \text{winitial(matname)} \), then (A2) is evaluated on the basis of \( \text{matname} \); the user is responsible for verifying that the VCE and other statistics so produced are appropriate.

All types of robust VCEs computed by \( \text{gmm} \) take the form

\[
\text{Var}(\hat{\beta}) = N^{-1} \left\{ \mathbf{G}(\hat{\beta})' \mathbf{W} \mathbf{G}(\hat{\beta}) \right\}^{-1} \mathbf{G}(\hat{\beta})' \mathbf{W} \mathbf{SW} \mathbf{G}(\hat{\beta}) \left\{ \mathbf{G}(\hat{\beta})' \mathbf{W} \mathbf{G}(\hat{\beta}) \right\}^{-1}
\]
For the one-step estimator, $W$ represents the initial weight matrix requested using the winitial() option, and $S$ is computed on the basis of the specification of the vce() option. The formulas for the $S$ matrix are identical to the ones that define the $\Lambda$ matrix in Weight matrix above, except that $S$ is computed after the moment equations are reevaluated using the final estimate of $\hat{\beta}$. For the two-step and iterated GMM estimators, computation of $W$ is controlled by the wmatrix() option on the basis of the penultimate estimate of $\hat{\beta}$.

For details on computation of the VCE matrix with dynamic panel-data models, see Panel-style instruments below.

### Hansen’s J statistic

Hansen’s (1982) $J$ test of overidentifying restrictions is $J = N \times Q(\hat{\beta})$. $J \sim \chi^2(m - k)$. If $m < k$, gmm issues an error message without estimating the parameters. If $m = k$, the model is just-identified and $J$ is saved as missing ("."). For the two-step and iterated GMM estimators, the $J$ statistic is based on the last-computed weight matrix as determined by the wmatrix() option. For the one-step estimator, gmm recomputes a weight matrix as described in the second paragraph of Variance–covariance matrix above. To obtain Hansen’s $J$ statistic, you use estat overid; see [R] gmm postestimation.

### Panel-style instruments

Here we discuss several issues that arise only when you specify panel-style instruments by using the xtinstruments() option. When you specify the xtinstruments() option, we can no longer consider the instruments for one observation in isolation; instead, we must consider the instrument matrix for an entire panel at once. In the following discussion, we let $T$ denote the number of time periods in a panel. To accommodate unbalanced datasets, conceptually we simply use zeros as instruments and residuals for time periods that are missing in a panel.

We consider the case where you specify both an equation in levels and an equation in differences, yielding two residual equations. Let $u_{pt}^L(\beta)$ denote the residual for the level equation for panel $p$ in period $t$, and let $u_{pt}^D(\beta)$ denote the residual for the corresponding difference equation. Now define the $2T \times 1$ vector $u_p(\beta)$ as

$$u_p(\beta) = [u_{p1}^L(\beta), u_{p2}^L(\beta), \ldots, u_{pT}^L(\beta), u_{p1}^D(\beta), u_{p2}^D(\beta), \ldots, u_{pT}^D(\beta)]$$

The $T + 1$ element of $u_p$ is $u_{p2}^D(\beta)$ because we lose the first observation of the difference equation because of differencing.

We write the moment conditions for the $p$th panel as $Z_p u_p(\beta)$. To see how $Z_p$ is defined, we will let $w_{pt}^L$ and $w_{pt}^D$ denote the vectors of panel-style instruments for the level and difference equations, respectively, and let time be denoted by $t$; we discuss their dimensions momentarily. Also let $x_{pt}^L$ and $x_{pt}^D$ denote the vectors of instruments specified in instruments() for the level and difference equations at time $t$. Without loss of generality, for our discussion, we assume that you specify the level equation first. Then $Z_p$ has the form
To see how the \( \mathbf{w} \) vectors are formed, we will suppose you specify
\[
\text{xtinstruments(eq(1): d, lags(a/b))}
\]

Then \( \mathbf{w}_t^L \) will be a \((b - a + 1) \times 1\) vector consisting of \(d_{t-a}, \ldots, d_{t-b}\). If \((t - a) \leq 0\), then instead, we set \(\mathbf{w}_t^L = 0\). If \((t - a) > 0\) but \((t - b) \leq 0\), then we create \(\mathbf{w}_t^L\) to consist of \(d_{t-a}, \ldots, d_1\). With this definition, \((b - a + 1)\) defines the maximum number of lags of \(d\) used, but \text{gmm} will proceed with fewer lags if all \((b - a + 1)\) lags are not available. If you specify two panel-style instruments, \(d\) and \(e\), say, then \(\mathbf{w}_t^L\) will consist of \(d_{t-a}, \ldots, d_1, e_{t-a}, \ldots, e_{t-b}\). \(\mathbf{w}_t^D\) is handled analogously.

The \(\mathbf{x}_t^L\) vectors are simply \(j \times 1\) vectors, where \(j\) is the number of regular instruments specified with the \text{instruments()} option; these vectors include a “1” unless you specify the \text{noconstant} suboption.

Looking carefully at (A4), you will notice that for dynamic panel-data models, moment conditions corresponding to the instruments \(\mathbf{x}_{pt}^L\) take the form
\[
E\left[\sum_{t=1}^{T} \mathbf{x}_{pt}^L u_{pt}^L(\beta)\right] = 0
\]
and likewise for \(\mathbf{x}_{pt}^D\). Instead of having separate moment conditions for each time period, there is one moment condition equal to the average of individual periods’ moments. See Arellano and Bond (1991, 280). To include separate moment conditions for each time period, instead of specifying, say,
\[
\text{xtinstruments(1: x)}
\]
you could instead first generate a variable called \text{one} equal to unity for all observations and specify
\[
\text{xtinstruments(1: x one)}
\]
(Creating the variable \text{one} is necessary because a constant is not automatically included in variable lists specified in \text{xtinstruments(}).)

Unbalanced panels are essentially handled by including zeros in rows and columns of \(\mathbf{Z}_p\) and \(\mathbf{u}_p(\beta)\) corresponding to missing time periods. However, the numbers of instruments and moment conditions reported by \text{gmm} do not reflect this trickery and instead reflect the numbers of instruments and moment conditions that are not manipulated in this way. Moreover, \text{gmm} includes code to work through these situations efficiently without actually having to fill in zeros.

When you specify \text{winitial(xt ...)}, the one-step unadjusted VCE is computed as
\[
\text{Var}(\hat{\beta}) = \hat{\sigma}_1^2 \mathbf{A}_H
\]
where \( \Lambda_H \) was defined previously as

\[
\hat{\sigma}^2_1 = (N - k)^{-1} \sum_{p=1}^{p=P} u_p^D(\hat{\beta})
\]

and \( u_p^D(\hat{\beta}) = [u_{p2}(\hat{\beta}), \ldots, u_{pT}(\hat{\beta})] \). Here we use \((N - k)^{-1}\) instead of \(N^{-1}\) to match xtdpd.

### Marginal predictions with unconditional standard errors

Here we describe how `margins` computes unconditional standard errors when used with the `vce(unconditional)` option after `gmm`. These standard errors account for the estimation of parameters in `gmm` before `margins` is used to make marginal predictions. They also account for variation in the covariates over the population.

`margins` with the `vce(unconditional)` option uses linearization to estimate the unconditional variance of \( \hat{\beta} \). Linearization uses the variance estimator for the total of a score variable for the marginal prediction \( p(\hat{\beta}) \) as an approximate estimator for \( \text{Var}\{p(\hat{\beta})\} \). See [SVY] Variance estimation for more details. Our derivation of the standard errors here is similar to the derivation of the standard errors for two-step \( M \) estimators. See Wooldridge (2010, sec. 12.4) for the latter.

Let \( x_i \) be a vector of covariate values, which includes all variables used in calculating the moment conditions, and let \( f(x_i, \beta) \) be a scalar-valued function returning the value of the predictions of interest.

`margins` computes estimates of

\[
\theta = p(\beta) = E\{f(x_i, \beta)|x_i \in S_p\}
\]

where \( S_p \) is a subpopulation of interest.

The indicator \( \delta_i(S_p) \) indicates whether observation \( i \) is in subpopulation \( S_p \).

\[
\delta_i(S_p) = \begin{cases} 
1, & i \in S_p \\
0, & i \notin S_p
\end{cases}
\]

Let \( \hat{\beta} \) be the vector of parameter estimates. Then `margins` estimates \( \theta = p(\beta) \) via

\[
\hat{\theta} = \frac{1}{w.} \sum_{i=1}^{N} \delta_i(S_p)w_if(x_i, \hat{\beta})
\]

where

\[
w. = \sum_{i=1}^{N} \delta_i(S_p)w_i
\]

and \( w_i \) is the weight for the \( i \)th observation.
In minimizing (A1), we see that the GMM estimator $\hat{\beta}$ is the value of $\beta$ that solves the score equations

$$0 = \mathbf{G}(\beta)' \mathbf{W} \left\{ N^{-1} \sum_{i=1}^{N} Z_i' u_i(\beta) \right\}$$

where $\mathbf{G}(\beta)$ was defined in (A3).

By the mean-value theorem, for some points $\beta_1, \ldots, \beta_q$ between $\beta$ and $\hat{\beta}$, we have

$$0 = \mathbf{G}(\hat{\beta})' \mathbf{W} \left\{ N^{-1} \sum_{i=1}^{N} Z_i' u_i(\beta) \right\} + \mathbf{G}_m (\hat{\beta} - \beta)$$

where

$$\mathbf{G}_m = N^{-1} \sum_{i=1}^{N} \left[ \frac{\partial \left\{ Z_i' u_i(\beta_j) \right\}}{\partial \beta_j} \right]_{j,l}$$

So we have

$$\sqrt{N} (\hat{\beta} - \beta) = - \left\{ \mathbf{G}(\hat{\beta})' \mathbf{W} \mathbf{G}_m \right\}^{-1} \mathbf{G}(\hat{\beta})' \mathbf{W} \left\{ N^{-0.5} \sum_{i=1}^{N} Z_i' u_i(\beta) \right\} \quad (A5)$$

The margin $\hat{\theta}$ is the solution to the score equations

$$\sum_{i=1}^{N} s_i(\theta, \hat{\beta}) = 0$$

where

$$s_i(\theta, \beta) = w_i \delta_i(S_p) \{ f(x_i, \beta) - \theta \}$$

When we do a mean-value expansion about point $\theta_1$ between $\theta$ and $\hat{\theta}$, we get

$$0 = \sum_{i=1}^{N} s_i(\theta, \hat{\beta}) - w.(\hat{\theta} - \theta)$$

So we have

$$\sqrt{N}(\hat{\theta} - \theta) = w^{-1} N^{-0.5} \sum_{i=1}^{N} s_i(\theta, \hat{\beta})$$

Using the mean-value theorem again, for point $\beta_m$ between $\beta$ and $\hat{\beta}$, we have

$$w^{-1} N^{-0.5} \sum_{i=1}^{N} s_i(\theta, \hat{\beta}) = w^{-1} \left\{ N^{-0.5} \sum_{i=1}^{N} s_i(\theta, \beta) + \sqrt{N} J(\beta_m) \left( \hat{\beta} - \beta \right) \right\}$$
where $\bar{J}(\beta_m)$ is the Jacobian of the margin at $\beta_m$,

$$
\bar{J}(\beta_m) = \left\{ N^{-1} \sum_{i=1}^{N} w_i \delta_i(S_p) \frac{\partial f(x_i, \beta_m)}{\partial \beta'_m} \right\}
$$

Using (A5), we get

$$
\sqrt{N}(\hat{\theta} - \theta) = w^{-1}N^{-0.5} \left[ \sum_{i=1}^{N} s_i(\theta, \beta) - \bar{J}(\beta_m) \left\{ G(\hat{\beta})'W G(\hat{\beta}) \right\}^{-1} G(\hat{\beta})'W \left\{ \sum_{i=1}^{N} Z_i'u_i(\beta) \right\} \right]
$$

$\hat{\theta}$ is asymptotically normal, and a consistent estimator of its variance is given by

$$
\text{Var}\{\sqrt{N}(\hat{\theta} - \theta)\} = \sum_{i=1}^{N} w^{-2} \left[ s_i(\hat{\theta}, \hat{\beta}) - \bar{J}(\hat{\beta}) \left\{ G(\hat{\beta})'W G(\hat{\beta}) \right\}^{-1} G(\hat{\beta})'WZ_i'u_i(\hat{\beta}) \right]^2
$$

See Wooldridge (2010, sec 12.4 and 12.5) for details.

gmm returns $N^{-1} \left\{ G(\hat{\beta})'W G(\hat{\beta}) \right\}^{-1}$ as the model-based variance. The scores are

$$
-G(\hat{\beta})'WZ_i'u_i(\hat{\beta})
$$

and may be predicted in postestimation; see [R] gmm postestimation. These scores correspond to derivatives of the criterion function $Q(\hat{\beta})$, scaled by $-1/2$. See Cameron and Trivedi (2005, sec. 6.3.2) for more details.

margins estimates the asymptotic standard error of $\hat{\theta}$ from the model-based variance, the scores, and its own predictions of $s_i$ and the Jacobian $\bar{J}(\beta)$.

predict

Description for predict

predict creates a new variable containing predictions such as linear predictions, residuals, and scores.

Menu for predict

Statistics > Postestimation

Syntax for predict

```
predict [type] newvar [if] [in] [, xb equation(#eqno|eqname)]

predict [type] newvar [if] [in], residuals [equation(#eqno|eqname)]

predict [type] {stub*|newvar1 ... newvar_q} [if] [in] [, residuals]

predict [type] {stub*|newvar1 ... newvar_p} [if] [in] [, scores]
```

Residuals are available both in and out of sample; type `predict ... if e(sample) ... if wanted only for the estimation sample.

Scores are available only for observations within the estimation sample.

You specify one new variable and (optionally) `equation()`, or you specify `stub*` or `q` or `p` new variables, where `q` is the number of moment equations and `p` is the number of parameters in the model.

Option for predict

```
```

xb, the default, calculates the linear prediction.

residuals calculates the residuals, the predicted values of the moment equations. This option requires that the length of the new variable list be equal to the number of moment equations, `q`. Otherwise, use `stub*` to have `predict` generate enumerated variables with prefix `stub`. If `equation()` is not specified, the `j`th new variable will contain the residuals for the `j`th moment equation.

equation(#eqno|eqname) specifies the equation for which residuals or linear predictions are desired.

The specified equation may be either a model equation or a moment equation.

If `xb` is specified, `equation()` is used to specify equations in the model. Specifying `equation(#1)` indicates that the calculation is to be made for the first model equation. Specifying `equation(demand)` would indicate that the calculation is to be made for the model equation named `demand`, assuming there is an equation named `demand` in the model.

If `residuals` is specified, `equation()` is used to specify moment equations. Specifying `equation(#1)` indicates that the calculation is to be made for the first moment equation. Specifying `equation(demand)` would indicate that the calculation is to be made for the moment equation named `demand`, assuming there is a moment equation named `demand` in the model.
If you specify one new variable name and omit `equation()`, results are the same as if you had specified `equation(#1)`.

For more information on using `predict` after multiple-equation estimation commands, see [R] `predict`.

`scores` calculates the parameter-level score equations, the first derivatives of the GMM criterion function with respect to the parameters scaled by $-0.5$. This option requires that the length of the new variable list be equal to the number of parameters, $p$. Otherwise, use `stub*` to have `predict` generate enumerated variables with prefix `stub`. The $j$th new variable will contain the $j$th score of the model.

**margins**

**Description for margins**

`margins` estimates margins of response for linear predictions.

