wald( newvar ) adds newvar of storage type type, where for each $i$ in the prediction sample, newvar[i] contains the Wald test statistic for the test of the hypothesis $H_0: g(\theta, x_i) = 0$.

p( newvar ) adds newvar of storage type type, where newvar[i] contains the $p$-value for the Wald test of $H_0: g(\theta, x_i) = 0$ versus the two-sided alternative.

ci( newvars ) requires the specification of two newvars, such that the $i$th observation of each will contain the left and right endpoints (respectively) of a confidence interval for $g(\theta, x_i)$. The level of the confidence intervals is determined by level(#).

level(#) specifies the confidence level, as a percentage, for confidence intervals. The default is level(95) or as set by set level; see [U] 20.8 Specifying the width of confidence intervals.

g( stub ) specifies that new variables, stub1, stub2, ..., stubk be created, where k is the dimension of $\theta$. stub1 will contain the observation-specific derivatives of $g(\theta, x_i)$ with respect to the first element, $\theta_1$, of $\theta$; stub2 will contain the derivatives of $g(\theta, x_i)$ with respect to $\theta_2$, etc.; If the derivative of $g(\theta, x_i)$ with respect to a particular coefficient in $\theta$ equals zero for all observations in the prediction sample, the stub variable for that coefficient is not created. The ordering of the parameters in $\theta$ is precisely that of the stored vector of parameter estimates $e(b)$. 
iterate(#) specifies the maximum number of iterations used to find the optimal step size in the calculation of numerical derivatives of \( g(\theta, x_i) \) with respect to \( \theta \). By default, the maximum number of iterations is 100, but convergence is usually achieved after only a few iterations. You should rarely have to use this option.

force forces the calculation of standard errors and other inference-related quantities in situations where predictnl would otherwise refuse to do so. The calculation of standard errors takes place by evaluating (at \( \hat{\theta} \)) the numerical derivative of \( g(\theta, x_i) \) with respect to \( \theta \). If predictnl detects that \( g(\cdot) \) is possibly a function of random quantities other than \( \hat{\theta} \), it will refuse to calculate standard errors or any other quantity derived from them. The force option forces the calculation to take place anyway. If you use the force option, there is no guarantee that any inference quantities (for example, standard errors) will be correct or that the values obtained can be interpreted.

The following option is available with predictnl but is not shown in the dialog box:

df(#) specifies that the \( F \) distribution with # denominator degrees of freedom be used for the reference distribution of the test statistic.

Remarks and examples

Remarks are presented under the following headings:

- Introduction
- Nonlinear transformations and standard errors
- Using xb() and predict()
- Multiple-equation (ME) estimators
- Test statistics and p-values
- Manipulability
- Confidence intervals

Introduction

predictnl and nlcom both use the delta method. They take a nonlinear transformation of the estimated parameter vector from some fitted model and apply the delta method to calculate the variance, standard error, Wald test statistic, etc., of this transformation. nlcom is designed for scalar functions of the parameters, and predictnl is designed for functions of the parameters and of the data, that is, for predictions.

Nonlinear transformations and standard errors

We begin by fitting a probit model to the low-birthweight data of Hosmer, Lemeshow, and Sturdivant (2013, 24). The data are described in detail in example 1 of [R] logistic.
. use https://www.stata-press.com/data/r16/lbw
(Hosmer & Lemeshow data)
. probit low lwt smoke ptl ht
Iteration 0: log likelihood = -117.336
Iteration 1: log likelihood = -106.75886
Iteration 2: log likelihood = -106.67852
Iteration 3: log likelihood = -106.67851
Probit regression                     Number of obs = 189
LR chi2(4) = 21.31                   Prob > chi2 = 0.0003
Log likelihood = -106.67851               Pseudo R2 = 0.0908

                               Coef.   Std. Err.      z    P>|z|     [95% Conf. Interval]
------------- ----------------- -------- -------- -------- ------------------
low          
  lwt         -.0095164   .0036875    -2.58   0.010    -.0167438   -.0022891
  smoke       .3487004   .2041772     1.71   0.088    -.0514794   .7488803
  ptl         .365667   .1921201     1.90   0.057   -.0108815   .7422154
  ht          1.082355   .4106730     2.64   0.008    .2774503   1.887259
  _cons       .4238985   .4823224     0.88   0.379   -.5214361   1.369233

Thus subject 180 in our data has an estimated probability of low birthweight of 23.6% with standard error 4.3%.

Used without options, predictnl is not much different from generate. By specifying the se(phat_se) option, we were able to obtain a variable containing the standard errors of the predictions; therein lies the utility of predictnl.
Using `xb()` and `predict()`

As was the case above, a prediction is often not a function of a few isolated parameters and their corresponding variables but instead is some (possibly elaborate) function of the entire linear predictor. For models with many predictors, the brute-force expression for the linear predictor can be cumbersome to type. An alternative is to use the inline function `xb()`. `xb()` is a shortcut for having to type \[ \_b[\_cons] + \_b[ht]*ht + \_b[ptl]*ptl + \ldots, \]

\[
\begin{align*}
. & \text{drop pat pat\_se} \\
. & \text{predictnl pat = norm(xb()), se(pat\_se)} \\
. & \text{list pat pat\_se lwt smoke ptl ht in -10/1}
\end{align*}
\]

which yields the same results. This approach is easier, produces more readable code, and is less prone to error, such as forgetting to include a term in the sum.

Here we used `xb()` without arguments because we have only one equation in our model. In multiple-equation (ME) settings, `xb()` (or equivalently `xb(#1)`) yields the linear predictor from the first equation, `xb(#2)` from the second, etc. You can also refer to equations by their names, for example, `xb(income)`.