**Menu for margins**

Statistics  >  Postestimation

**Syntax for margins**

```
margins [marginlist] [ , options ]
margins [marginlist] , predict(statistic ...) [ predict(statistic ...) ... ] [ options ]
```

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>xb</code></td>
<td>linear prediction; the default</td>
</tr>
<tr>
<td><code>residuals</code></td>
<td>not allowed with <code>margins</code></td>
</tr>
</tbody>
</table>

`xb` defaults to the first equation.

Statistics not allowed with `margins` are functions of stochastic quantities other than $e(b)$.

For the full syntax, see [R] `margins`. 
estat

Description for estat

`estat overid` reports Hansen’s $J$ statistic, which is used to determine the validity of the overidentifying restrictions in a GMM model. If the model is correctly specified in the sense that $E\{z_i u_i(\beta)\} = 0$, then the sample analog to that condition should hold at the estimated value of $\beta$. Hansen’s $J$ statistic is valid only if the weight matrix is optimal, meaning that it equals the inverse of the covariance matrix of the moment conditions. Therefore, `estat overid` only reports Hansen’s $J$ statistic after two-step or iterated estimation, or if you specified `winitial(matname)` when calling `gmm`. In the latter case, it is your responsibility to determine the validity of the $J$ statistic.

Menu for estat

Statistics > Postestimation

Syntax for estat

`estat overid`

Remarks and examples

As we noted in Introduction of [R] gmm, underlying generalized method of moments (GMM) estimators is a set of $l$ moment conditions, $E\{z_i u_i(\beta)\} = 0$. When $l$ is greater than the number of parameters, $k$, any size-$k$ subset of the moment conditions would yield a consistent parameter estimate. We remarked that the parameter estimates we would obtain would in general depend on which $k$ moment conditions we used. However, if all our moment conditions are indeed valid, then the parameter estimates should not differ too much regardless of which $k$ moment conditions we used to estimate the parameters. The test of overidentifying restrictions is a model specification test based on this observation. The test of overidentifying restrictions requires that the number of moment conditions be greater than the number of parameters in the model.

Recall that the GMM criterion function is

$$Q = \left\{ \frac{1}{N} \sum_i z_i u_i(\beta) \right\}' W \left\{ \frac{1}{N} \sum_i z_i u_i(\beta) \right\}$$

The test of overidentifying restrictions is remarkably simple. If $W$ is an optimal weight matrix, under the null hypothesis $H_0: E\{z_i u_i(\beta)\} = 0$, the test statistic $J = N \times Q \sim \chi^2(l - k)$. A large test statistic casts doubt on the null hypothesis.

For the test to be valid, $W$ must be optimal, meaning that $W$ must be the inverse of the covariance matrix of the moment conditions:

$$W^{-1} = E\{z_i u_i(\beta) u'_i(\beta) z'_i\}$$

Therefore, `estat overid` works only after the two-step and iterated estimators, or if you supplied your own initial weight matrix by using the `winitial(matname)` option to `gmm` and used the one-step estimator.
Often the overidentifying restrictions test is interpreted as a test of the validity of the instruments $z$. However, other forms of model misspecification can sometimes lead to a significant test statistic. See Hall (2005, sec. 5.1) for a discussion of the overidentifying restrictions test and its behavior in correctly and misspecified models.

### Example 1

In example 6 of [R] `gmm`, we fit an exponential regression model of the number of doctor visits based on the person’s gender, income, possession of private health insurance, and presence of a chronic disease. We argued that the variable `income` may be endogenous; we used the person’s age and race as additional instrumental variables. Here we refit the model and test the specification of the model. We type

```
use https://www.stata-press.com/data/r16/docvisits
.gmm (docvis - exp({xb:private chronic female income} + {b0})),
> instruments(private chronic female age black hispanic)
(output omitted)
estat overid
```

Test of overidentifying restriction:
Hansen’s J chi2(2) = 9.52598 (p = 0.0085)

The $J$ statistic is significant even at the 1% significance level, so we conclude that our model is misspecified. One possibility is that age and race directly affect the number of doctor visits, so we are not justified in excluding them from the model.

A simple technique to explore whether any of the instruments is invalid is to examine the statistics

$$r_j = W_{jj}^{1/2} \left\{ \frac{1}{N} \sum_{i=1}^{N} z_{ij} u_i(\hat{\beta}) \right\}$$

for $j = 1, \ldots, k$, where $W_{jj}$ denotes the $j$th diagonal element of $W$, $u_i(\hat{\beta})$ denotes the sample residuals, and $k$ is the number of instruments. If all the instruments are valid, then the scaled sample moments should at least be on the same order of magnitude. If one (or more) instrument’s $r_j$ is large in absolute value relative to the others, then that could be an indication that instrument is not valid.

In Stata, we type

```
.predict double r if e(sample), residuals // obtain residual from the model
.matrix W = e(W) // retrieve weight matrix
.local i 1
// loop over each instrument and compute $r_j$
. foreach var of varlist private chronic female age black hispanic {
    .   generate double r'var' = r*'var'*sqrt(W['i', 'i'])
    .   local ++i'
}
.summarize r*
```

<table>
<thead>
<tr>

<td>-.017435</td>
<td>1.08567</td>
<td>-5.509386</td>
<td>31.53512</td>
</tr>
</tbody>
</table>
We notice that the $r_j$ statistics for age, black, and hispanic are larger than those for the other instruments in our model, supporting our suspicion that age and race may have a direct impact on the number of doctor visits.

Stored results

`estat overid` stores the following in r():

Scalars
- $r(J)$: Hansen’s $J$ statistic
- $r(J_{df})$: $J$ statistic degrees of freedom
- $r(J_{p})$: $J$ statistic $p$-value

**grmeanby** — Graph means and medians by categorical variables

### Description

`grmeanby` graphs the (optionally weighted) means or medians of `varname` according to the values of the variables in `varlist`. The variables in `varlist` may be string or numeric and, if numeric, may be labeled.

### Quick start

Graph means of `v1` for each level of categorical variables `cvar1`, `cvar2`, and `cvar3`  
`grmeanby cvar1 cvar2 cvar3, sum(v1)`

As above, but graph medians

`grmeanby cvar1 cvar2 cvar3, sum(v1) median`  

As above, but use + as the marker

`grmeanby cvar1 cvar2 cvar3, sum(v1) median msymbol(+)`

### Menu

<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>twoway_options</td>
<td>any options other than by() documented in [G-3] twoway_options</td>
</tr>
</tbody>
</table>

*summarize(varname) is required.

aweights and fweights are allowed; see [U] 11.1.6 weight.

**Options**

**Main**

summarize(varname) is required; it specifies the name of the variable whose mean or median is to be graphed.

median specifies that the graph is to be of medians, not means.

**Plot**

cline_options affect the rendition of the lines through the markers, including their color, pattern, and width; see [G-3] cline_options.

marker_options affect the rendition of markers drawn at the plotted points, including their shape, size, color, and outline; see [G-3] marker_options.

marker_label_options specify if and how the markers are to be labeled; see [G-3] marker_label_options.

**Y axis, X axis, Titles, Legend, Overall**

twoway_options are any of the options documented in [G-3] twoway_options, excluding by(). These include options for titling the graph (see [G-3] title_options) and for saving the graph to disk (see [G-3] saving_option).

**Remarks and examples**

The idea of graphing means of categorical variables was shown in Chambers and Hastie (1992, 3). Because this was shown in the context of an S function for making such graphs, it doubtless has roots going back further than that. grmeanby is, in any case, another implementation of what we will assume is their idea.
Example 1

Using a variation of our auto dataset, we graph the mean of mpg by foreign, rep77, rep78, and make:

```
use https://www.stata-press.com/data/r16/auto1
(Automobile Models)
. grmeanby foreign rep77 rep78 make, sum(mpg)
```

If we had wanted a graph of medians rather than means, we could have typed

```
. grmeanby foreign rep77 rep78 make, sum(mpg) median
```

</tbody>
</table>

where `name-consistent` and `name-efficient` are names under which estimation results were stored via `estimates store`; see [R] estimates store.

A period (.) may be used to refer to the last estimation results, even if these were not already stored. Not specifying `name-efficient` is equivalent to specifying the last estimation results as “.”.

Options

**constant** specifies that the estimated intercept(s) be included in the model comparison; by default, they are excluded. The default behavior is appropriate for models in which the constant does not have a common interpretation across the two models.

`alleqs` specifies that all the equations in the models be used to perform the Hausman test; by default, only the first equation is used.

`skipeqs(eqlist)` specifies in `eqlist` the names of equations to be excluded from the test. Equation numbers are not allowed in this context, because the equation names, along with the variable names, are used to identify common coefficients.

`equations(matchlist)` specifies, by number, the pairs of equations that are to be compared.

The `matchlist` in `equations()` should follow the syntax

```
#_c:#_e [,#_c:#_e[,...]]
```

where `#_c` (`#_e`) is an equation number of the always-consistent (efficient under $H_0$) estimator. For instance, `equations(1:1)`, `equations(1:1, 2:2)`, or `equations(1:2)`.

If `equations()` is not specified, then equations are matched on equation names.
equations() handles the situation in which one estimator uses equation names and the other does not. For instance, equations(1:2) means that equation 1 of the always-consistent estimator is to be tested against equation 2 of the efficient estimator. equations(1:1, 2:2) means that equation 1 is to be tested against equation 1 and that equation 2 is to be tested against equation 2. If equations() is specified, the alleqs and skipeqs options are ignored.

force specifies that the Hausman test be performed, even though the assumptions of the Hausman test seem not to be met, for example, because the estimators were pweighted or the data were clustered.

df(#) specifies the degrees of freedom for the Hausman test. The default is the matrix rank of the variance of the difference between the coefficients of the two estimators.

sigmamore and sigmaless specify that the two covariance matrices used in the test be based on a common estimate of disturbance variance (σ²).

sigmamore specifies that the covariance matrices be based on the estimated disturbance variance from the efficient estimator. This option provides a proper estimate of the contrast variance for so-called tests of exogeneity and overidentification in instrumental-variables regression.

sigmaless specifies that the covariance matrices be based on the estimated disturbance variance from the consistent estimator.

These options can be specified only when both estimators store e(sigma) or e(rmse), or with the xtreg command. e(sigma_e) is stored after the xtreg command with the fe or mle option. e(rmse) is stored after the xtreg command with the re option.

sigmamore or sigmaless are recommended when comparing fixed-effects and random-effects linear regression because they are much less likely to produce a non–positive-definite-differenced covariance matrix (although the tests are asymptotically equivalent whether or not one of the options is specified).

Advanced

tconsistent(string) and tefficient(string) are formatting options. They allow you to specify the headers of the columns of coefficients that default to the names of the models. These options will be of interest primarily to programmers.

Remarks and examples

hausman is a general implementation of Hausman’s (1978) specification test, which compares an estimator \( \hat{\theta}_1 \) that is known to be consistent with an estimator \( \hat{\theta}_2 \) that is efficient under the assumption being tested. The null hypothesis is that the estimator \( \hat{\theta}_2 \) is indeed an efficient (and consistent) estimator of the true parameters. If this is the case, there should be no systematic difference between the two estimators. If there exists a systematic difference in the estimates, you have reason to doubt the assumptions on which the efficient estimator is based.

The assumption of efficiency is violated if the estimator is pweighted or the data are clustered, so hausman cannot be used. The test can be forced by specifying the force option with hausman. For an alternative to using hausman in these cases, see [R] suest.

To use hausman, you

. (compute the always-consistent estimator)
. estimates store name-consistent
. (compute the estimator that is efficient under H_0)
. hausman name-consistent .
Alternatively, you can turn this around:

. (compute the estimator that is efficient under $H_0$)
. estimates store name-efficient
. (fit the less-efficient model)
. (compute the always-consistent estimator)
. hausman . name-efficient

You can, of course, also compute and store both the always-consistent and efficient-under-$H_0$ estimators and perform the Hausman test with

. hausman name-consistent name-efficient

Example 1

We are studying the factors that affect the wages of young women in the United States between 1970 and 1988, and we have a panel-data sample of individual women over that time span.

We assume that this model is consistent for the true parameters and store the results by using estimates store under a name, fixed:

. estimates store fixed

Now we fit a random-effects model as a fully efficient specification of the individual effects under the assumption that they are random and follow a normal distribution. We then compare these estimates with the previously stored results by using the hausman command.

b = consistent under Ho and Ha; obtained from xtreg
B = inconsistent under Ha, efficient under Ho; obtained from xtreg
Test: Ho: difference in coefficients not systematic

\[
\chi_2(3) = (b-B)'((V_b-V_B)^{-1})(b-B) = 260.40
\]

Prob>\chi2 = 0.0000

Under the current specification, our initial hypothesis that the individual-level effects are adequately modeled by a random-effects model is resoundingly rejected. This result is based on the rest of our model specification, and random effects might be appropriate for some alternate model of wages.

Jerry Allen Hausman (1946–) is an American economist and econometrician. He was born in West Virginia and went on to study economics at Brown and Oxford. He joined the MIT faculty in 1972 and continues to teach there. He currently researches new goods and their effects on consumer welfare and its measurement in the Consumer Price Index along with regulation and competition in the telecommunications industry.

Hausman is best known for his many contributions to econometrics. In 1978, he published his now famous paper giving the Hausman specification test. The work remains one of the most widely cited econometrics papers. He has also done extensive work in applied microeconomics pertaining to governments role in the economy, including antitrust regulation, public finance, and taxation.

In 1980, Hausman received the Frisch Medal, a biennial award from the Econometric Society recognizing exceptional applied work, for his paper with David Wise on attrition bias. In 1985, he won the John Bates Clark Award from the American Economics Association, which is given for outstanding contributions to economics by an economist under 40 years of age. In 2012, the Advances in Econometrics book series devoted an entire volume to Hausman and his contributions to econometrics.

Example 2

A stringent assumption of multinomial and conditional logit models is that outcome categories for the model have the property of independence of irrelevant alternatives (IIA). Stated simply, this assumption requires that the inclusion or exclusion of categories does not affect the relative risks associated with the regressors in the remaining categories.

One classic example of a situation in which this assumption would be violated involves the choice of transportation mode; see McFadden (1974). For simplicity, postulate a transportation model with the four possible outcomes: rides a train to work, takes a bus to work, drives the Ford to work, and drives the Chevrolet to work. Clearly, “drives the Ford” is a closer substitute to “drives the Chevrolet” than it is to “rides a train” (at least for most people). This means that excluding “drives the Ford” from the model could be expected to affect the relative risks of the remaining options and that the model would not obey the IIA assumption.
Using the data presented in [R] `mlogit`, we will use a simplified model to test for IIA. The choice of insurance type among indemnity, prepaid, and uninsured is modeled as a function of age and gender. The indemnity category is allowed to be the base category, and the model including all three outcomes is fit. The results are then stored under the name `allcats`.

. estimates store allcats

Under the IIA assumption, we would expect no systematic change in the coefficients if we excluded one of the outcomes from the model. (For an extensive discussion, see Hausman and McFadden [1984].) We reestimate the parameters, excluding the uninsured outcome, and perform a Hausman test against the fully efficient full model.

\]

= 0.08

Prob>\chi^2 = 0.9944
(V_b-V_B is not positive definite)

The syntax of the if condition on the mlogit command simply identified the "Uninsured" category with the insure value label; see [U] 12.6.3 Value labels. On examining the output from hausman, we see that there is no evidence that the IIA assumption has been violated.

Because the Hausman test is a standardized comparison of model coefficients, using it with mlogit requires that the base outcome be the same in both competing models. In particular, if the most-frequent category (the default base outcome) is being removed to test for IIA, you must use the baseoutcome() option in mlogit to manually set the base outcome to something else. Or you can use the equation() option of the hausman command to align the equations of the two models.