**Technical note**

Most estimation commands in Stata allow the postestimation calculation of linear predictors and their standard errors via `predict`. For example, to obtain these for the first (or only) equation in the model, you could type

\[
\begin{align*}
& \text{predict } xvar, \text{ xb} \\
& \text{predict } stdpvar, \text{ stdp}
\end{align*}
\]

Equivalently, you could type

\[
\begin{align*}
& \text{predictnl } xvar = xb(), \text{ se(stdpvar)}
\end{align*}
\]

but we recommend the first method, as it is faster. As we demonstrated above, however, `predictnl` is more general.

Returning to our `probit` example, we can further simplify the calculation by using the inline function `predict()`. `predict(pred_options)` works by substituting, within our `predictnl` expression, the calculation performed by

\[
\begin{align*}
& \text{predict ...}, \text{ pred\_options}
\end{align*}
\]
In our example, we are interested in the predicted probabilities after a probit regression, normally obtained via

```
predict ..., p
```

We can obtain these predictions (and standard errors) by using

```
. drop phat phat_se
. predictnl phat = predict(p), se(phat_se)
. list phat phat_se lwt smoke ptl ht in -10/l

</tbody>
</table>
```

which again replicates what we have already done by other means. However, this version did not require knowledge of the formula for the predicted probabilities after a probit regression—`predict(p)` took care of that for us.

Because the predicted probability is the default prediction after `probit`, we could have just used `predict()` without arguments, namely,

```
. predictnl phat = predict(), se(phat_se)
```

Also, the expression `pnl_exp` can be inordinately complicated, with multiple calls to `predict()` and `xb()`. For example,

```
. predictnl phat = normal(invnormal(predict()) + predict(xb)/xb() - 1),
    > se(phat_se)
```

is perfectly valid and will give the same result as before, albeit a bit inefficiently.

**Technical note**

When using `predict()` and `xb()`, the formula for the calculation is substituted within `pnl_exp`, not the values that result from the application of that formula. To see this, note the subtle difference between

```
. predict xbeta, xb
. predictnl phat = normal(xbeta), se(phat_se)
```

and

```
. predictnl phat = normal(xb()), se(phat_se)
```
Both sequences will yield the same \( \hat{p} \), yet for the first sequence, \( \hat{p} \) will equal zero for all observations. The reason is that, once evaluated, \( \text{xb}() \) will contain the values of the linear predictor, yet these values are treated as fixed and nonstochastic as far as \text{predictnl} \ is concerned. By contrast, because \( \text{xb}() \) is shorthand for the formula used to calculate the linear predictor, it contains not values, but references to the estimated regression coefficients and corresponding variables. Thus the second method produces the desired result.

**Multiple-equation (ME) estimators**

In [R] \text{mlogit}, data on insurance choice (Tarlov et al. 1989; Wells et al. 1989) were examined, and a multinomial logit was used to assess the effects of age, gender, race, and site of study (one of three sites) on the type of insurance:

```
use https://www.stata-press.com/data/r16/sysdsn1, clear
(Health insurance data)
.mlogit insure age male nonwhite i.site, nolog
Multinomial logistic regression
Number of obs = 615
LR chi2(10) = 42.99
Prob > chi2 = 0.0000
Log likelihood = -534.36165 Pseudo R2 = 0.0387
```

Of particular interest is the estimation of the relative risk, which, for a given selection, is the ratio of the probability of making that selection to the probability of selecting the base category (Indemnity here), given a set of covariate values. In a multinomial logit model, the relative risk (when comparing to the base category) simplifies to the exponentiated linear predictor for that selection.

Using this example, we can estimate the observation-specific relative risks of selecting a prepaid plan over the base category (with standard errors) by either referring to the Prepaid equation by name or number,

```
.predictnl RRppaid = exp(xb(Prepaid)), se(SERRppaid)
```
or

```
predictnl RRppaid = exp(xb(#1)), se(SERRppaid)
```

because Prepaid is the first equation in the model.

Those of us for whom the simplified formula for the relative risk does not immediately come to
mind may prefer to calculate the relative risk directly from its definition, that is, as a ratio of two
predicted probabilities. After `mlogit`, the predicted probability for a category may be obtained using
`predict`, but we must specify the category as the outcome:

```
predictnl RRppaid = predict(outcome(Prepaid))/predict(outcome(Indemnity)),
> se(SERRppaid)
(1 missing value generated)
```

The “(1 missing value generated)” message is not an error; further examination of the data would
reveal that age is missing in one observation and that the offending observation (among others) is
not in the estimation sample. Just as with `predict`, `predictnl` can generate predictions in or out
of the estimation sample.

Thus we estimate (among other things) that a white, female, 73-year-old from site 2 is less likely
to choose a prepaid plan over an indemnity plan—her relative risk is about 62% with standard error
15%.

### Test statistics and p-values

Often a standard error calculation is just a means to an end, and what is really desired is a test
of the hypothesis,

$$H_0 : g(\theta, x_i) = 0$$

versus the two-sided alternative.

We can use `predictnl` to obtain the Wald test statistics or p-values (or both) for the above tests,
whether or not we want standard errors. To obtain the Wald test statistics, we use the `wald()` option;
for p-values, we use `p()`.

Returning to our `mlogit` example, suppose that we wanted for each observation a test of whether
the relative risk of choosing a prepaid plan over an indemnity plan is different from one. One way
to do this would be to define $g(\cdot)$ to be the relative risk minus one and then test whether $g(\cdot)$ is
different from zero.
. predictnl RRm1 = exp(xb(Prepaid)) - 1, wald(W_RRm1) p(sig_RRm1)
(1 missing value generated)

predictnl — Obtain nonlinear predictions, standard errors, etc., after estimation

Predictions and standard errors are computed using the nonlinear predictions.

The newly created variable \( W_{RRm1} \) contains the Wald test statistic for each observation, and \( \text{sig}_{RRm1} \) contains the \( p \)-value. Thus our 73-year-old white female represented by the first observation would have a relative risk of choosing prepaid over indemnity that is significantly different from 1, at least at the 5% level. For this test, it was not necessary to generate a variable containing the standard error of the relative risk minus 1, but we could have done so had we wanted. We could have also omitted specifying \( \text{wald}(W_{RRm1}) \) if all we cared about were, say, the \( p \)-values for the tests.

In this regard, predictnl acts as an observation-specific version of testnl, with the test results vectorized over the observations in the data. The \( p \)-values are pointwise—they are not adjusted to reflect any simultaneous testing over the observations in the data.

### Manipulability

There are many ways to specify \( g(\theta, x_i) \) to yield tests such that, for multiple specifications of \( g(\cdot) \), the theoretical conditions for which

\[
H_0: g(\theta, x_i) = 0
\]

is true will be equivalent. However, this does not mean that the tests themselves will be equivalent. This is known as the manipulability of the Wald test for nonlinear hypotheses; also see [R] boxcox.

As an example, consider the previous section where we defined \( g(\cdot) \) to be the relative risk between choosing a prepaid plan over an indemnity plan, minus 1. We could also have defined \( g(\cdot) \) to be the risk difference—the probability of choosing a prepaid plan minus the probability of choosing an indemnity plan. Either specification of \( g(\cdot) \) yields a mathematically equivalent specification of \( H_0: g(\cdot) = 0 \); that is, the risk difference will equal zero when the relative risk equals one. However, the tests themselves do not give the same results:
. predictnl RD = predict(outcome(Prepaid)) - predict(outcome(Indemnity)), > wald(W_RD) p(sig_RD)
(1 missing value generated)

In certain cases (such as subject 8), the difference can be severe enough to potentially change the conclusion. The reason for this inconsistency is that the nonlinear Wald test is actually a standard Wald test of a first-order Taylor approximation of \( g(\cdot) \), and this approximation can differ according to how \( g(\cdot) \) is specified.

As such, keep in mind the manipulability of nonlinear Wald tests when drawing scientific conclusions.

Confidence intervals

We can also use `predictnl` to obtain confidence intervals for the observation-specific \( g(\theta, x_i) \) by using the `ci()` option to specify two new variables to contain the left and right endpoints of the confidence interval, respectively. For example, we could generate confidence intervals for the risk differences calculated previously:

. drop RD
. predictnl RD = predict(outcome(Prepaid)) - predict(outcome(Indemnity)), > ci(RD_lcl RD_rcl)
(1 missing value generated)

The confidence level, here, 95%, is either set using the `level()` option or obtained from the current default level, `c(level)`; see [U] 20.8 Specifying the width of confidence intervals.
From the above output, we can see that, for subjects 1, 8, and 10, a 95% confidence interval for the risk difference does not contain zero, meaning that, for these subjects, there is some evidence of a significant difference in risks.

The confidence intervals calculated by predictnl are pointwise; there is no adjustment (such as a Bonferroni correction) made so that these confidence intervals may be considered jointly at the specified level.

**Methods and formulas**

For the \(i\)th observation, consider the transformation \(g(\theta, x_i)\), estimated by \(g(\hat{\theta}, x_i)\), for the \(1 \times k\) parameter vector \(\theta\) and data \(x_i\) (\(x_i\) is assumed fixed). The variance of \(g(\hat{\theta}, x_i)\) is estimated by

\[
\hat{\text{Var}}\left\{g(\hat{\theta}, x_i)\right\} = GGV'
\]

where \(G\) is the vector of derivatives

\[
G = \left\{ \frac{\partial g(\theta, x_i)}{\partial \theta} \bigg|_{\theta=\hat{\theta}} \right\}_{(1 \times k)}
\]

and \(V\) is the estimated variance–covariance matrix of \(\hat{\theta}\). Standard errors, \(\hat{\text{se}}\{g(\hat{\theta}, x_i)\}\), are obtained as the square roots of the variances.

The Wald test statistic for testing

\[H_0: g(\theta, x_i) = 0\]

versus the two-sided alternative is given by

\[
W_i = \frac{\left\{g(\hat{\theta}, x_i)\right\}^2}{\hat{\text{Var}}\left\{g(\hat{\theta}, x_i)\right\}}
\]

When the variance–covariance matrix of \(\hat{\theta}\) is an asymptotic covariance matrix, \(W_i\) is approximately distributed as \(\chi^2\) with 1 degree of freedom. For linear regression, \(W_i\) is taken to be approximately distributed as \(F_{1,r}\), where \(r\) is the residual degrees of freedom from the original model fit. The \(p\)-values for the observation-by-observation tests of \(H_0\) versus the two-sided alternative are given by

\[
p_i = \text{Pr}(T > W_i)
\]

where \(T\) is either a \(\chi^2\)- or \(F\)-distributed random variable, as described above.

A \((1 - \alpha) \times 100\%\) confidence interval for \(g(\theta, x_i)\) is given by

\[
g(\hat{\theta}, x_i) \pm z_{\alpha/2} \left[\hat{\text{se}}\left\{g(\hat{\theta}, x_i)\right\}\right]
\]

when \(W_i\) is \(\chi^2\)-distributed, and

\[
g(\hat{\theta}, x_i) \pm t_{\alpha/2,r} \left[\hat{\text{se}}\left\{g(\hat{\theta}, x_i)\right\}\right]
\]
when $W_i$ is $F$-distributed. $z_p$ is the $1 - p$ quantile of the standard normal distribution, and $t_{p,r}$ is the $1 - p$ quantile of the $t$ distribution with $r$ degrees of freedom.

probit — Probit regression

Description
probit fits a probit model for a binary dependent variable, assuming that the probability of a positive outcome is determined by the standard normal cumulative distribution function. probit can compute robust and cluster–robust standard errors and adjust results for complex survey designs.