Having the missing values for the square root of the diagonal of the covariance matrix of the differences is not comforting, but it is also not surprising. This covariance matrix is guaranteed to be positive definite only asymptotically (it is a consequence of the assumption that one of the estimators is efficient), and assurances are not made about the diagonal elements. Negative values along the diagonal are possible, and the fourth column of the table is provided mainly for descriptive use.

We can also perform the Hausman IIA test against the remaining alternative in the model:

. mlogit insure age male if insure != "Prepaid":insure

The Hausman specification test is used to compare two estimators, one consistent under the null hypothesis (Ho) and one efficient under the null hypothesis (Ha). The test statistic is:

\[ \chi^2(3) = (b-B)'[(V_b-V_B)^{-1}](b-B)\]

where \(b\) is the consistent estimator under Ho and Ha; \(B\) is the inconsistent estimator under Ha, efficient under Ho; \(V_b\) and \(V_B\) are the variance matrices of \(b\) and \(B\) respectively.

In the example shown, the test statistic is negative, indicating that we cannot reject the null hypothesis. This is not an unusual outcome for the Hausman test, especially with a relatively small sample size.

Are we surprised by the results of the Hausman test in this example? Not really. Judging from the z statistics on the original multinomial logit model, we were struggling to identify any structure in the data with the current specification. Even when we were willing to assume IIA and computed the efficient estimator under this assumption, few of the effects could be identified as statistically different from those on the base category. Trying to base a Hausman test on a contrast (difference) between two poor estimates is just asking too much of the existing data.

In example 2, we encountered a case in which the Hausman was not well defined. Unfortunately, in our experience this happens fairly often. Stata provides an alternative to the Hausman test that overcomes this problem through an alternative estimator of the variance of the difference between the two estimators. This other estimator is guaranteed to be positive semidefinite. This alternative estimator also allows a widening of the scope of problems to which Hausman-type tests can be applied by relaxing the assumption that one of the estimators is efficient. For instance, you can perform Hausman-type tests to clustered observations and survey estimators. See [R] `suest` for details.

**Stored results**

`hausman` stores the following in `r()`:

Scalars
- `r(chi2)` \(\chi^2\) statistic
- `r(df)` degrees of freedom for the statistic
- `r(p)` \(p\)-value for the \(\chi^2\)
- `r(rank)` rank of \((V_b-V_B)^{-1}\)
Methods and formulas

The Hausman statistic is distributed as $\chi^2$ and is computed as

$$H = (\beta_c - \beta_e)'(V_c - V_e)^{-1}(\beta_c - \beta_e)$$

where

- $\beta_c$ is the coefficient vector from the consistent estimator
- $\beta_e$ is the coefficient vector from the efficient estimator
- $V_c$ is the covariance matrix of the consistent estimator
- $V_e$ is the covariance matrix of the efficient estimator

When the difference in the variance matrices is not positive definite, a Moore–Penrose generalized inverse is used. As noted in Gourieroux and Monfort (1995, 125–128), the choice of generalized inverse is not important asymptotically.

The number of degrees of freedom for the statistic is the rank of the difference in the variance matrices. When the difference is positive definite, this is the number of common coefficients in the models being compared.

Acknowledgment

Portions of `hausman` are based on an early implementation by Jeroen Weesie of the Department of Sociology at Utrecht University, The Netherlands.

heckman — Heckman selection model

Description

heckman fits regression models with selection by using either Heckman’s two-step consistent estimator or full maximum likelihood.

Quick start

Heckman model of \( y \) on \( x_1 \) with \( v_1 \) predicting selection when binary variable \( \text{selected} \) indicates selection status

\[
\text{heckman } y \ x_1, \text{select(\text{selected} = v_1 \ x_1)}
\]

As above, and generate \( v_2 \) containing the inverse Mills’s ratio

\[
\text{heckman } y \ x_1, \text{select(\text{selected} = v_1 \ x_1)} \text{ mills(}v_2\text{)}
\]

Same as above

\[
\text{heckman } y \ x_1, \text{select(\text{selected} = v_1 \ x_1)} \text{ nshazard(}v_2\text{)}
\]

Fit a Heckman model using the two-step estimation method

\[
\text{heckman } y \ x_1, \text{select(\text{selected} = v_1 \ x_1)} \text{ twostep}
\]

As above, and display first-stage probit estimates

\[
\text{heckman } y \ x_1, \text{select(\text{selected} = v_1 \ x_1)} \text{ twostep first}
\]

Syntax

Basic syntax

```stata
heckman depvar [indepvars], select(varlist) [twostep]
```
or

```stata
heckman depvar [indepvars], select(depvar = varlist) [twostep]
```

Full syntax for maximum likelihood estimates only

```stata
heckman depvar [indepvars] [if] [in] [weight],
   select([depvar =] varlist [, noconstant offset(varname)])
   [heckman_ml_options]
```

Full syntax for Heckman’s two-step consistent estimates only

```stata
heckman depvar [indepvars] [if] [in], twostep
   select([depvar =] varlist [, noconstant]) [heckman_ts_options]
```

**Options for Heckman selection model (ML)**

<table>
<thead>
<tr>
<th>Model</th>
<th>mle requests that the maximum likelihood estimator be used. This is the default.</th>
</tr>
</thead>
<tbody>
<tr>
<td>select([ depvar = ] varlist [, noconstant offset(varname=o) ] )</td>
<td>specifies the variables and options for the selection equation. It is an integral part of specifying a Heckman model and is required. The selection equation should contain at least one variable that is not in the outcome equation.</td>
</tr>
</tbody>
</table>
If \( \text{depvar} \) is specified, it should be coded as 0 or 1, with 0 indicating an observation not selected and 1 indicating a selected observation. If \( \text{depvar} \) is not specified, observations for which \( \text{depvar} \) is not missing are assumed selected, and those for which \( \text{depvar} \) is missing are assumed not selected.

\text{noconstant} \) suppresses the selection constant term (intercept).

\text{offset(} \text{varname} \text{)} \) specifies that selection offset \( \text{varname} \) be included in the model with the coefficient constrained to be 1.

\text{noconstant, offset(} \text{varname} \text{)}, \text{constraints(} \text{constraints} \text{)}; see [R] Estimation options.

\text{vce(} \text{vcetype} \text{)} \) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (\text{oim, opg}), that are robust to some kinds of misspecification (\text{robust}), that allow for intragroup correlation (\text{cluster clustvar}), and that use bootstrap or jackknife methods (\text{bootstrap, jackknife}); see [R] vce option.

\text{level(} \text{#} \text{)}; see [R] Estimation options.

\text{first} \) specifies that the first-step probit estimates of the selection equation be displayed before estimation.

\text{lrmodel}; see [R] Estimation options.

\text{nshazard(} \text{newvar} \text{)} \) and \text{mills(} \text{newvar} \text{)} are synonyms; either will create a new variable containing the nonselection hazard—what \text{Heckman (1979)} referred to as the inverse of the Mills ratio—from the selection equation. The nonselection hazard is computed from the estimated parameters of the selection equation.

\text{nocnsreport}; see [R] Estimation options.

\text{display_options: noci, nopvalues, noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(} \text{#} \text{)}, \text{fvwrapon(} \text{style} \text{)}, \text{cformat(} \%\text{fmt} \text{)}, \text{pformat(} \%\text{fmt} \text{)}, \text{sformat(} \%\text{fmt} \text{)}, and \text{nolstretch}; see [R] Estimation options.

\text{maximize_options: difficult, technique(} \text{algorithm_spec} \text{)}, \text{iterate(} \text{#} \text{)}, \text{[no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(} \text{#} \text{)}, \text{ltolerance(} \text{#} \text{)}, \text{ntolerance(} \text{#} \text{)}, \text{nonrtolerance, and from(} \text{init_specs} \text{)}; see [R] Maximize. These options are seldom used.

Setting the optimization type to \text{technique(bhhh)} resets the default \text{vcetype to vce(opg)}.

The following options are available with \text{heckman} but are not shown in the dialog box:
\text{collinear, coeflegend}; see [R] Estimation options.

\text{Options for Heckman selection model (two-step)}

\text{twostep} \) specifies that \text{Heckman’s (1979)} two-step efficient estimates of the parameters, standard errors, and covariance matrix be produced.
select([depvar, = varlist[, noconstant]]) specifies the variables and options for the selection equation. It is an integral part of specifying a Heckman model and is required. The selection equation should contain at least one variable that is not in the outcome equation.

If depvar is specified, it should be coded as 0 or 1, with 0 indicating an observation not selected and 1 indicating a selected observation. If depvar is not specified, observations for which depvar is not missing are assumed selected, and those for which depvar is missing are assumed not selected.

noconstant suppresses the selection constant term (intercept).

rhosigma, rhotrunc, rholimited, and rhoforce are rarely used options to specify how the two-step estimator (option twostep) handles unusual cases in which the two-step estimate of \( \rho \) is outside the admissible range for a correlation, \([-1, 1]\). When \(|\rho| > 1\), the two-step estimate of the coefficient variance–covariance matrix may not be positive definite and thus may be unusable for testing. The default is rhosigma.

rhosigma specifies that \( \rho \) be truncated, as with the rhotrunc option, and that the estimate of \( \sigma \) be made consistent with \( \hat{\rho} \), the truncated estimate of \( \rho \). So, \( \hat{\sigma} = \beta_m \hat{\rho} \); see Methods and formulas for the definition of \( \beta_m \). Both the truncated \( \rho \) and the new estimate of \( \hat{\sigma} \) are used in all computations to estimate the two-step covariance matrix.

rhotrunc specifies that \( \rho \) be truncated to lie in the range \([-1, 1]\). If the two-step estimate is less than \(-1\), \( \rho \) is set to \(-1\); if the two-step estimate is greater than 1, \( \rho \) is set to 1. This truncated value of \( \rho \) is used in all computations to estimate the two-step covariance matrix.

rholimited specifies that \( \rho \) be truncated only in computing the diagonal matrix \( D \) as it enters \( V_{\text{twostep}} \) and \( Q \); see Methods and formulas. In all other computations, the untruncated estimate of \( \rho \) is used.

rhoforce specifies that the two-step estimate of \( \rho \) be retained, even if it is outside the admissible range for a correlation. This option may, in rare cases, lead to a non–positive-definite covariance matrix.

These options have no effect when estimation is by maximum likelihood, the default. They also have no effect when the two-step estimate of \( \rho \) is in the range \([-1, 1]\).

vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (conventional) and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.

vce(conventional), the default, uses the two-step variance estimator derived by Heckman.

level(#) specifies that the first-step probit estimates of the selection equation be displayed before estimation.

nshazard(newvar) and mills(newvar) are synonyms; either will create a new variable containing the nonselection hazard—what Heckman (1979) referred to as the inverse of the Mills ratio—from the selection equation. The nonselection hazard is computed from the estimated parameters of the selection equation.
The following option is available with `heckman` but is not shown in the dialog box:

```plaintext
coeflegend; see [R] Estimation options.
```

## Remarks and examples

The Heckman selection model (Gronau 1974; Lewis 1974; Heckman 1976) assumes that there exists an underlying regression relationship,

\[ y_j = x_j \beta + u_{1j} \quad \text{regression equation} \]

The dependent variable, however, is not always observed. Rather, the dependent variable for observation \( j \) is observed if

\[ z_j \gamma + u_{2j} > 0 \quad \text{selection equation} \]

where

\[ u_1 \sim N(0, \sigma) \]
\[ u_2 \sim N(0, 1) \]
\[ \text{corr}(u_1, u_2) = \rho \]

When \( \rho \neq 0 \), standard regression techniques applied to the first equation yield biased results. `heckman` provides consistent, asymptotically efficient estimates for all the parameters in such models.

In one classic example, the first equation describes the wages of women. Women choose whether to work, and thus, from our point of view as researchers, whether we observe their wages in our data. If women made this decision randomly, we could ignore that not all wages are observed and use ordinary regression to fit a wage model. Such an assumption of random participation, however, is unlikely to be true; women who would have low wages may be unlikely to choose to work, and thus the sample of observed wages is biased upward. In the jargon of economics, women choose not to work when their personal reservation wage is greater than the wage offered by employers. Thus women who choose not to work might have even higher offer wages than those who do work—they may have high offer wages, but they have even higher reservation wages. We could tell a story that competency is related to wages, but competency is rewarded more at home than in the labor force.

In any case, in this problem—which is the paradigm for most such problems—a solution can be found if there are some variables that strongly affect the chances for observation (the reservation wage) but not the outcome under study (the offer wage). Such a variable might be the number of children in the home. (Theoretically, we do not need such identifying variables, but without them, we depend on functional form to identify the model. It would be difficult for anyone to take such results seriously because the functional form assumptions have no firm basis in theory.)

### Example 1

In the syntax for `heckman`, `depvar` and `indepvars` are the dependent variable and regressors for the underlying regression model to be fit \( (y = X\beta) \), and `varlist` are the variables \((Z)\) thought to determine whether `depvar` is observed or unobserved (selected or not selected). In our female wage example, the number of children at home would be included in the second list. By default, `heckman` assumes that missing values (see [U] 12.2.1 Missing values) of `depvar` imply that the dependent variable is
unobserved (not selected). With some datasets, it is more convenient to specify a binary variable \((\text{depvar}_s)\) that identifies the observations for which the dependent is observed/selected \((\text{depvar}_s \neq 0)\) or not observed \((\text{depvar}_s = 0)\); \texttt{heckman} will accommodate either type of data. Here we have a (fictional) dataset on 2,000 women, 1,343 of whom work:

\begin{verbatim}
use https://www.stata-press.com/data/r16/womenwk
.summarize age educ married children wage
Variable | Obs Mean Std. Dev. Min Max
---------|--------|-----------------|-----|---------------------|
age | 2,000 | 36.208 | 8.28656 | 20 | 59
education | 2,000 | 13.084 | 3.045912 | 10 | 20
married | 2,000 | 0.6705 | 0.4701492 | 0 | 1
children | 2,000 | 1.6445 | 1.398963 | 0 | 5
wage | 1,343 | 23.69217 | 6.305374 | 5.88497 | 45.80979
\end{verbatim}

We will assume that the hourly wage is a function of education and age, whereas the likelihood of working (the likelihood of the wage being observed) is a function of marital status, the number of children at home, and (implicitly) the wage (via the inclusion of age and education, which we think determine the wage):

\begin{verbatim}
. heckman wage educ age, select(married children educ age)
Iteration 0: log likelihood = -5178.7009

\end{verbatim}

\texttt{heckman} assumes that \texttt{wage} is the dependent variable and that the first variable list (\texttt{educ} and \texttt{age}) are the determinants of \texttt{wage}. The variables specified in the \texttt{select()} option (\texttt{married}, \texttt{children}, \texttt{educ}, and \texttt{age}) are assumed to determine whether the dependent variable is observed (the selection equation). Thus we fit the model

\[ \text{wage} = \beta_0 + \beta_1 \text{educ} + \beta_2 \text{age} + u_1 \]
and we assumed that wage is observed if

\[ \gamma_0 + \gamma_1 \text{married} + \gamma_2 \text{children} + \gamma_3 \text{educ} + \gamma_4 \text{age} + u_2 > 0 \]

where \( u_1 \) and \( u_2 \) have correlation \( \rho \).

The reported results for the wage equation are interpreted exactly as though we observed wage data for all women in the sample; the coefficients on age and education level represent the estimated marginal effects of the regressors in the underlying regression equation. The results for the two ancillary parameters require some explanation. \texttt{heckman} does not directly estimate \( \rho \); to constrain \( \rho \) within its valid limits, and for numerical stability during optimization, it estimates the inverse hyperbolic tangent of \( \rho \):

\[
\text{atanh } \rho = \frac{1}{2} \ln \left( \frac{1 + \rho}{1 - \rho} \right)
\]

This estimate is reported as \texttt{/athrho}. In the bottom panel of the output, \texttt{heckman} undoes this transformation for you: the estimated value of \( \rho \) is 0.7035061. The standard error for \( \rho \) is computed using the delta method, and its confidence intervals are the transformed intervals of \texttt{/athrho}.