Quick start
Probit model of y on continuous variable x1
probit y x1

Add square of x1
probit y c.x1##c.x1

As above, but report bootstrap standard errors
probit y c.x1##c.x1, vce(bootstrap)

Bootstrap estimates of coefficients
bootstrap _b: probit y c.x1##c.x1

Adjust for complex survey design using svyset data and add x2
svy: probit y c.x1##c.x1 x2

Options

- noconstant, offset(varname), constraints(constraints); see [R] Estimation options.

asis specifies that all specified variables and observations be retained in the maximization process. This option is typically not specified and may introduce numerical instability. Normally probit drops variables that perfectly predict success or failure in the dependent variable along with their associated observations. In those cases, the effective coefficient on the dropped variables is infinity (negative infinity) for variables that completely determine a success (failure). Dropping the variable
and perfectly predicted observations has no effect on the likelihood or estimates of the remaining coefficients and increases the numerical stability of the optimization process. Specifying this option forces retention of perfect predictor variables and their associated observations.

\[ \text{SE/Robust} \]

\[ \text{vce(vcetype)} \] specifies the type of standard error reported, which includes types that are derived from asymptotic theory (\texttt{oim}), that are robust to some kinds of misspecification (\texttt{robust}), that allow for intragroup correlation (\texttt{cluster clustvar}), and that use bootstrap or jackknife methods (\texttt{bootstrap, jackknife}); see \[R\] \texttt{vce option}.

\[ \text{Reporting} \]

\[ \text{level(##)} \]; see \[R\] \texttt{Estimation options}.\n
\[ \text{nocnsreport} \]; see \[R\] \texttt{Estimation options}.

\[ \text{display_options: noci, nopvalues, noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(##), fvwrapon(style), cformat(\%fmt), pformat(\%fmt), sformat(\%fmt), and nolstretch}; \text{see \[R\] \texttt{Estimation options}.} \]

\[ \text{Maximization} \]

\[ \text{maximize_options: difficult, technique(algorithm_spec), iterate(##), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(##), ltolerance(##), nrtolerance(##), nonrtolerance, and from(init_specs)}; \text{see \[R\] \texttt{Maximize}. These options are seldom used.} \]

The following options are available with \texttt{probit} but are not shown in the dialog box:

\[ \text{nocoef} \] specifies that the coefficient table not be displayed. This option is sometimes used by programmers but is of no use interactively.

\[ \text{collinear, coeflegend}; \text{see \[R\] \texttt{Estimation options}.} \]

\section*{Remarks and examples}

Remarks are presented under the following headings:

- Robust standard errors
- Model identification
- Video examples

\texttt{probit} fits maximum likelihood models with dichotomous dependent (left-hand-side) variables coded as 0/1 (more precisely, coded as 0 and not 0).

For grouped data or data in binomial form, a \texttt{probit} model can be fit using \texttt{glm} with the family(binomial) and link(probit) options.

\begin{itemize}
  \item \texttt{Example 1}
\end{itemize}

We have data on the make, weight, and mileage rating of 22 foreign and 52 domestic automobiles. We wish to fit a \texttt{probit} model explaining whether a car is foreign based on its weight and mileage. Here is an overview of our data:
. use https://www.stata-press.com/data/r16/auto
(1978 Automobile Data)
. keep make mpg weight foreign
. describe

(2 unique values)

foreign is labeled and all values are documented in the label.

The foreign variable takes on two unique values, 0 and 1. The value 0 denotes a domestic car, and 1 denotes a foreign car.

The model that we wish to fit is

\[ Pr(\text{foreign} = 1) = \Phi(\beta_0 + \beta_1 \text{weight} + \beta_2 \text{mpg}) \]

where \( \Phi \) is the cumulative normal distribution.

To fit this model, we type

. probit foreign weight mpg
Iteration 0:  log likelihood =  -45.03321
Iteration 1:  log likelihood =  -27.914626
(output omitted)
Iteration 5:  log likelihood =  -26.844189

Probit regression  Number of obs =  74
LR chi2(2) =  36.38
Prob > chi2 =  0.0000
Log likelihood =  -26.844189 Pseudo R2 = 0.4039

| foreign | Coef.  | Std. Err. | z     | P>|z| |  [95% Conf. Interval] |
|---------|--------|-----------|-------|------|-----------------------|
| weight  | -.0023355 | .0005661 | -4.13 | 0.000 | -.003445 -.0012261 |
| mpg     | -.1039503 | .0515689 | -2.02 | 0.044 | -.2050235 -.0028772 |
| _cons   | 8.275464  | 2.554142  | 3.24  | 0.001 | 3.269437 13.28149   |
We find that heavier cars are less likely to be foreign and that cars yielding better gas mileage are also less likely to be foreign, at least holding the weight of the car constant.

See [R] Maximize for an explanation of the output.

### Technical note

Stata interprets a value of 0 as a negative outcome (failure) and treats all other values (except missing) as positive outcomes (successes). Thus if your dependent variable takes on the values 0 and 1, then 0 is interpreted as failure and 1 as success. If your dependent variable takes on the values 0, 1, and 2, then 0 is still interpreted as failure, but both 1 and 2 are treated as successes.

If you prefer a more formal mathematical statement, when you type `probit y x`, Stata fits the model

$$\Pr(y_j \neq 0 | x_j) = \Phi(x_j \beta)$$

where $\Phi$ is the standard cumulative normal.

### Robust standard errors

If you specify the `vce(robust)` option, `probit` reports robust standard errors; see [U] 20.22 Obtaining robust variance estimates.