Similarly, \( \sigma \), the standard error of the residual in the wage equation, is not directly estimated; for numerical stability, \texttt{heckman} instead estimates \( \ln \sigma \). The untransformed \texttt{sigma} is reported at the end of the output: 6.004797.

Finally, some researchers—especially economists—are used to the selectivity effect summarized not by \( \rho \) but by \( \lambda = \rho \sigma \). \texttt{heckman} reports this, too, along with an estimate of the standard error and confidence interval.

\section*{Technical note}

If each of the equations in the model had contained many regressors, the \texttt{heckman} command could have become long. An alternate way of specifying our wage model would be to use Stata’s global macros. The following lines are an equivalent way of specifying our model:

\begin{verbatim}
. global wageeq "wage educ age"
. global seleq "married children educ age"
. heckman $wageeq, select($seleq)
\end{verbatim}

\section*{Technical note}

The reported model \( \chi^2 \) test is a Wald test that all coefficients in the regression model (except the constant) are 0. \texttt{heckman} is an estimation command, so you can use \texttt{test}, \texttt{testnl}, or \texttt{lrtest} to perform tests against whatever nested alternate model you choose; see \cite{[R] test}, \cite{[R] testnl}, and \cite{[R] lrtest}.

The estimation of \( \rho \) and \( \sigma \) in the forms \texttt{atanh } \rho and \texttt{ln } \sigma extends the range of these parameters to infinity in both directions, thus avoiding boundary problems during the maximization. Tests of \( \rho \) must be made in the transformed units. However, because \texttt{atanh}(0) = 0, the reported test for \texttt{atanh } \rho = 0 is equivalent to the test for \( \rho = 0 \).
The likelihood-ratio test reported at the bottom of the output is an equivalent test for $\rho = 0$ and is computationally the comparison of the joint likelihood of an independent probit model for the selection equation and a regression model on the observed wage data against the Heckman model likelihood. Because $\chi^2 = 61.20$, this clearly justifies the Heckman selection equation with these data.

Example 2

`heckman` supports the Huber/White/sandwich estimator of variance under the `vce(robust)` and `vce(cluster clustvar)` options or when `pweights` are used for population-weighted data; see [U] 20.22 Obtaining robust variance estimates. We can obtain robust standard errors for our wage model by specifying clustering on county of residence (the `county` variable).

```
. heckman wage educ age, select(married children educ age) vce(cluster county)
Iteration 0: log pseudolikelihood = -5178.7009
Iteration 1: log pseudolikelihood = -5178.3049
Iteration 2: log pseudolikelihood = -5178.3045
```

Wald test of indep. eqns. (rho = 0): chi2(1) = 38.81 Prob > chi2 = 0.0000

The robust standard errors tend to be a bit larger, but we notice no systematic differences. This finding is not surprising because the data were not constructed to have any county-specific correlations or any other characteristics that would deviate from the assumptions of the Heckman model.
Example 3

Stata also produces Heckman’s (1979) two-step efficient estimator of the model with the `twostep` option. Maximum likelihood estimation of the parameters can be time consuming with large datasets, and the two-step estimates may provide a good alternative in such cases. Continuing with the women’s wage model, we can obtain the two-step estimates with Heckman’s consistent covariance estimates by typing

```
. heckman wage educ age, select(married children educ age) twostep
```

Heckman selection model -- two-step estimates

Technical note

The Heckman selection model depends strongly on the model being correct, much more so than ordinary regression. Running a separate probit or logit for sample inclusion followed by a regression, referred to in the literature as the two-part model (Manning, Duan, and Rogers 1987)—not to be confused with Heckman’s two-step procedure—is an especially attractive alternative if the regression part of the model arose because of taking a logarithm of zero values. When the goal is to analyze an underlying regression model or to predict the value of the dependent variable that would be observed in the absence of selection, however, the Heckman model is more appropriate. When the goal is to predict an actual response, the two-part model is usually the better choice.

The Heckman selection model can be unstable when the model is not properly specified or if a specific dataset simply does not support the model’s assumptions. For example, let’s examine the solution to another simulated problem.
. use https://www.stata-press.com/data/r16/twopart

LR test of indep. eqns. (rho = 0): chi2(1) = 25.67  Prob > chi2 = 0.0000

The model has converged to a value of \( \rho \) that is 1.0—within machine-rounding tolerances. Given the form of the likelihood for the Heckman selection model, this implies a division by zero, and it is surprising that the model solution turns out as well as it does. Reparameterizing \( \rho \) has allowed the estimation to converge, but we clearly have problems with the estimates. Moreover, if this had occurred in a large dataset, waiting for convergence might take considerable time.

This dataset was not intentionally developed to cause problems. It is actually generated by a "Heckman process" and when generated starting from different random values can be easily estimated. The luck of the draw here merely led to data that, despite the source, did not support the assumptions of the Heckman model.

The two-step model is generally more stable when the data are problematic. It even tolerates estimates of \( \rho \) less than \(-1\) and greater than 1. For these reasons, the two-step model may be preferred when exploring a large dataset. Still, if the maximum likelihood estimates cannot converge, or converge to a value of \( \rho \) that is at the boundary of acceptable values, there is scant support for fitting a Heckman selection model on the data. Heckman (1979) discusses the implications of \( \rho \) being exactly 1 or 0, together with the implications of other possible covariance relationships among the model’s determinants.
Stored results

heckman (maximum likelihood) stores the following in e():

Scalars
- **e(N)**: number of observations
- **e(N_selected)**: number of selected observations
- **e(N_nonselected)**: number of nonselected observations
- **e(k)**: number of parameters
- **e(k_eq)**: number of equations in e(b)
- **e(k_eq_model)**: number of equations in overall model test
- **e(k_aux)**: number of auxiliary parameters
- **e(k_dv)**: number of dependent variables
- **e(df_m)**: model degrees of freedom
- **e(ll)**: log likelihood
- **e(ll_0)**: log likelihood, constant-only model
- **e(N_clust)**: number of clusters
- **e(lambda)**: \( \lambda \)
- **e(selambda)**: standard error of \( \lambda \)
- **e(sigma)**: \( \sigma \)
- **e(chi2)**: \( \chi^2 \)
- **e(chi2_c)**: \( \chi^2 \) for comparison test
- **e(p)**: \( p \)-value for model test
- **e(p_c)**: \( p \)-value for comparison test
- **e(rho)**: \( \rho \)
- **e(rank)**: rank of e(V)
- **e(rank0)**: rank of e(V) for constant-only model
- **e(ic)**: number of iterations
- **e(rc)**: return code
- **e(converged)**: 1 if converged, 0 otherwise

Macros
- **e(cmd)**: heckman
- **e(cmdline)**: command as typed
- **e(depvar)**: names of dependent variables
- **e(wtype)**: weight type
- **e(wexp)**: weight expression
- **e(title)**: title in estimation output
- **e(title2)**: secondary title in estimation output
- **e(clustvar)**: name of cluster variable
- **e(offset1)**: offset for regression equation
- **e(offset2)**: offset for selection equation
- **e(mills)**: variable containing nonselection hazard (inverse of Mills’s ratio)
- **e(chi2type)**: Wald or LR; type of model \( \chi^2 \) test
- **e(chi2_ct)**: Wald or LR; type of model \( \chi^2 \) test corresponding to e(chi2_c)
- **e(vcetype)**: vcetype specified in vce()
- **e(opt)**: type of optimization
- **e(which)**: max or min; whether optimizer is to perform maximization or minimization
- **e(method)**: ml
- **e(ml_method)**: type of ml method
- **e(user)**: name of likelihood-evaluator program
- **e(technique)**: maximization technique
- **e(properties)**: b V
- **e(predict)**: program used to implement predict
- **e(marginsok)**: predictions allowed by margins
- **e(marginsnotok)**: predictions disallowed by margins
- **e(asbalanced)**: factor variables fvset as asbalanced
- **e(asobserved)**: factor variables fvset as asobserved
Matrices
  e(b) coefficient vector
  e(Cns) constraints matrix
  e(ilog) iteration log (up to 20 iterations)
  e(gradient) gradient vector
  e(V) variance–covariance matrix of the estimators
  e(V_modelbased) model-based variance

Functions
  e(sample) marks estimation sample

heckman (two-step) stores the following in e():

Scalars
  e(N) number of observations
  e(N_selected) number of selected observations
  e(N_nonselected) number of nonselected observations
  e(df_m) model degrees of freedom
  e(lambda) \( \lambda \)
  e(selambda) standard error of \( \lambda \)
  e(sigma) \( \sigma \)
  e(chi2) \( \chi^2 \)
  e(p) \( p \)-value for comparison test
  e(rho) \( \rho \)
  e(rank) rank of e(V)

Macros

  e(marginsnotok) predictions disallowed by margins
  e(asbalanced) factor variables fvset as asbalanced
  e(asobserved) factor variables fvset as asobserved

James Joseph Heckman (1944– ) was born in Chicago in 1944 and studied mathematics at Colorado College and economics at Princeton. He has taught economics at Columbia and (since 1973) at the University of Chicago. He has worked on developing a scientific basis for economic policy evaluation, with emphasis on models of individuals or disaggregated groups and the problems and possibilities created by heterogeneity, diversity, and unobserved counterfactual states. In 2000, he shared the Nobel Prize in Economics with Daniel L. McFadden.
Methods and formulas

Regression estimates using the nonselection hazard (Heckman 1979) provide starting values for maximum likelihood estimation.

The regression equation is

\[ y_j = \mathbf{x}_j \beta + u_{1j} \]

The selection equation is

\[ \mathbf{z}_j \gamma + u_{2j} > 0 \]

where

\[ u_1 \sim N(0, \sigma) \]
\[ u_2 \sim N(0, 1) \]
\[ \text{corr}(u_1, u_2) = \rho \]

The log likelihood for observation \( j \), \( \ln L_j = l_j \), is

\[
l_j = \begin{cases} 
    w_j \ln \Phi \left( \frac{\mathbf{z}_j \gamma + (y_j - \mathbf{x}_j \beta) \rho / \sigma}{\sqrt{1 - \rho^2}} \right) - \frac{w_j}{2} \left( \frac{y_j - \mathbf{x}_j \beta}{\sigma} \right)^2 - w_j \ln(\sqrt{2\pi}\sigma) & y_j \text{ observed} \\
    w_j \ln \Phi(-\mathbf{z}_j \gamma) & y_j \text{ not observed}
\end{cases}
\]

where \( \Phi(\cdot) \) is the standard cumulative normal and \( w_j \) is an optional weight for observation \( j \).

In the maximum likelihood estimation, \( \sigma \) and \( \rho \) are not directly estimated. Directly estimated are \( \ln \sigma \) and \( \text{atanh} \rho \):

\[ \text{atanh} \rho = \frac{1}{2} \ln \left( \frac{1 + \rho}{1 - \rho} \right) \]

The standard error of \( \lambda = \rho \sigma \) is approximated through the propagation of error (delta) method; that is,

\[ \text{Var}(\lambda) \approx \mathbf{D} \text{Var}\left\{\left(\text{atanh} \rho \ln \sigma\right)\right\} \mathbf{D}' \]

where \( \mathbf{D} \) is the Jacobian of \( \lambda \) with respect to \( \text{atanh} \rho \) and \( \ln \sigma \).

With maximum likelihood estimation, this command supports the Huber/White/sandwich estimator of the variance and its clustered version using \textit{vce(robust)} and \textit{vce(cluster clustvar)}, respectively. See \textbf{[P] _robust}, particularly \textit{Maximum likelihood estimators} and \textit{Methods and formulas}.

The maximum likelihood version of heckman also supports estimation with survey data. For details on VCEs with survey data, see \textbf{[SVY] Variance estimation}.

The two-step estimates are computed using Heckman’s (1979) procedure.

Probit estimates of the selection equation

\[ \Pr(y_j \text{ observed} \mid \mathbf{z}_j) = \Phi(\mathbf{z}_j \gamma) \]
are obtained. From these estimates, the nonselection hazard—what Heckman (1979) referred to as the inverse of the Mills ratio, \( m_j \)—for each observation \( j \) is computed as

\[
m_j = \frac{\phi(z_j \hat{\gamma})}{\Phi(z_j \hat{\gamma})}
\]

where \( \phi \) is the normal density. We also define

\[
\delta_j = m_j(m_j + \hat{\gamma} z_j)
\]

Following Heckman, the two-step parameter estimates of \( \beta \) are obtained by augmenting the regression equation with the nonselection hazard \( m \). Thus the regressors become \( [X \ m] \), and we obtain the additional parameter estimate \( \beta_m \) on the variable containing the nonselection hazard.

A consistent estimate of the regression disturbance variance is obtained using the residuals from the augmented regression and the parameter estimate on the nonselection hazard,

\[
\hat{\sigma}^2 = \frac{e'e + \beta_m^2 \sum_{j=1}^{N} \delta_j}{N}
\]

The two-step estimate of \( \rho \) is then

\[
\hat{\rho} = \frac{\beta_m}{\hat{\sigma}}
\]

Heckman derived consistent estimates of the coefficient covariance matrix on the basis of the augmented regression.

Let \( W = [X \ m] \) and \( R \) be a square, diagonal matrix of dimension \( N \), with \( (1 - \hat{\rho}^2 \delta_j) \) as the diagonal elements. The conventional VCE is

\[
V_{\text{twostep}} = \hat{\sigma}^2(W'W)^{-1}(W'RW + Q)(W'W)^{-1}
\]

where

\[
Q = \hat{\rho}^2(W'DZ)V_p(Z'DW)
\]

where \( D \) is the square, diagonal matrix of dimension \( N \) with \( \delta_j \) as the diagonal elements; \( Z \) is the data matrix of selection equation covariates; and \( V_p \) is the variance–covariance estimate from the probit estimation of the selection equation.

These statistics are available both in and out of sample; type predict ... if e(sample) ... if wanted only for the estimation sample.

stdf is not allowed with svy estimation results.

where a and b may be numbers or variables; a missing (a ≥ .) means −∞, and b missing (b ≥ .) means +∞; see [U] 12.2.1 Missing values.
Options for predict

xb, the default, calculates the linear prediction \(x_j b\).

stdp calculates the standard error of the prediction, which can be thought of as the standard error of the predicted expected value or mean for the observation’s covariate pattern. The standard error of the prediction is also referred to as the standard error of the fitted value.

stdf calculates the standard error of the forecast, which is the standard error of the point prediction for 1 observation. It is commonly referred to as the standard error of the future or forecast value. By construction, the standard errors produced by stdf are always larger than those produced by stdp; see Methods and formulas in [R] regress postestimation.

stdpsel calculates the standard error of the linear prediction for the selection equation.

pr() calculates the expected value of the dependent variable \(y_j\), the default, calculates the linear prediction \(x_j b\).

\(pr(a, b)\) calculates \(Pr(a < x_j b + u_1 < b)\), the probability that \(y_j \mid x_j\) would be observed in the interval \((a, b)\).

\(pr(20, 30)\) calculates \(Pr(20 < x_j b + u_1 < 30)\); \(pr(lb, ub)\) calculates \(Pr(lb < x_j b + u_1 < ub)\); and \(pr(20, ub)\) calculates \(Pr(20 < x_j b + u_1 < ub)\).

\(pr(20, .)\) calculates \(Pr(20 < x_j b + u_1 < \infty)\); \(pr(., 30)\) calculates \(Pr(-\infty < x_j b + u_1 < 30)\); \(pr(lb, .)\) calculates \(Pr(-\infty < x_j b + u_1 < \infty)\); \(pr(., ub)\) calculates \(Pr(-\infty < x_j b + u_1 < ub)\); and \(pr(., ub)\) calculates \(Pr(lb < x_j b + u_1 < ub)\) elsewhere.

\(e(a, b)\) calculates \(E(x_j b + u_1 \mid a < x_j b + u_1 < b)\), the expected value of \(y_j \mid x_j\) conditional on \(y_j \mid x_j\) being in the interval \((a, b)\), meaning that \(y_j \mid x_j\) is truncated.

\(e(20, 30)\) calculates \(E(x_j b + u_1 \mid 20 < x_j b + u_1 < 30)\); \(e(lb, ub)\) calculates \(E(x_j b + u_1 \mid lb < x_j b + u_1 < ub)\); and \(e(20, ub)\) calculates \(E(x_j b + u_1 \mid 20 < x_j b + u_1 < ub)\) elsewhere.

\(y^*(a, b)\) calculates \(E(y^*_j), \text{ where } y^*_j = a \text{ if } x_j b + u_j \leq a, y^*_j = b \text{ if } x_j b + u_j \geq b, \text{ and } y^*_j = x_j b + u_j \text{ otherwise, meaning that } y^*_j \text{ is not selected. } a \text{ and } b \text{ are specified as they are for } pr().\)

psel calculates the probability of selection (or being observed):
\[Pr(y_j \text{ observed}) = Pr(z_j \gamma + u_{2j} > 0).\]

nooffset is relevant when you specify offset(varname) for heckman. It modifies the calculations made by predict so that they ignore the offset variable; the linear prediction is treated as \(x_j b\) rather than as \(x_j b + \text{offset}_j\).
heckman postestimation — Postestimation tools for heckman

scores, not available with twostep, calculates equation-level score variables.

The first new variable will contain $\partial \ln L / \partial (x_j \beta)$.
The second new variable will contain $\partial \ln L / \partial (z_j \gamma)$.
The third new variable will contain $\partial \ln L / \partial (\text{atanh} \rho)$.
The fourth new variable will contain $\partial \ln L / \partial (\ln \sigma)$.

margins

Description for margins

margins estimates margins of response for linear predictions, probabilities, expected values, and nonselection hazards.

Menu for margins

Statistics > Postestimation

*ycond and yexpected are not allowed with margins after heckman, twostep.

Statistics not allowed with margins are functions of stochastic quantities other than $e(b)$.

For the full syntax, see [R] margins.
Remarks and examples

Example 1

The default statistic produced by 	exttt{predict} after 	exttt{heckman} is the expected value of the dependent variable from the underlying distribution of the regression model. In the wage model of \texttt{[R] heckman}, this is the expected wage rate among all women, regardless of whether they were observed to participate in the labor force:

```
. use https://www.stata-press.com/data/r16/womenwk
. heckman wage educ age, select(married children educ age) vce(cluster county) (output omitted)
. predict heckwage (option \texttt{xb} assumed; fitted values)
```

It is instructive to compare these predicted wage values from the Heckman model with an ordinary regression model—a model without the selection adjustment:

```
. regress wage educ age

Source | SS       df MS
---------|----------|--------
Model    | 13524.0337 2 6762.01687
Residual | 39830.8609 1,340 29.7245231
Total    | 53354.8946 1,342 39.7577456

Number of obs = 1,343
F(2, 1340) = 227.49
Prob > F = 0.0000
R-squared = 0.2535
Adj R-squared = 0.2524

wage            Coef. Std. Err.  t    P>|t|    [95% Conf. Interval]
------------- |------------|--------|--------|---------------------|---------------------|
education      | .8965829   | .0498061 | 18.00  | 0.000               | .7988765 .9942893   |
age           | .1465739   | .0187135 | 7.83   | 0.000               | .109863 .1832848    |
_cons          | 6.084875   | .8896182 | 6.84   | 0.000               | 4.339679 7.830071   |

. predict regwage (option \texttt{xb} assumed; fitted values)
. summarize heckwage regwage

    Variable | Obs  | Mean    | Std. Dev. | Min | Max
-------------|------|---------|-----------|-----|-----
 heckwage   | 2,000| 21.15532| 3.83965   | 14.6479 | 32.85949|
 regwage     | 2,000| 23.12291| 3.241911  | 17.98218 | 32.66439|
```

Because this dataset was concocted, we know the true coefficients of the wage regression equation to be 1, 0.2, and 1, respectively. We can compute the true mean wage for our sample:

```
. generate truewage = 1 + .2*age + 1*educ
. summarize truewage

    Variable | Obs  | Mean   | Std. Dev. | Min | Max
-------------|------|--------|-----------|-----|-----
 truewage    | 2,000| 21.3256| 3.797904  | 15  | 32.8
```

Whereas the mean of the predictions from \texttt{heckman} is within 18 cents of the true mean wage, ordinary regression yields predictions that are on average about $1.80 per hour too high because of the selection effect. The regression predictions also show somewhat less variation than the true wages.

The coefficients from \texttt{heckman} are so close to the true values that they are not worth testing. Conversely, the regression equation is significantly off but seems to give the right sense. Would we be led far astray if we relied on the OLS coefficients? The effect of age is off by more than 5 cents per year of age, and the coefficient on education level is off by about 10%. We can test the OLS coefficient on education level against the true value by using \texttt{test}.
. test educ = 1  
( 1) education = 1  
F( 1, 1340) = 4.31  
Prob > F = 0.0380

Not only is the OLS coefficient on education substantially lower than the true parameter, but the difference from the true parameter is also statistically significant beyond the 5% level. We can perform a similar test for the OLS age coefficient:

. test age = .2  
( 1) age = .2  
F( 1, 1340) = 8.15  
Prob > F = 0.0044

We find even stronger evidence that the OLS regression results are biased away from the true parameters.

Example 2

Several other interesting aspects of the Heckman model can be explored with predict. Continuing with our wage model, we can obtain the expected wages for women conditional on participating in the labor force with the ycond option. Let’s get these predictions and compare them with actual wages for women participating in the labor force.

. use https://www.stata-press.com/data/r16/womenwk, clear
. heckman wage educ age, select(married children educ age)  
(output omitted)
. predict hcndwage, ycond
. summarize wage hcndwage if wage != .

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>wage</td>
<td>1,343</td>
<td>23.69217</td>
<td>6.305374</td>
<td>5.88497</td>
<td>45.80979</td>
</tr>
<tr>
<td>hcndwage</td>
<td>1,343</td>
<td>23.68239</td>
<td>3.335087</td>
<td>16.18337</td>
<td>33.7567</td>
</tr>
</tbody>
</table>

We see that the average predictions from heckman are close to the observed levels but do not have the same mean. These conditional wage predictions are available for all observations in the dataset but can be directly compared only with observed wages, where individuals are participating in the labor force.

What if we were interested in making predictions about mean wages for all women? Here the expected wage is 0 for those who are not expected to participate in the labor force, with expected participation determined by the selection equation. These values can be obtained with the yexpected option of predict. For comparison, a variable can be generated where the wage is set to 0 for nonparticipants.

. predict hexpwage, yexpected
. generate wage0 = wage  
(657 missing values generated)
. replace wage0 = 0 if wage == .  
(657 real changes made)
. summarize hexp wage0

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>hexp</td>
<td>2,000</td>
<td>15.92511</td>
<td>5.979336</td>
<td>2.492469</td>
<td>32.45858</td>
</tr>
<tr>
<td>wage0</td>
<td>2,000</td>
<td>15.90929</td>
<td>12.27081</td>
<td>0</td>
<td>45.80979</td>
</tr>
</tbody>
</table>

Again we note that the predictions from `heckman` are close to the observed mean hourly wage rate for all women. Why aren’t the predictions using `ycond` and `yexpected` equal to their observed sample equivalents? For the Heckman model, unlike linear regression, the sample moments implied by the optimal solution to the model likelihood do not require that these predictions match observed data. Properly accounting for the additional variation from the selection equation requires that the model use more information than just the sample moments of the observed wages.

</table>

*select() is required.
The full specification is `select([depvar_s =] varlist_s [, noconstant offset(varname_o)])`.

indepvars and varlist_s may contain factor variables; see [U] 11.4.3 Factor variables.
depvar, indepvars, depvar_s, and varlist_s may contain time-series operators; see [U] 11.4.4 Time-series varlists.
bayes, bootstrap, by, jackknife, rolling, statsby, and svy are allowed; see [U] 11.1.10 Prefix commands.
For more details, see [BAYES] bayes: heckoprobit.
Weights are not allowed with the bootstrap prefix; see [R] bootstrap.
vce(), first, and weights are not allowed with the svy prefix; see [SVY] svy.
pweights, fweights, and iweights are allowed; see [U] 11.1.6 weight.
collinear and coeflegend do not appear in the dialog box.
See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

Options

```
select([depvar_s =] varlist_s [, noconstant offset(varname_o)]) specifies the variables and options for the selection equation. It is an integral part of specifying a selection model and is
```
required. The selection equation should contain at least one variable that is not in the outcome equation.

If \textit{depvar} \texttt{s} is specified, it should be coded as 0 or 1, 0 indicating an observation not selected and 1 indicating a selected observation. If \textit{depvar} \texttt{s} is not specified, observations for which \textit{depvar} is not missing are assumed selected, and those for which \textit{depvar} is missing are assumed not selected.

\texttt{noconstant} suppresses the selection constant term (intercept).

\texttt{offset(varname)} specifies that selection offset \textit{varname} be included in the model with the coefficient constrained to be 1.

\texttt{offset(varname), constraints(constraints)}; see \texttt{[R] Estimation options}.

\texttt{vce(vcetype)} specifies the type of standard error reported, which includes types that are derived from asymptotic theory (\texttt{opg}, \texttt{ov}), that are robust to some kinds of misspecification (\texttt{robust}), that allow for intragroup correlation (\texttt{cluster clustvar}), and that use bootstrap or jackknife methods (\texttt{bootstrap}, \texttt{jackknife}); see \texttt{[R] vce_option}.

\texttt{level(#)}; see \texttt{[R] Estimation options}.

\texttt{first} specifies that the first-step probit estimates of the selection equation be displayed before estimation.

\texttt{noheader} suppresses the header above the parameter table.

\texttt{nofootnote} suppresses the footnotes displayed below the parameter table.

\texttt{nocnsreport}; see \texttt{[R] Estimation options}.

\texttt{display_options}: \texttt{noci, nopvalues, nomitted, vsquish, noemptycells, baselevels, allbaselevels, noglabel, fvwrap(#), fvwrapon(style), cformat(\%mt), pformat(\%mt), sformat(\%mt), and nolstretch}; see \texttt{[R] Estimation options}.

\texttt{Maximization}

\texttt{maximize_options}: \texttt{difficult, technique(algorithm_spec), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(init_specs)}; see \texttt{[R] Maximize}. These options are seldom used.

Setting the optimization type to \texttt{technique(bhhh)} resets the default \texttt{vcetype} to \texttt{vce(opg)}.

The following options are available with \texttt{heckoprobit} but are not shown in the dialog box:
\texttt{collinear, coeflegend}; see \texttt{[R] Estimation options}.

\textbf{Remarks and examples}

\texttt{heckoprobit} estimates the parameters of a regression model for an ordered categorical outcome from a nonrandom sample known as a selected sample. Selected samples suffer from “selection on unobservables” because the errors that determine whether a case is missing are correlated with the errors that determine the outcome.
For ordered categorical regression from samples that do not suffer from selection on unobservables, see [R] oprobit or [R] ologit. For regression of a continuous outcome variable from a selected sample, see [R] heckman.

Even though we are interested in modeling a single ordinal outcome, there are two dependent variables in the ordered probit sample-selection model because we must also model the sample-selection process. First, there is the ordinal outcome \( y_j \). Second, there is a binary variable that indicates whether each case in the sample is observed or unobserved. To handle the sample-selection problem, we model both dependent variables jointly. Both variables are categorical. Their categorical values are determined by the values of linear combinations of covariates and normally distributed error terms relative to certain cutpoints that partition the real line. The error terms used in the determination of selection and the ordinal outcome value may be correlated.

The probability that the ordinal outcome \( y_j \) is equal to the value \( v_h \) is given by the probability that \( x_j \beta + u_{1j} \) falls within the cutpoints \( \kappa_{h-1} \) and \( \kappa_h \),

\[
Pr(y_j = v_h) = Pr(\kappa_{h-1} < x_j \beta + u_{1j} \leq \kappa_h)
\]

where \( x_j \) is the outcome covariates, \( \beta \) is the coefficients, and \( u_{1j} \) is a random-error term. The observed outcome values \( v_1, \ldots, v_H \) are integers such that \( v_i < v_m \) for \( i < m \). \( \kappa_0 \) is taken as \(-\infty\) and \( \kappa_H \) is taken as \(+\infty\).

We model the selection process for the outcome by

\[
s_j = 1(z_j \gamma + u_{2j} > 0)
\]

where \( s_j = 1 \) if we observed \( y_j \) and 0 otherwise, \( z_j \) is the covariates used to model the selection process, \( \gamma \) is the coefficients for the selection process, \( 1(\cdot) \) denotes the indicator function, and \( u_{2j} \) is a random-error term.

\((u_{1j}, u_{2j})\) have bivariate normal distribution with mean zero and variance matrix

\[
\begin{bmatrix}
1 & \rho \\
\rho & 1
\end{bmatrix}
\]

When \( \rho \neq 0 \), standard ordered probit techniques applied to the outcome equation yield inconsistent results. heckoprobit provides consistent, asymptotically efficient estimates for all the parameters in such models.

De Luca and Perotti (2011) describe the maximum likelihood estimator used in heckoprobit.

Example 1

We have a simulated dataset containing a sample of 5,000 women, 3,480 of whom work. The outcome of interest is a woman’s job satisfaction, and we suspect that unobservables that determine job satisfaction and the unobservables that increase the likelihood of employment are correlated. Women may make a decision to work based on how satisfying their job would be. We estimate the parameters of an ordered probit sample-selection model for the outcome of job satisfaction (satisfaction) with selection on employment (work). Age (age) and years of education (education) are used as outcome covariates, and we also expect that they affect selection. Additional covariates for selection are marital status (married) and the number of children at home (children).

Here we estimate the parameters of the model with heckoprobit. We use the factorial interaction of married and children in select(). This specifies that the number of children and marital status affect selection, and it allows the effect of the number of children to differ among married and nonmarried women. The factorial interaction is specified using factor-variable notation, which is described in [U] 11.4.3 Factor variables.
The output shows several iteration logs. The first iteration log corresponds to running the ordered probit model for those observations in the sample where we have observed the outcome. The second iteration log corresponds to running the selection probit model, which models whether we observe
our outcome of interest. If $\rho = 0$, the sum of the log likelihoods from these two models will equal the log likelihood of the ordered probit sample-selection model; this sum is printed in the iteration log as the comparison log likelihood. The final iteration log is for fitting the full ordered probit sample-selection model.

The Wald test in the header is highly significant, indicating a good model fit. All the covariates are statistically significant. The likelihood-ratio test in the footer indicates that we can reject the null hypothesis that the errors for outcome and selection are uncorrelated. This means that we should use the ordered probit sample-selection model instead of the simple ordered probit model.

The positive estimate of 0.63 for $\rho$ indicates that unobservables that increase job satisfaction tend to occur with unobservables that increase the chance of having a job.