#### Example 2

For the model from example 1, the robust calculation increases the standard error of the coefficient on `mpg` by almost 15%:

```
. probit foreign weight mpg, vce(robust) nolog
```

<table>
<thead>
<tr>
<th></th>
<th>Robust</th>
<th></th>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>foreign</td>
<td>Coef.</td>
<td>Std. Err.</td>
<td>z</td>
<td>P&gt;</td>
<td>z</td>
</tr>
<tr>
<td>weight</td>
<td>-.0023355</td>
<td>.0004934</td>
<td>-4.73</td>
<td>0.000</td>
<td>-.0033025</td>
</tr>
<tr>
<td>mpg</td>
<td>-.1039503</td>
<td>.0593548</td>
<td>-1.75</td>
<td>0.080</td>
<td>-.2202836</td>
</tr>
<tr>
<td>_cons</td>
<td>8.275464</td>
<td>2.539177</td>
<td>3.26</td>
<td>0.001</td>
<td>3.298769</td>
</tr>
</tbody>
</table>

Without `vce(robust)`, the standard error for the coefficient on `mpg` was reported to be 0.052 with a resulting confidence interval of $[-0.21, -0.00]$.

#### Example 3

The `vce(cluster clustvar)` option can relax the independence assumption required by the probit estimator to independence between clusters. To demonstrate, we will switch to a different dataset.

We are studying unionization of women in the United States and have a dataset with 26,200 observations on 4,434 women between 1970 and 1988. We will use the variables `age` (the women were 14–26 in 1968, and our data span the age range of 16–46), `grade` (years of schooling completed, ranging from 0 to 18), `not_smsa` (28% of the person-time was spent living outside an SMSA—standard metropolitan statistical area), `south` (41% of the person-time was in the South), and `year`. Each of
these variables is included in the regression as a covariate along with the interaction between south and year. This interaction, along with the south and year variables, is specified in the `probit` command using factor-variables notation, `south##c.year`. We also have variable `union`, indicating union membership. Overall, 22% of the person-time is marked as time under union membership, and 44% of these women have belonged to a union.

We fit the following model, ignoring that the women are observed an average of 5.9 times each in these data:

```
use https://www.stata-press.com/data/r16/union, clear
(NLS Women 14-24 in 1968)
.probit union age grade not_smsa south##c.year
```

The reported standard errors in this model are probably meaningless. Women are observed repeatedly, and so the observations are not independent. Looking at the coefficients, we find a large southern effect against unionization and a time trend for the south that is almost significantly different from the overall downward trend. The `vce(cluster clustvar)` option provides a way to fit this model and obtains correct standard errors:
. probit union age grade not_smsa south#c.year, vce(cluster id)
Iteration 0:  log pseudolikelihood =  -13864.23
Iteration 1:  log pseudolikelihood =  -13545.541
Iteration 2:  log pseudolikelihood =  -13544.385
Iteration 3:  log pseudolikelihood =  -13544.385
Probit regression
Number of obs =  26,200
Wald chi2(6) =  166.53
Prob > chi2 =  0.0000
Log pseudolikelihood =  -13544.385
(Std. Err. adjusted for 4,434 clusters in idcode)
Pseudo R2 =  0.0231

|          | Robust Coef. | Std. Err. | z     | P>|z|     | [95% Conf. Interval] |
|----------|--------------|-----------|-------|---------|----------------------|
| union    |              |           |       |         |                      |
| age      | .0118481     | .0056625  | 2.09  | 0.036   | .0007499 .0229463    |
| grade    | .0267365     | .0078124  | 3.42  | 0.001   | .0114244 .0420486    |
| not_smsa | -.1293525    | .0403885  | -3.20 | 0.001   | -.2085125 -.0501925  |
| 1.south  | -.8281077    | .3201584  | -2.59 | 0.010   | -1.455607 -.206089   |
| year     | -.0080931    | .0060829  | -1.33 | 0.183   | -.0200153 .0038292   |
| south#c.year 1 | .0057369 | .0040133 | 1.43  | 0.153   | -.002129 .0136029    |
| _cons    | -.6542487    | .3485976  | -1.88 | 0.061   | -1.337487 .02899     |

These standard errors are larger than those reported by the inappropriate conventional calculation. By comparison, another model we could fit is an equal-correlation population-averaged probit model:

. xtprobit union age grade not_smsa south#c.year, pa
Iteration 1:  tolerance =  .12544249
Iteration 2:  tolerance =  .0034686
Iteration 3:  tolerance =  .00017448
Iteration 4:  tolerance =  8.382e-06
Iteration 5:  tolerance =  3.997e-07
GEE population-averaged model
Number of obs =  26,200
Group variable:  idcode Number of groups =  4,434
Link:  probit Obs per group:
Family:  binomial min =  1
Correlation:  exchangeable avg =  5.9
             max =  12
Wald chi2(6) =  242.57
Prob > chi2 =  0.0000
Scale parameter:  1

|          | Coef. | Std. Err. | z     | P>|z|     | [95% Conf. Interval] |
|----------|-------|-----------|-------|---------|----------------------|
| union    |       |           |       |         |                      |
| age      | .0089699 | .0053208 | 1.69  | 0.092   | -.0014586 .0193985   |
| grade    | .0333174 | .0062352 | 5.34  | 0.000   | .0210966 .0455382    |
| not_smsa | -.0715717 | .027543 | -2.60 | 0.009   | -.1255551 -.0175884  |
| 1.south  | -1.017368 | .207931 | -4.89 | 0.000   | -1.424905 -.6098308  |
| year     | -.0062708 | .0055314 | -1.13 | 0.257   | -.0171122 .0045706   |
| south#c.year 1 | .0086294 | .00258  | 3.34  | 0.001   | .0035727 .013686     |
| _cons    | -.8670997 | .2947711 | -2.94 | 0.003   | -1.44484 -.2893592   |
The coefficient estimates are similar, but these standard errors are smaller than those produced by `probit, vce(cluster clustvar)`, as we would expect. If the equal-correlation assumption is valid, the population-averaged probit estimator above should be more efficient.