### Stored results

`heckoprobit` stores the following in `e()`:

Scalars
- `e(N)` number of observations
- `e(N_selected)` number of selected observations
- `e(N_nonselected)` number of nonselected observations
- `e(N_cd)` number of completely determined observations
- `e(k_cat)` number of categories
- `e(k)` number of parameters
- `e(k_eq)` number of equations in `e(b)`
- `e(k_eq_model)` number of equations in overall model test
- `e(k_aux)` number of auxiliary parameters
- `e(k_dv)` number of dependent variables
- `e(df_m)` model degrees of freedom
- `e(ll)` log likelihood
- `e(ll_c)` log likelihood, comparison model
- `e(N_clust)` number of clusters
- `e(chi2)` $\chi^2$
- `e(chi2_c)` $\chi^2$ for comparison test
- `e(p)` $p$-value for model test
- `e(p_c)` $p$-value for comparison test
- `e(rho)` $\rho$
- `e(rank)` rank of `e(V)`
- `e(ic)` number of iterations
- `e(rc)` return code
- `e(converged)` 1 if converged, 0 otherwise
De Luca and Perotti (2011) provide an introduction to this model.

The ordinal outcome equation is

\[
y_j = \sum_{h=1}^{H} v_h 1(\kappa_{h-1} < x_j\beta + u_{1j} \leq \kappa_h)
\]

where \(x_j\) is the outcome covariates, \(\beta\) is the coefficients, and \(u_{1j}\) is a random-error term. The observed outcome values \(v_1, \ldots, v_H\) are integers such that \(v_i < v_m\) for \(i < m\). \(\kappa_1, \ldots, \kappa_{H-1}\) are real numbers such that \(\kappa_i < \kappa_m\) for \(i < m\). \(\kappa_0\) is taken as \(-\infty\) and \(\kappa_H\) is taken as \(+\infty\).

The selection equation is

\[
s_j = 1(z_j\gamma + u_{2j} > 0)
\]

where \(s_j = 1\) if we observed \(y_j\) and 0 otherwise, \(z_j\) is the covariates used to model the selection process, \(\gamma\) is the coefficients for the selection process, and \(u_{2j}\) is a random-error term.
\((u_{1j}, u_{2j})\) have bivariate normal distribution with mean zero and variance matrix

\[
\begin{bmatrix}
1 & \rho \\
\rho & 1
\end{bmatrix}
\]

Let \(a_j = z_j \gamma + \text{offset}_j^\gamma\) and \(b_j = x_j \beta + \text{offset}_j^\beta\). This yields the log likelihood

\[
\ln L = \sum_{j \not\in S} w_j \ln \{\Phi (-a_j)\} + \sum_{h=1}^H \sum_{j \in S_{y_j=v_h}} w_j \ln \{\Phi_2(a_j, \kappa_h - b_j, -\rho) - \Phi_2(a_j, \kappa_{h-1} - b_j, -\rho)\}
\]

where \(S\) is the set of observations for which \(y_j\) is observed, \(\Phi_2(\cdot)\) is the cumulative bivariate normal distribution function (with mean \([0 0]'\)), \(\Phi(\cdot)\) is the standard cumulative normal, and \(w_j\) is an optional weight for observation \(j\).

In the maximum likelihood estimation, \(\rho\) is not directly estimated. Directly estimated is \(\text{atanh} \rho\):

\[
\text{atanh} \rho = \frac{1}{2} \ln \left( \frac{1 + \rho}{1 - \rho} \right)
\]

From the form of the likelihood, it is clear that if \(\rho = 0\), the log likelihood for the ordered probit sample-selection model is equal to the sum of the ordered probit model for the outcome \(y\) and the selection model. We can perform a likelihood-ratio test by comparing the log likelihood of the full model with the sum of the log likelihoods for the ordered probit and selection models.

If you do not specify outcome(), pmargin (with one new variable specified) assumes outcome(#1).

You specify one or k new variables with pmargin, where k is the number of outcomes.

You specify one new variable with psel, xb, stdp, xbsel, and stdpsel.

These statistics are available both in and out of sample; type predict ... if e(sample) ... if wanted only for the estimation sample.

Options for predict

pmargin, the default, calculates the predicted marginal probabilities.

You specify one or k new variables, where k is the number of categories of the outcome variable y_j. If you specify the outcome() option, you must specify one new variable. If you specify one new variable and do not specify outcome(), outcome(#1) is assumed.
When \texttt{outcome()} is specified, the marginal probability that \( y_j \) is equal to the level \texttt{outcome()} is calculated. When \texttt{outcome()} is not specified, the marginal probabilities for each outcome level are calculated.

\texttt{p1} calculates the predicted bivariate probabilities of outcome levels with selection.

You specify one or \( k \) new variables, where \( k \) is the number of categories of the outcome variable \( y_j \). If you specify the \texttt{outcome()} option, you must specify one new variable. If you specify one new variable and do not specify \texttt{outcome()}, \texttt{outcome(#1)} is assumed.

When \texttt{outcome()} is specified, the bivariate probability that \( y_j \) is equal to the level \texttt{outcome()} and that \( y_j \) is observed is calculated. When \texttt{outcome()} is not specified, the bivariate probabilities for each outcome level and selection are calculated.

\texttt{p0} calculates the predicted bivariate probabilities of outcome levels with no selection.

You specify one or \( k \) new variables, where \( k \) is the number of categories of the outcome variable \( y_j \). If you specify the \texttt{outcome()} option, you must specify one new variable. If you specify one new variable and do not specify \texttt{outcome()}, \texttt{outcome(#1)} is assumed.

When \texttt{outcome()} is specified, the bivariate probability that \( y_j \) is equal to the level \texttt{outcome()} and that \( y_j \) is not observed is calculated. When \texttt{outcome()} is not specified, the bivariate probabilities for each outcome level and no selection are calculated.

\texttt{pcond1} calculates the predicted probabilities of outcome levels conditional on selection.

You specify one or \( k \) new variables, where \( k \) is the number of categories of the outcome variable \( y_j \). If you specify the \texttt{outcome()} option, you must specify one new variable. If you specify one new variable and do not specify \texttt{outcome()}, \texttt{outcome(#1)} is assumed.

When \texttt{outcome()} is specified, the probability that \( y_j \) is equal to the level \texttt{outcome()} given that \( y_j \) is observed is calculated. When \texttt{outcome()} is not specified, the probabilities for each outcome level conditional on selection are calculated.

\texttt{pcond0} calculates the predicted probabilities of outcome levels conditional on no selection.

You specify one or \( k \) new variables, where \( k \) is the number of categories of the outcome variable \( y_j \). If you specify the \texttt{outcome()} option, you must specify one new variable. If you specify one new variable and do not specify \texttt{outcome()}, \texttt{outcome(#1)} is assumed.

When \texttt{outcome()} is specified, the probability that \( y_j \) is equal to the level \texttt{outcome()} given that \( y_j \) is not observed is calculated. When \texttt{outcome()} is not specified, the probabilities for each outcome level conditional on no selection are calculated.

\texttt{psel} calculates the predicted univariate (marginal) probability of selection.

\texttt{xb} calculates the linear prediction for the outcome variable, which is \( x_j \beta \) if \texttt{offset()} was not specified and \( x_j \beta + \text{offset}_j \beta \) if \texttt{offset()} was specified.

\texttt{stdp} calculates the standard error of the prediction, which can be thought of as the standard error of the predicted expected value or mean for the observation’s covariate pattern. The standard error of the prediction is also referred to as the standard error of the fitted value.

\texttt{xbsel} calculates the linear prediction for the selection equation, which is \( z_j \gamma \) if \texttt{offset()} was not specified in \texttt{select()} and \( z_j \gamma + \text{offset}_j \gamma \) if \texttt{offset()} was specified in \texttt{select()}.

\texttt{stdpsel} calculates the standard error of the linear prediction for the selection equation.

\texttt{outcome(outcome)} specifies the outcome for which predicted probabilities are to be calculated. \texttt{outcome()} should contain either one value of the dependent variable or one of \#1, \#2, \ldots, with \#1 meaning the first category of the dependent variable, \#2 meaning the second category, etc.
nooffset is relevant only if you specified offset(\texttt{varname}) for heckoprobit. It modifies the calculations made by \texttt{predict} so that they ignore the offset variable; the linear prediction is treated as $x_j \beta$ rather than as $x_j \beta + \text{offset}_j$.

\texttt{scores} calculates equation-level score variables.

The first new variable will contain $\partial \ln L / \partial (x_j \beta)$.

The second new variable will contain $\partial \ln L / \partial (z_j \gamma)$.

When the dependent variable takes $k$ different values, new variables three through $k + 1$ will contain $\partial \ln L / \partial (\kappa_{j-2})$.

The last new variable will contain $\partial \ln L / \partial (\text{atanh} \ \rho)$.

\section*{margins}

\subsection*{Description for margins}

\texttt{margins} estimates margins of response for probabilities and linear predictions.

\subsection*{Menu for margins}

\texttt{Statistics} > \texttt{Postestimation}

\subsection*{Syntax for margins}

\begin{verbatim}
margins [\texttt{marginlist}] [ , \texttt{options}]  
margins [\texttt{marginlist}] , \texttt{predict(statistic ...)} [\texttt{predict(statistic ...)} ...] [\texttt{options}]\end{verbatim}

\begin{tabular}{ll}
\textbf{statistic} & \textbf{Description} \\
\hline
\texttt{default} & marginal probabilities for each outcome \\
\texttt{pmargin} & marginal probabilities \\
\texttt{p1} & bivariate probabilities of levels with selection \\
\texttt{p0} & bivariate probabilities of levels with no selection \\
\texttt{pcond1} & probabilities of levels conditional on selection \\
\texttt{pcond0} & probabilities of levels conditional on no selection \\
\texttt{psel} & selection probability \\
\texttt{xb} & linear prediction \\
\texttt{xbsel} & linear prediction for selection equation \\
\texttt{stdp} & not allowed with \texttt{margins} \\
\texttt{stdpsel} & not allowed with \texttt{margins} \\
\end{tabular}

\texttt{pmargin}, \texttt{p1}, \texttt{p0}, \texttt{pcond1}, and \texttt{pcond0} default to the first outcome.

Statistics not allowed with \texttt{margins} are functions of stochastic quantities other than $\mathbf{e}(\mathbf{b})$.

For the full syntax, see [R] \texttt{margins}.
Remarks and examples

Example 1

In example 1 of [R] heckoprobit, we examined a simulated dataset of 5,000 women, 3,480 of whom work and can thus report job satisfaction. Using job satisfaction (satisfaction) as the outcome variable and employment (work) as the selection variable, we estimated the parameters of an ordered probit sample-selection model. Covariates age (age), years of education (education), number of children (children), and marital status (married) are expected to affect selection. The outcome, job satisfaction, is affected by age (age) and education (education).

We first reestimate the parameters of the regression, but this time we request a robust variance estimator:

```
. use https://www.stata-press.com/data/r16/womensat
(Job satisfaction, female)
. heckoprobit satisfaction education age,
> select(work=education age i.married##c.children) vce(robust)
(output omitted)
```

We then use margins (see [R] margins) to estimate the average marginal effect of education on the probability of having low job satisfaction.

```
. margins, dydx(education) vce(unconditional)
Average marginal effects Number of obs = 5,000
dy/dx w.r.t. : education
1._predict : Pr(satisfaction=1), predict(pmargin outcome(1))
2._predict : Pr(satisfaction=2), predict(pmargin outcome(2))
3._predict : Pr(satisfaction=3), predict(pmargin outcome(3))
4._predict : Pr(satisfaction=4), predict(pmargin outcome(4))

<table>
<thead>
<tr>
<th></th>
<th>Unconditional</th>
<th>Number of obs = 5,000</th>
</tr>
</thead>
<tbody>
<tr>
<td>dy/dx</td>
<td>Std. Err.</td>
<td>z</td>
</tr>
<tr>
<td>education</td>
<td></td>
<td></td>
</tr>
<tr>
<td>_predict</td>
<td></td>
<td></td>
</tr>
<tr>
<td>1</td>
<td>-.0234776</td>
<td>.0019176</td>
</tr>
<tr>
<td>2</td>
<td>-.0230858</td>
<td>.0015143</td>
</tr>
<tr>
<td>3</td>
<td>-.0020603</td>
<td>.001142</td>
</tr>
<tr>
<td>4</td>
<td>.0486238</td>
<td>.0018593</td>
</tr>
</tbody>
</table>
```

The estimated average marginal effect of education on the probability of having low job satisfaction is approximately −0.023.

Methods and formulas

The ordinal outcome equation is

\[
y_j = \sum_{h=1}^{H} v_h \mathbb{I} (\kappa_{h-1} < x_j \beta + u_{1j} \leq \kappa_h)
\]

where \( x_j \) is the outcome covariates, \( \beta \) is the coefficients, and \( u_{1j} \) is a random-error term. The observed outcome values \( v_1, \ldots, v_H \) are integers such that \( v_i < v_m \) for \( i < m \). \( \kappa_1, \ldots, \kappa_{H-1} \) are real numbers such that \( \kappa_i < \kappa_m \) for \( i < m \). \( \kappa_0 \) is taken as \(-\infty\) and \( \kappa_H \) is taken as \(+\infty\).
The selection equation is
\[ s_j = 1 \left( z_j \gamma + u_{2j} > 0 \right) \]
where \( s_j = 1 \) if we observed \( y_j \) and 0 otherwise, \( z_j \) is the covariates used to model the selection process, \( \gamma \) is the coefficients for the selection process, and \( u_{2j} \) is a random-error term.

\((u_{1j}, u_{2j})\) have bivariate normal distribution with mean zero and variance matrix
\[
\begin{bmatrix}
1 & \rho \\
\rho & 1
\end{bmatrix}
\]

The probability of selection is
\[ \Pr(s_j = 1) = \Phi(z_j \gamma + \text{offset}_j^\gamma) \]
\( \Phi(\cdot) \) is the standard cumulative normal distribution function.

The probability of selection and the outcome \( y_j = v_h \) is
\[ \Pr(y_j = v_h, s_j = 1) = \Phi_2 \left( z_j \gamma + \text{offset}_j^\gamma, \kappa_h - x_j \beta - \text{offset}_j^\beta, -\rho \right) - \Phi_2 \left( z_j \gamma + \text{offset}_j^\gamma, \kappa_{h-1} - x_j \beta - \text{offset}_j^\beta, -\rho \right) \]
\( \Phi_2(\cdot) \) is the cumulative bivariate normal distribution function (with mean \([0 \ 0]'\)).

The probability of \( y_j \) not being selected and the outcome \( y_j = v_h \) is
\[ \Pr(y_j = v_h, s_j = 0) = \Phi_2 \left( -z_j \gamma - \text{offset}_j^\gamma, \kappa_h - x_j \beta - \text{offset}_j^\beta, \rho \right) - \Phi_2 \left( -z_j \gamma - \text{offset}_j^\gamma, \kappa_{h-1} - x_j \beta - \text{offset}_j^\beta, \rho \right) \]

The probability of outcome \( y_j = v_h \) given selection is
\[ \Pr(y_j = v_h | s_j = 1) = \frac{\Pr(y_j = v_h, s_j = 1)}{\Pr(s_j = 1)} \]

The probability of outcome \( y_j = v_h \) given \( y_j \) is not selected is
\[ \Pr(y_j = v_h | s_j = 0) = \frac{\Pr(y_j = v_h, s_j = 0)}{\Pr(s_j = 0)} \]

The marginal probabilities of the outcome \( y_j \) are
\[ \Pr(y_j = v_1) = \Phi(\kappa_1 - x_j \beta - \text{offset}_j^\beta) \]
\[ \Pr(y_j = v_H) = 1 - \Phi(\kappa_{H-1} - x_j \beta - \text{offset}_j^\beta) \]
\[ \Pr(y_j = v_h) = \Phi(\kappa_h - x_j \beta - \text{offset}_j^\beta) - \Phi(\kappa_{h-1} - x_j \beta - \text{offset}_j^\beta) \]

[U] 20 Estimation and postestimation commands
heckpoisson — Poisson regression with sample selection

Description

heckpoisson fits a Poisson regression model with endogenous sample selection. This is sometimes called nonignorability of selection, missing not at random, or selection bias. Unlike the standard Poisson model, there is no assumption of equidispersion.