Is the assumption valid? That is a difficult question to answer. The default population-averaged estimates correspond to an assumption of exchangeable correlation within person. It would not be unreasonable to assume an AR(1) correlation within person or to assume that the observations are correlated but that we do not wish to impose any structure. See [XT] `xtprobit` and [XT] `xtgee` for full details.

`probit, vce(cluster clustvar)` is robust to assumptions about within-cluster correlation. That is, it inefficiently sums within cluster for the standard error calculation rather than attempting to exploit what might be assumed about the within-cluster correlation.

**Model identification**

The `probit` command has one more feature that is probably the most useful. It will automatically check the model for identification and, if the model is underidentified, drop whatever variables and observations are necessary for estimation to proceed.

> **Example 4**

Have you ever fit a probit model where one or more of your independent variables perfectly predicted one or the other outcome?

For instance, consider the following data:

<table>
<thead>
<tr>
<th>Outcome y</th>
<th>Independent variable x</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>1</td>
</tr>
<tr>
<td>0</td>
<td>1</td>
</tr>
<tr>
<td>0</td>
<td>0</td>
</tr>
<tr>
<td>1</td>
<td>0</td>
</tr>
</tbody>
</table>

Say that we wish to predict the outcome on the basis of the independent variable. The outcome is always zero when the independent variable is one. In our data, \( \Pr(y = 0 \mid x = 1) = 1 \), which means that the probit coefficient on \( x \) must be minus infinity with a corresponding infinite standard error. At this point, you may suspect that we have a problem.

Unfortunately, not all such problems are so easily detected, especially if you have many independent variables in your model. If you have ever had such difficulties, then you have experienced one of the more unpleasant aspects of computer optimization. The computer has no idea that it is trying to solve for an infinite coefficient as it begins its iterative process. All it knows is that, at each step, making the coefficient a little bigger, or a little smaller, works wonders. It continues on its merry way until either 1) the whole thing comes crashing to the ground when a numerical overflow error occurs or 2) it reaches some predetermined cutoff that stops the process. Meanwhile, you have been waiting. And the estimates that you finally receive, if any, may be nothing more than numerical roundoff.

Stata watches for these sorts of problems, alerts you, fixes them, and then properly fits the model.

Let’s return to our automobile data. Among the variables we have in the data is one called `repair` that takes on three values. A value of 1 indicates that the car has a poor repair record, 2 indicates an average record, and 3 indicates a better-than-average record. Here is a tabulation of our data:
. use https://www.stata-press.com/data/r16/repair
(1978 Automobile Data)
. tabulate foreign repair

<table>
<thead>
<tr>
<th>Car type</th>
<th>1</th>
<th>2</th>
<th>3</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>Domestic</td>
<td>10</td>
<td>27</td>
<td>9</td>
<td>46</td>
</tr>
<tr>
<td>Foreign</td>
<td>0</td>
<td>3</td>
<td>9</td>
<td>12</td>
</tr>
<tr>
<td>Total</td>
<td>10</td>
<td>30</td>
<td>18</td>
<td>58</td>
</tr>
</tbody>
</table>

All the cars with poor repair records (repair = 1) are domestic. If we were to attempt to predict foreign on the basis of the repair records, the predicted probability for the repair = 1 category would have to be zero. This in turn means that the probit coefficient must be minus infinity, and that would set most computer programs buzzing.

Let’s try using Stata on this problem.

. probit foreign b3.repair

note: 1.repair != 0 predicts failure perfectly
1.repair dropped and 10 obs not used

Iteration 0: log likelihood = -26.992087
Iteration 1: log likelihood = -22.276479
Iteration 2: log likelihood = -22.229184
Iteration 3: log likelihood = -22.229138
Iteration 4: log likelihood = -22.229138

Probit regression
Number of obs = 48
LR chi2(1) = 9.53
Prob > chi2 = 0.0020
Log likelihood = -22.229138
Pseudo R2 = 0.1765

| foreign | Coef. | Std. Err. | z     | P>|z|  | [95% Conf. Interval] |
|---------|-------|-----------|-------|------|----------------------|
| repair  |       |           |       |      |                      |
| 1       | 0 (empty) |          |       |      |                      |
| 2       | -1.281552 | .4297326 | -2.98 | 0.003 | -2.123812 to -.4392911 |
| _cons   | 1.16e-16 | .295409  | 0.00  | 1.000 | -.578991 to .578991   |

Remember that all the cars with poor repair records (repair = 1) are domestic, so the model cannot be fit, or at least it cannot be fit if we restrict ourselves to finite coefficients. Stata noted that fact “note: 1.repair != 0 predicts failure perfectly”. This is Stata’s mathematically precise way of saying what we said in English. When repair is 1, the car is domestic.

Stata then went on to say, “1.repair dropped and 10 obs not used”. This is Stata eliminating the problem. First, 1.repair had to be removed from the model because it would have an infinite coefficient. Then the 10 observations that led to the problem had to be eliminated, as well, so as not to bias the remaining coefficients in the model. The 10 observations that are not used are the 10 domestic cars that have poor repair records.

Stata then fit what was left of the model, using the remaining observations. Because no observations remained for cars with poor repair records, Stata reports “(empty)” in the row for repair = 1.
Technical note

Stata is pretty smart about catching these problems. It will catch “one-way causation by a dummy variable”, as we demonstrated above.

Stata also watches for “two-way causation”, that is, a variable that perfectly determines the outcome, both successes and failures. Here Stata says that the variable “predicts outcome perfectly” and stops. Statistics dictate that no model can be fit.

Stata also checks your data for collinear variables; it will say “so-and-so omitted because of collinearity”. No observations need to be eliminated here and model fitting will proceed without the offending variable.

It will also catch a subtle problem that can arise with continuous data. For instance, if we were estimating the chances of surviving the first year after an operation, and if we included in our model age, and if all the persons over 65 died within the year, Stata will say, “age >= 65 predicts failure perfectly”. It will then inform us about how it resolves the issue and fit what can be fit of our model.

probit (and logit, logistic, and ivprobit) will also occasionally fail to converge and then display messages such as

Note: 4 failures and 0 successes completely determined.

The cause of this message and what to do if you see it are described in [R] logit.

Video examples

Probit regression with continuous covariates
Probit regression with categorical and continuous covariates

Stored results

probit stores the following in e():

Scalars
  e(N) number of observations
  e(N_cds) number of completely determined successes
  e(N_cdf) number of completely determined failures
  e(k) number of parameters
  e(k_eq) number of equations in e(b)
  e(k_eq_model) number of equations in overall model test
  e(k_dv) number of dependent variables
  e(df_m) model degrees of freedom
  e(r2_p) pseudo-R-squared
  e(ll) log likelihood
  e(ll_0) log likelihood, constant-only model
  e(N_clust) number of clusters
  e(chi2) $\chi^2$
  e(p) $p$-value for model test
  e(rank) rank of e(V)
  e(ic) number of iterations
  e(rc) return code
  e(converged) 1 if converged, 0 otherwise
Macros

e(cmd)                 probit

  e(wtype)             weight type
  e(wexp)              weight expression
  e(title)             title in estimation output
  e(clustvar)          name of cluster variable
  e(offset)            linear offset variable
  e(chi2type)          Wald or LR; type of model \( \chi^2 \) test
  e(vcetype)           vcetype specified in vce()
  e(title)             title used to label Std. Err.
  e(opt)               type of optimization
  e(which)             max or min; whether optimizer is to perform maximization or minimization
  e(ml_method)         type of ml method
  e(user)              name of likelihood-evaluator program
  e(technique)         maximization technique
  e(properties)        b V
  e(estat_cmd)         program used to implement estat
  e(predict)           program used to implement predict
  e(marginsok)         predictions allowed by margins
  e(marginsnotok)      predictions disallowed by margins
  e(asbalanced)        factor variables fvset as asbalanced
  e(asobserved)        factor variables fvset as asobserved

Matrices

e(b)                  coefficient vector
  e(Cns)               constraints matrix
  e(ilog)              iteration log (up to 20 iterations)
  e(gradient)          gradient vector
  e(mns)               vector of means of the independent variables
  e(rules)             information about perfect predictors
  e(V)                 variance–covariance matrix of the estimators
  e(V_modelbased)      model-based variance

Functions

e(sample)            marks estimation sample

Methods and formulas

Probit analysis originated in connection with bioassay, and the word probit, a contraction of “probability unit”, was suggested by Bliss (1934a, 1934b). For an introduction to probit and logit, see, for example, Aldrich and Nelson (1984), Cameron and Trivedi (2010), Long (1997), Pampel (2000), or Powers and Xie (2008). Long and Freese (2014, chap. 5 and 6) and Jones (2007, chap. 3) provide introductions to probit and logit, along with Stata examples.

The log-likelihood function for probit is

\[
\ln L = \sum_{j \in S} w_j \ln \Phi(x_j \beta) + \sum_{j \not\in S} w_j \ln \left\{1 - \Phi(x_j \beta)\right\}
\]

where \( \Phi \) is the cumulative normal and \( w_j \) denotes the optional weights. \( \ln L \) is maximized, as described in [R] Maximize.

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using vce(robust) and vce(cluster clustvar), respectively. See [P] _robust, particularly Maximum likelihood estimators and Methods and formulas. The scores are calculated as \( u_j = \{\phi(x_j b) / \Phi(x_j b)\} x_j \) for the positive outcomes and \(-[\phi(x_j b) / (1 - \Phi(x_j b))] x_j\) for the negative outcomes, where \( \phi \) is the normal density.
probit also supports estimation with survey data. For details on VCEs with survey data, see [SVY] Variance estimation.

Chester Ittner Bliss (1899–1979) was born in Ohio. He was educated as an entomologist, earning degrees from Ohio State and Columbia, and was employed by the United States Department of Agriculture until 1933. When he lost his job because of the Depression, Bliss then worked with R. A. Fisher in London and at the Institute of Plant Protection in Leningrad before returning to a post at the Connecticut Agricultural Experiment Station in 1938. He was also a lecturer at Yale for 25 years. Among many contributions to biostatistics, his development and application of probit methods to biological problems are outstanding.

Postestimation commands

The following postestimation commands are of special interest after `probit`:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>estat classification</td>
<td>report various summary statistics, including the classification table</td>
</tr>
<tr>
<td>estat gof</td>
<td>Pearson or Hosmer–Lemeshow goodness-of-fit test</td>
</tr>
<tr>
<td>lroc</td>
<td>compute area under ROC curve and graph the curve</td>
</tr>
<tr>
<td>lsens</td>
<td>graph sensitivity and specificity versus probability cutoff</td>
</tr>
</tbody>
</table>

These commands are not appropriate after the `svy` prefix.