Quick start

Poisson model of y on x1 with z1 predicting selection when binary variable selected indicates selection status

```stata
heckpoisson y x1, select(selected = z1)
```

Add categorical variable a using factor-variables syntax

```stata
heckpoisson y x1 i.a, select(selected = z1 i.a)
```

Report results as incidence-rate ratios

```stata
heckpoisson y x1 i.a, select(selected = z1 i.a) irr
```

Add robust standard errors

```stata
heckpoisson y x1 i.a, select(selected = z1 i.a) vce(robust)
```

Include exposure variable expose to account for different exposure levels

```stata
heckpoisson y x1 i.a, select(selected = z1 i.a) exposure(expose)
```

Menu

Statistics > Sample-selection models > Poisson model with sample selection

940
Syntax

```
heckpoisson  depvar indepvars [if] [in] [weight],
            select([depvar_s =] indepvars_s [, noconstant offset(varname_os)])
            [options]
```

*select() is required.

The full specification is `select([ depvar_s =] indepvars_s [, noconstant offset(varname_os)])`.

`indepvars` and `indepvars_s` may contain factor variables; see [U] 11.4.3 Factor variables.

`indepvars` and `indepvars_s` may contain time-series operators; see [U] 11.4.4 Time-series varlists.

bootstrap, by, jackknife, rolling, statsby, and svy are allowed; see [U] 11.1.10 Prefix commands.

Weights are not allowed with the bootstrap prefix; see [R] bootstrap.

vce() and weights are not allowed with the svy prefix; see [SVY] svy.

fweights, iweights, and pweights are allowed; see [U] 11.1.6 weight.

collinear and coeflegend do not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.
select([depvar_s = indepvars_s [, noconstant offset(varname_os)]) specifies the variables and options for the selection equation. It is an integral part of specifying a sample-selection model and is required.

If depvar_s is specified, it should be coded as 0 or 1, with 0 indicating an observation not selected and 1 indicating a selected observation. If depvar_s is not specified, then observations for which depvar is not missing are assumed selected and those for which depvar is missing are assumed not selected.

noconstant suppresses the selection constant term (intercept).

offset(varname_os) specifies that selection offset varname_os be included in the model with the coefficient constrained to be 1.

noconstant, exposure(varname_e), offset(varname_o), constraints(constraints); see [R] Estimation options.

vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim, opg), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.

level(#); see [R] Estimation options.

irr reports estimated coefficients transformed to incidence-rate ratios, that is, \( e^{\beta_i} \), rather than \( \beta_i \). Standard errors and confidence intervals are similarly transformed. This option affects how results are displayed, not how they are estimated or stored. irr may be specified at estimation or when replaying previously estimated results.

nocnsreport; see [R] Estimation options.

display_options: noci, nopvalues, noomitted, vsquish, noemptycells, baselevels, allbaselevels, nobl, fwrap(#), fvwrap(style), cformat(%,fmt), pformat(%,fmt), sformat(%,fmt), and nolstretch; see [R] Estimation options.

intpoints(#) specifies the number of integration points to use for quadrature. The default is intpoints(25), which means that 25 quadrature points are used. The maximum number of allowed integration points is 128.

The more integration points, the more accurate the approximation to the log likelihood. However, computation time increases with the number of quadrature points and is roughly proportional to the number of points used.

maximize_options: difficult, technique(algorithm_spec), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(init_specs); see [R] Maximize. These options are seldom used.
The following options are available with `heckpoisson` but are not shown in the dialog box: `collinear`, `coeflegend`; see [R] Estimation options.

**Remarks and examples**

When analyzing observational data, we must consider the possibility that we cannot treat the observations for which we have data as if they were selected at random. Suppose we are interested in the number of after-school tutoring sessions a child attends. If unobservable variables that affect which students attend the sessions, for example, family stability, also affect the number of visits we observe, then a condition known as endogenous sample selection is present. This phenomenon is sometimes simply referred to as sample selection or called missing not at random, nonignorability of selection, or selection bias. When endogenous sample selection occurs, conventional estimation techniques are not appropriate. Cameron and Trivedi (2010, 556–562) and Greene (2018, 950–957) provide good introductions to the concept of endogenous sample selection.

The venerable Heckman estimator handles endogenous sample selection when the outcome of interest is modeled by linear regression; see [R] `heckman`. However, the Heckman estimator is not appropriate for count outcomes because its linear model for the outcome could produce negative predicted values and does not restrict the predicted values to integers.

There are different methods for estimating the parameters of a count-data model with endogenous sample selection. `heckpoisson` implements the maximum likelihood estimator derived in Terza (1998); see also Cameron and Trivedi (2013, chap. 10) for a discussion of this estimator.

The model consists of one equation for the count outcome, $y$, and one equation for a binary selection indicator, $s$. The indicator $s$ is always observed and takes values of 0 or 1. But the outcome $y$ is observed only if $s = 1$, that is, we have complete information about the covariates of interest and selection status. However, the value of the primary outcome of interest, $y$, is sometimes unknown.

More formally, the count outcome $y$ is assumed to have a Poisson distribution, conditional on the covariates, with conditional mean

$$E(y_j|x_j, \epsilon_{1j}) = \exp(x_j\beta + \epsilon_{1j})$$

Poisson regression equation

However, we only observe $y$ for observation $j$ if $s_j = 1$:

$$s_j = \begin{cases} 1, & \text{if } w_j\gamma + \epsilon_{2j} > 0 \\ 0, & \text{otherwise} \end{cases}$$

selection equation

where

$$\epsilon_1 \sim N(0, \sigma)$$

$$\epsilon_2 \sim N(0, 1)$$

$$\text{corr}(\epsilon_1, \epsilon_2) = \rho$$

When $\rho \neq 0$, standard Poisson regression based on the observed $y$ yields biased estimates. `heckpoisson` provides consistent, asymptotically efficient estimates for the parameters in such models.

Unlike the standard Poisson regression, the Poisson model with sample selection allows underdispersion and overdispersion.
Example 1: Poisson model with sample selection

Suppose we want to know the effect of research and development (R&D) expenditures on the number of patents obtained by a firm in the last two years. The patent dataset contains fictional data on the number of patents (npatents) of 10,000 firms in different sectors. After reading in the data, we tabulate the frequencies of npatents against an indicator for whether a firm applied for patents (applied).

```
. use https://www.stata-press.com/data/r16/patent
    (Fictional data on patents and R&D)
. tabulate npatents applied, missing
```

```

The output shows that npatents is missing for about half of the sample because some firms did not apply for any patents. Some firms prefer to keep their discoveries as trade secrets instead of applying for patents. The sample selection will be endogenous if the unobservable variables that affect which firms apply for patents also affect the number of patents obtained. Therefore, we do not want to use a standard Poisson model for these data.

We model npatents as a function of R&D expenditures (expenditure) and a categorical variable indicating whether the firm is in the information technology (IT) sector (tech). We model the selection indicator applied as a function of expenditure, tech, and firm size (size), which is excluded from the outcome model.

Wald test of indep. eqns. (rho = 0): chi2(1) = 16.64 Prob > chi2 = 0.0000

The coefficient estimates reported by heckpoisson can be interpreted similarly to those reported by poisson. For example, the positive coefficient on expenditure tells us that increasing R&D expenditures is associated with an increasing number of patents. However, the magnitude of the effect cannot be directly determined by the coefficients. The best way to obtain interpretable effects is by using margins. See example 1 in [R] heckpoisson postestimation for more information.

The estimated correlation between the selection errors and outcome errors is 0.8, and the Wald test in the footer indicates that we can reject the null hypothesis of zero correlation. This positive and significant correlation estimate implies that unobservable factors that increase the number of patents a firm is awarded tend to occur with unobservable factors that also increase the chance of a firm being willing to apply for patents.
Technical note

In practice, we rely on the strength of the relationship between size and applied and the fact that size does not appear in the model for npatents to pin down the parameter estimates. Technically, we do not need this exclusion restriction, but identification from the functional form alone tends to be weak. For a discussion of this point, see Cameron and Trivedi (2010, 558–562).

Example 2: Obtaining incidence-rate ratios

In some cases, we may wish to view the parameters as incidence-rate ratios (IRRs). That is, we want to hold all the x's in the model constant except one, say, the i_th. The IRR for a one-unit change in $x_i$ is

$$e^{\ln(E)+\beta_1 x_1 + \cdots + \beta_i (x_i+1) + \cdots + \beta_k x_k + \epsilon_1}$$

For instance, we may want to know the relative incidence rate of patents as the expenditure changes or the relative incidence rate of patents as sectors change from non-IT to IT.

We can use option irr to display the coefficient estimates transformed to IRRs. This option may be specified when we originally fit our model or on replay. Because we have already fit the model, we specify irr below using the replay syntax.

```
. heckpoisson, irr
```

Note: Estimates are transformed only in the first equation.
Note: _cons estimates baseline incidence rate.
Wald test of indep. eqns. (rho = 0): chi2(1) = 16.64 Prob > chi2 = 0.0000
The IRR for IT is about 1.8, meaning that the expected number of patents in the IT sector is 1.8 times more than in the non-IT sector.

Stored results

`heckpoisson` stores the following in `e()`:

Scalars
- `e(N)` number of observations
- `e(N_selected)` number of selected observations
- `e(N_nonselected)` number of nonselected observations
- `e(k)` number of parameters
- `e(k_eq)` number of equations in `e(b)`
- `e(k_eq_model)` number of equations in overall model test
- `e(k_aux)` number of auxiliary parameters
- `e(k_dv)` number of dependent variables
- `e(df_m)` model degrees of freedom
- `e(ll)` log likelihood
- `e(N_clust)` number of clusters
- `e(chi2)` $\chi^2$
- `e(chi2_c)` $\chi^2$ for comparison, $\rho=0$ test
- `e(n_quad)` number of quadrature points
- `e(p)` $p$-value for model test
- `e(p_c)` $p$-value for comparison test
- `e(rank)` rank of `e(V)`
- `e(ic)` number of iterations
- `e(rc)` return code
- `e(converged)` 1 if converged, 0 otherwise

Macros
- `e(cmd)` `heckpoisson`
- `e(cmdline)` command as typed
- `e(depvar)` name of dependent variable
- `e(wtype)` weight type
- `e(wexp)` weight expression
- `e(title)` title in estimation output
- `e(title2)` secondary title in estimation output
- `e(clustvar)` name of cluster variable
- `e(offset1)` offset for regression equation
- `e(offset2)` offset for selection equation
- `e(chi2type)` Wald; type of model $\chi^2$ test
- `e(chi2_ct)` Wald; type of comparison $\chi^2$ test
- `e(vce)` `vcetype` specified in `vce()`
- `e(vcetype)` title used to label Std. Err.
- `e(opt)` type of optimization
- `e(which)` `max` or `min`; whether optimizer is to perform maximization or minimization
- `e(ml_method)` type of `ml` method
- `e(user)` name of likelihood-evaluator program
- `e(technique)` maximization technique
- `e(properties)` `b V`
- `e(predict)` program used to implement `predict`
- `e(marginsok)` predictions allowed by `margins`
- `e(marginsnotok)` predictions disallowed by `margins`
- `e(asbalanced)` factor variables `fvset` as `asbalanced`
- `e(asobserved)` factor variables `fvset` as `asobserved`
Matrices
- `e(b)` — coefficient vector
- `e(Cns)` — constraints matrix
- `e(ilog)` — iteration log (up to 20 iterations)
- `e(gradient)` — gradient vector
- `e(V)` — variance–covariance matrix of the estimators
- `e(V_modelbased)` — model-based variance

Functions
- `e(sample)` — marks estimation sample

Methods and formulas

`heckpoisson` implements Terza’s maximum likelihood estimator for the parameters of a count-data model with endogenous sample selection (Terza 1998).

Suppose that the count outcome $y_j$ has covariates $x_j$ and that $y_j$ has a Poisson distribution, conditional on $x_j$, with conditional mean

$$E(y_j|x_j, \epsilon_{1j}) = \mu_j = \exp(x_j\beta + \epsilon_{1j})$$

and

$$\Pr(Y = y_j|x_j, \epsilon_{1j}) = \frac{\mu_j^{y_j} e^{-\mu_j}}{y_j!}$$

We only observe $y_j$ when $s_j$, the selection outcome, which is the binary outcome from a latent-variable model with covariates $w_j$, is equal to 1.

$$s_j = \begin{cases} 1, & \text{if } w_j\gamma + \epsilon_{2j} > 0 \\ 0, & \text{otherwise} \end{cases}$$

The error terms $\epsilon_1$ and $\epsilon_2$ are assumed to have bivariate normal distribution with zero mean and covariance matrix

$$\begin{bmatrix} \sigma^2 & \sigma \rho \\ \sigma \rho & 1 \end{bmatrix}$$

where $\sigma$ and $\rho$ have their usual interpretation for the bivariate normal distribution. A nonzero $\rho$ implies that the selected sample is not representative of the whole population and therefore that inference based on standard Poisson regression using the observed sample is incorrect.

In maximum likelihood estimation, $\ln \sigma$ and $\text{atanh} \rho$ are estimated rather than directly estimating $\sigma$ and $\rho$.

$$\text{atanh} \rho = \frac{1}{2} \ln \left( \frac{1 + \rho}{1 - \rho} \right)$$

The joint log likelihood is given by

$$\ln L(\theta) = \sum_{i=1}^{N} [s_j \times \ln \{\Pr(y_j, s_j = 1)\mid x_j, w_j, \theta\} + (1 - s_j) \times \ln \{\Pr(s_j = 0)\mid w_j, \theta\}]$$

where $\theta$ denotes $(\beta, \gamma, \rho, \sigma)$ for notational simplicity.
The joint probability \( \Pr(y_j, s_j = 1|x_j, w_j, \theta) \) can be obtained by integrating the conditional probability \( \Pr(y_j, s_j = 1|x_j, w_j, \theta, \epsilon_1) \) over \( \epsilon_1 \). More precisely,

\[
\Pr(y_j, s_j = 1|x_j, w_j, \theta) = \int_{-\infty}^{\infty} \Pr(y_j|x_j, \epsilon_1) \Phi \left( \frac{w_j \gamma + \rho / \sigma \epsilon_1}{\sqrt{1 - \rho^2}} \right) \phi(\epsilon_1 / \sigma) d\epsilon_1 \tag{1}
\]

where \( \phi(\cdot) \) is the standard normal density function and \( \Phi(\cdot) \) is the standard normal cumulative density function. \( \Pr(s_j = 0|w_j, \theta) \) is similarly derived.

\[
\Pr(s_j = 0|w_j, \theta) = \int_{-\infty}^{\infty} \Phi \left( -\frac{w_j \gamma + \rho / \sigma \epsilon_1}{\sqrt{1 - \rho^2}} \right) \phi(\epsilon_1 / \sigma) d\epsilon_1 \tag{2}
\]

The integrations in (1) and (2) have no closed form and must be approximated using Gauss–Hermite quadrature.

\texttt{heckpoisson} supports the Huber/White/sandwich estimator of the variance and its clustered version using \texttt{vce(robust)} and \texttt{vce(cluster clustvar)}, respectively. See [P] \_\texttt{robust}, particularly \textit{Maximum likelihood estimators} and \textit{Methods and formulas}.

\texttt{heckpoisson} also supports estimation with survey data. For details on VCEs with survey data, see [SVY] \texttt{Variance estimation}.

These statistics are available both in and out of sample; type predict ... if e(sample) ... if wanted only for the estimation sample.

Options for predict

- **n**, the default, calculates the predicted number of events, which is \( \exp( x_j \beta + \sigma^2 / 2 ) \) if neither offset() nor exposure() was specified when the model was fit; is \( \exp( x_j \beta + \sigma^2 / 2 + \text{offset}_j ) \) if offset() was specified; or is \( \exp( x_j \beta + \sigma^2 / 2 ) \times \text{exposure}_i \) if exposure() was specified.

- **ir** calculates the incidence rate \( \exp( x_j \beta + \sigma^2 / 2 ) \), which is the predicted number of events when exposure is 1. Specifying ir is equivalent to specifying n when neither offset() nor exposure() was specified when the model was fit.

- **ncond** calculates the predicted number of events conditional on \( y_j \) being observed, which is \( \exp( x_j \beta + \sigma^2 / 2 ) \Phi( w_j \gamma + \rho \sigma ) / \Phi( w_j \gamma ) \).

- **pr(n)** calculates the probability \( \Pr( y_j = n ) \), where n is a nonnegative integer that may be specified as a number or a variable.
\( \text{pr}(a, b) \) calculates the probability \( \Pr(a \leq y_j \leq b) \), where \( a \) and \( b \) are nonnegative integers that may be specified as numbers or variables;

- \( b \) missing \( (b \geq .) \) means \( +\infty \);
- \( \text{pr}(20, .) \) calculates \( \Pr(y_j \geq 20) \);
- \( \text{pr}(20, b) \) calculates \( \Pr(y_j \geq 20) \) in observations for which \( b \geq . \) and calculates \( \Pr(20 \leq y_j \leq b) \) elsewhere.

\( \text{pr}(., b) \) produces a syntax error. A missing value in an observation of the variable \( a \) causes a missing value in that observation for \( \text{pr}(a, b) \).

\( \text{psel} \) calculates the probability of selection (or being observed):
\[
\Pr(y_j \text{ observed}) = \Pr(w_j \gamma + \epsilon_{2j} > 0)
\]

\( \text{xb} \) calculates the linear prediction for the dependent count variable, which is \( x_j \beta \) if neither \( \text{offset()} \) nor \( \text{exposure()} \) was specified; \( x_j \beta + \text{offset}_j \) if \( \text{offset()} \) was specified; or \( x_j \beta + \ln(\text{exposure}_j) \) if \( \text{exposure()} \) was specified.

\( \text{xbsel} \) calculates the linear prediction for the selection equation, which is \( w_j \gamma \) if \( \text{offset()} \) was not specified in \( \text{select()} \) and is \( w_j \gamma + \text{offset}_j \) if \( \text{offset()} \) was specified in \( \text{select()} \).

\( \text{nooffset} \) is relevant only if you specified \( \text{offset()} \) or \( \text{exposure()} \) when you fit the model. It modifies the calculations made by \( \text{predict} \) so that they ignore the offset or exposure variable; the linear prediction is treated as \( x_j \beta \) rather than as \( x_j \beta + \text{offset}_j \) or \( x_j \beta + \ln(\text{exposure}_j) \).

\( \text{scores} \) calculates equation-level score variables.

- The first new variable will contain \( \partial \ln L / \partial (x_j \beta) \).
- The second new variable will contain \( \partial \ln L / \partial (w_j \gamma) \).
- The third new variable will contain \( \partial \ln L / \partial \tanh \rho \).
- The fourth new variable will contain \( \partial \ln L / \partial \ln \sigma \).
margins

Description for margins

margins estimates margins of response for number of events, incidence rates, conditional predicted number of events, probabilities, and linear predictions.

Menu for margins

Statistics  >  Postestimation

Syntax for margins

margins [marginlist] [ , options ]
margins [marginlist], predict(statistic ...) [predict(statistic ...) ...] [options]

Statistics not allowed with margins are functions of stochastic quantities other than $e(b)$.

For the full syntax, see [R] margins.

Remarks and examples

Example 1: Obtaining margins for a count model with selection

In example 1 of [R] heckpoisson, we fit a model for the number of patents. In that example, we are interested in the effect of R&D expenditures on the number of patents received by a firm. We continue that example to determine the magnitude of the effect of R&D expenditures on the number of patents and compare this effect for IT and non-IT sectors.

After reading in the data and fitting the model, we use margins to estimate the effect of an increase of a million dollars in R&D expenditures (expenditure) on the number of patents (npatents) for firms in the IT and non-IT sectors (tech).

To do this, we use the at() option of margins. We use the observed values in our first scenario, so we tell margins to set expenditure equal to itself. For our second scenario, we tell margins to set expenditure equal to the observed value plus 1 because expenditures are measured in millions of dollars. We include the post option so that we can perform additional calculations later.
. use https://www.stata-press.com/data/r16/patent
(Fictional data on patents and R&D)
. quietly heckpoisson npatents expenditure i.tech,
> select(applied = expenditure size i.tech)
. margins i.tech, at(expenditure = generate(expenditure))
> at(expenditure = generate(expenditure+1)) post

<table>
<thead>
<tr>
<th>Predictive margins</th>
<th>Number of obs = 10,000</th>
</tr>
</thead>
<tbody>
<tr>
<td>Model VCE</td>
<td>OIM</td>
</tr>
<tr>
<td>Expression</td>
<td>Predicted number of events, predict()</td>
</tr>
<tr>
<td>1._at</td>
<td>expenditure = expenditure</td>
</tr>
<tr>
<td>2._at</td>
<td>expenditure = expenditure+1</td>
</tr>
</tbody>
</table>

| Delta-method | Margin | Std. Err. | z     | P>|z|  | [95% Conf. Interval] |
|--------------|--------|-----------|-------|------|---------------------|
| _at#tech     |        |           |       |      |                     |
| 1 non-IT se..| 1.276213 | .0556644 | 22.93 | 0.000| 1.167112 1.385313   |
| 1#IT sector  | 2.287013 | .080119  | 28.55 | 0.000| 2.129983 2.444044   |
| 2 non-IT se..| 2.099539 | .131364  | 15.98 | 0.000| 1.84207 2.357007    |
| 2#IT sector  | 3.76244  | .2226221 | 16.90 | 0.000| 3.326109 4.198771   |

The output indicates that the expected number of patents for non-IT firms is about 1.28 compared with 2.29 for firms in the IT sector.

The second scenario shows the expected number of patents after our hypothetical increase in R&D expenditures. In the non-IT sector, the expected number of patents received would be about 2.10 compared with 3.76 in the IT sector. It appears that increasing expenditures may have a larger effect for IT firms—the difference between the two scenarios is 1.47 for IT firms and only 0.82 for non-IT firms. We can test whether the effect of increasing expenditures is different for IT and non-IT firms. We use lincom to obtain an estimate of the difference in the differences between scenarios for the two sectors and a test of its significance. We ask for the differences by referring to the scenarios as 1._at and 2._at and by referring to the sector using the value that corresponds to the IT sector indicator, 1.tech for IT firms and 0.tech otherwise.

. lincom (_b[2._at#1.tech] - _b[1._at#1.tech]) -
> (_b[2._at#0.tech] - _b[1._at#0.tech])
( 1) 1bn._at#0bn.tech - 1bn._at#1.tech - 2._at#0bn.tech + 2._at#1.tech = 0

| Coef.      | Std. Err. | z      | P>|z|  | [95% Conf. Interval] |
|------------|-----------|--------|------|---------------------|
| (1)        | .6521006  | .0917299 | 7.11 | 0.000  | .4723133 .8318878  |

We find that the expected effect of increasing R&D expenditures by one million dollars is 0.65 patents larger for IT firms than for non-IT firms, and this difference is significantly different from 0.

Methods and formulas

Suppose that the count outcome \( y_j \) has covariates \( x_j \) and the selection outcome \( s_j \) has covariates \( w_j \). \( y_j \) is assumed to have a Poisson distribution, conditional on \( x_j \), with conditional mean

\[
E(y_j|x_j, \epsilon_{1j}) = \mu_j = \exp(x_j \beta + \epsilon_{1j})
\]
$s_j$ is a binary outcome from a latent-variable model:

$$s_j = \begin{cases} 
1, & \text{if } w_i \gamma + \epsilon_{2j} > 0 \\
0, & \text{otherwise}
\end{cases}$$

The expectation of $y_j$ conditional on covariates $x_j$ for the whole population is

$$E(y_j|x_j) = \exp(x_j \beta + \sigma^2/2)$$

Furthermore, if we want the expectation of $y_j$ only if it was observed, then the formula is

$$E(y_j|x_j, w_j, s_j = 1) = \exp(x_j \beta + \sigma^2/2) \frac{\Phi(w_j \gamma + \rho \sigma)}{\Phi(w_j \gamma)}$$

We note that if $\rho = 0$, this expectation is the same as its population version.

We can also predict the probability of $y_j$ conditional on $x_j$. Note that although $y_j$ is Poisson-distributed conditional on $\epsilon_1$ and $x_j$, the distribution of $y_j$ is unknown unconditional on $\epsilon_1$.

$$\Pr(y_j = n|x_j) = \int_{-\infty}^{\infty} \Pr(y_j = n|x_j, \epsilon_1) \phi(\epsilon_1 / \sigma) d\epsilon_1$$

As in the implementation of log likelihood, we approximate this integral by Gauss–Hermite quadrature.

### SE/Robust

```
vce(vcetype) vcetype may be oim, robust, cluster clustvar, opg, bootstrap, or jackknife
```

### Reporting

```
level(#) set confidence level; default is level(95)
first report first-step probit estimates
lrmodel perform the likelihood-ratio model test instead of the default Wald test
noconsreport do not display constraints
display_options control columns and column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling
```

### Maximization

```
maximize_options control the maximization process; seldom used
collinear keep collinear variables
coefflegend display legend instead of statistics
```

*select() is required.

The full specification is `select([depvars =] varlist [, noconstant offset(varname)])`. `indepvars` and `varlist` may contain factor variables; see [U] 11.4.3 Factor variables.

`depvar`, `indepvars`, `depvars`, and `varlist` may contain time-series operators; see [U] 11.4.4 Time-series varlists.

`bayes`, `bootstrap`, `by`, `fp`, `jackknife`, `rolling`, `statsby`, and `svy` are allowed; see [U] 11.1.10 Prefix commands.

For more details, see [BAYES] bayes: heckprobit.

Weights are not allowed with the bootstrap prefix; see [R] bootstrap.
`vce()`, `first`, `lrmodel`, and weights are not allowed with the `svy` prefix; see [SVY] svy.

`pweights`, `fweights`, and `iweights` are allowed; see [U] 11.1.6 weight.
`collinear` and `coefflegend` do not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

## Options

The full specification is `select([depvars =] varlist [, noconstant offset(varname)])`. This specifies the variables and options for the selection equation. It is an integral part of specifying a selection model and is
required. The selection equation should contain at least one variable that is not in the outcome equation.

If \( \text{depvar} \) is specified, it should be coded as 0 or 1, 0 indicating an observation not selected and 1 indicating a selected observation. If \( \text{depvar} \) is not specified, observations for which \( \text{depvar} \) is not missing are assumed selected, and those for which \( \text{depvar} \) is missing are assumed not selected.

\text{noconstant} \) suppresses the selection constant term (intercept).

\text{offset(varname_o)} \) specifies that selection offset \( \text{varname}_o \) be included in the model with the coefficient constrained to be 1.

\text{noconstant, offset(varname)}, \text{constraints(constraints); see [R] Estimation options.}

\text{vce(vcetype)} \) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (\text{oim, opg}), that are robust to some kinds of misspecification (\text{robust}), that allow for intragroup correlation (\text{cluster clustvar}), and that use bootstrap or jackknife methods (\text{bootstrap, jackknife}); see [R] \text{vce option.}

\text{level(#); see [R] Estimation options.}

\text{first} \) specifies that the first-step probit estimates of the selection equation be displayed before estimation.

\text{lrmodel, nocnsreport; see [R] Estimation options.}

\text{display_options: noci, nopvalues, noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(#), fvwrapon(style), cformat(\%fmt), pformat(\%fmt), sformat(\%fmt), and nolstretch; see [R] Estimation options.}

\text{Maximize} \) options: \text{difficult, technique(algorithm_spec), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), rtolerance(#), nonrtolerance, and from(init_specs); see [R] \text{Maximize.} \) These options are seldom used.

Setting the optimization type to \text{technique(bhhh)} \) resets the default \text{vcetype} \) to \text{vce(opg)}. The following options are available with \text{heckprobit} \) but are not shown in the dialog box:

\text{collinear, coeflegend}; see [R] \text{Estimation options.}
Remarks and examples

The probit model with sample selection (Van de Ven and Van Pragg 1981) assumes that there exists an underlying relationship

\[ y_j^* = x_j \beta + u_{1j} \]  

such that we observe only the binary outcome

\[ y_{j, \text{probit}} = (y_j^* > 0) \]

The dependent variable, however, is not always observed. Rather, the dependent variable for observation \( j \) is observed if

\[ y_{j, \text{select}} = (z_j \gamma + u_{2j} > 0) \]

where

\[ u_1 \sim N(0, 1) \]
\[ u_2 \sim N(0, 1) \]

\[ \text{corr}(u_1, u_2) = \rho \]

When \( \rho \neq 0 \), standard probit techniques applied to the first equation yield biased results. \texttt{heckprobit} provides consistent, asymptotically efficient estimates for all the parameters in such models.

For the model to be well identified, the selection equation should have at least one variable that is not in the probit equation. Otherwise, the model is identified only by functional form, and the coefficients have no structural interpretation.

Example 1

We use the data from Pindyck and Rubinfeld (1998). In this dataset, the variables are whether children attend private school (\texttt{private}), number of years the family has been at the present residence (\texttt{years}), log of property tax (\texttt{logptax}), log of income (\texttt{loginc}), and whether one voted for an increase in property taxes (\texttt{vote}).

In this example, we alter the meaning of the data. Here we assume that we observe whether children attend private school only if the family votes for increasing the property taxes. This assumption is not true in the dataset, and we make it only to illustrate the use of this command.

We observe whether children attend private school only if the head of household voted for an increase in property taxes. We assume that the vote is affected by the number of years in residence, the current property taxes paid, and the household income. We wish to model whether children are sent to private school on the basis of the number of years spent in the current residence and the current property taxes paid.

. heckprobit private years logptax, select(vote=years loginc logptax)

Fitting probit model:
Iteration 0:  log likelihood = -17.122381
Iteration 1:  log likelihood = -16.243974
(output omitted)
Iteration 5:  log likelihood = -15.883655

Fitting selection model:
Iteration 0:  log likelihood = -63.036914
Iteration 1:  log likelihood = -58.534843
Iteration 2:  log likelihood = -58.497292
Iteration 3:  log likelihood = -58.497288
Comparison:  log likelihood = -74.380943

Fitting starting values:
Iteration 0:  log likelihood = -40.895684
Iteration 1:  log likelihood = -16.654497
(output omitted)
Iteration 6:  log likelihood = -15.753765

Fitting full model:
Iteration 0:  log likelihood = -75.010619  (not concave)
Iteration 1:  log likelihood = -74.287758
Iteration 2:  log likelihood = -74.250143
Iteration 3:  log likelihood = -74.245088
Iteration 4:  log likelihood = -74.244973
Iteration 5:  log likelihood = -74.244973

Probit model with sample selection
Number of obs = 95
Selected = 59
Nonselected = 36

Wald chi2(2) = 1.04
Log likelihood = -74.24497
Prob > chi2 = 0.5935