The following standard postestimation commands are also available:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>contrast</td>
<td>contrasts and ANOVA-style joint tests of estimates</td>
</tr>
<tr>
<td>estat ic</td>
<td>Akaike’s and Schwarz’s Bayesian information criteria (AIC and BIC)</td>
</tr>
<tr>
<td>estat summarize</td>
<td>summary statistics for the estimation sample</td>
</tr>
<tr>
<td>estat vce</td>
<td>variance–covariance matrix of the estimators (VCE)</td>
</tr>
<tr>
<td>estat (svy)</td>
<td>postestimation statistics for survey data</td>
</tr>
<tr>
<td>estimates</td>
<td>cataloging estimation results</td>
</tr>
<tr>
<td>*forecast</td>
<td>dynamic forecasts and simulations</td>
</tr>
<tr>
<td>*hausman</td>
<td>Hausman’s specification test</td>
</tr>
<tr>
<td>lincom</td>
<td>point estimates, standard errors, testing, and inference for linear</td>
</tr>
<tr>
<td></td>
<td>combinations of coefficients</td>
</tr>
<tr>
<td>lincom</td>
<td>link test for model specification</td>
</tr>
<tr>
<td>*lrtest</td>
<td>likelihood-ratio test</td>
</tr>
<tr>
<td>margins</td>
<td>marginal means, predictive margins, marginal effects, and average marginal</td>
</tr>
<tr>
<td></td>
<td>effects</td>
</tr>
<tr>
<td>marginsplot</td>
<td>graph the results from margins (profile plots, interaction plots, etc.)</td>
</tr>
<tr>
<td>nlncom</td>
<td>point estimates, standard errors, testing, and inference for nonlinear</td>
</tr>
<tr>
<td></td>
<td>combinations of coefficients</td>
</tr>
<tr>
<td>predict</td>
<td>predictions, residuals, influence statistics, and other diagnostic measures</td>
</tr>
<tr>
<td>predictnl</td>
<td>point estimates, standard errors, testing, and inference for generalized</td>
</tr>
<tr>
<td></td>
<td>predictions</td>
</tr>
<tr>
<td>pwcompare</td>
<td>pairwise comparisons of estimates</td>
</tr>
<tr>
<td>suest</td>
<td>seemingly unrelated estimation</td>
</tr>
<tr>
<td>test</td>
<td>Wald tests of simple and composite linear hypotheses</td>
</tr>
<tr>
<td>testnl</td>
<td>Wald tests of nonlinear hypotheses</td>
</tr>
</tbody>
</table>

*forecast, hausman, and lrtest are not appropriate with svy estimation results. forecast is also not appropriate with mi estimation results.
**predict**

**Description for predict**

`predict` creates a new variable containing predictions such as probabilities, linear predictions, standard errors, deviance residuals, and equation-level scores.

**Menu for predict**

Statistics > Postestimation

**Syntax for predict**

```
predict [type] newvar [if] [in] [, statistic nooffset rules asif]
```

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>pr</code></td>
<td>probability of a positive outcome; the default</td>
</tr>
<tr>
<td><code>xb</code></td>
<td>linear prediction</td>
</tr>
<tr>
<td><code>stdp</code></td>
<td>standard error of the linear prediction</td>
</tr>
<tr>
<td><code>*deviance</code></td>
<td>deviance residual</td>
</tr>
<tr>
<td><code>score</code></td>
<td>first derivative of the log likelihood with respect to $x_j \beta$</td>
</tr>
</tbody>
</table>

Unstarred statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample. Starred statistics are calculated only for the estimation sample, even when `if e(sample)` is not specified.

**Options for predict**

- `pr`, the default, calculates the probability of a positive outcome.
- `xb` calculates the linear prediction.
- `stdp` calculates the standard error of the linear prediction.
- `deviance` calculates the deviance residual.
- `score` calculates the equation-level score, $\partial \ln L / \partial (x_j \beta)$.
- `nooffset` is relevant only if you specified `offset(varname)` for `probit`. It modifies the calculations made by `predict` so that they ignore the offset variable; the linear prediction is treated as $x_j \beta$ rather than as $x_j \beta + \text{offset}_j$.
- `rules` requests that Stata use any rules that were used to identify the model when making the prediction. By default, Stata calculates missing for excluded observations.
- `asif` requests that Stata ignore the rules and exclusion criteria and calculate predictions for all observations possible using the estimated parameter from the model.
margins

Description for margins

margins estimates margins of response for probabilities and linear predictions.

Menu for margins

Statistics > Postestimation

Syntax for margins

margins [marginlist] [, options]
margins [marginlist], predict(statistic ...) [predict(statistic ...) ...] [options]

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>pr</td>
<td>probability of a positive outcome; the default</td>
</tr>
<tr>
<td>xb</td>
<td>linear prediction</td>
</tr>
<tr>
<td>stdp</td>
<td>not allowed with margins</td>
</tr>
<tr>
<td>deviance</td>
<td>not allowed with margins</td>
</tr>
<tr>
<td>score</td>
<td>not allowed with margins</td>
</tr>
</tbody>
</table>

Statistics not allowed with margins are functions of stochastic quantities other than e(b).

For the full syntax, see [R] margins.

Remarks and examples

Remarks are presented under the following headings:

Obtaining predicted values
Performing hypothesis tests

Obtaining predicted values

Once you have fit a probit model, you can obtain the predicted probabilities by using the predict command for both the estimation sample and other samples; see [U] 20 Estimation and postestimation commands and [R] predict. Here we will make only a few additional comments.

predict without arguments calculates the predicted probability of a positive outcome. With the xb option, predict calculates the linear combination $x_j b$, where $x_j$ are the independent variables in the $j$th observation and $b$ is the estimated parameter vector. This is known as the index function because the cumulative density indexed at this value is the probability of a positive outcome.

In both cases, Stata remembers any rules used to identify the model and calculates missing for excluded observations unless rules or asif is specified. This is covered in the following example.

With the stdp option, predict calculates the standard error of the prediction, which is not adjusted for replicated covariate patterns in the data.
You can calculate the unadjusted-for-replicated-covariate-patterns diagonal elements of the hat matrix, or leverage, by typing

```
predict pred
.predict stdp, stdp
.generate hat = stdp^2*pred*(1-pred)
```

**Example 1**

In example 4 of [R] probit, we fit the probit model `probit foreign b3.repair`. To obtain predicted probabilities, we type

```
predict p
(option pr assumed; Pr(foreign))
(10 missing values generated)
.summarize foreign p
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>foreign</td>
<td>58</td>
<td>.2068966</td>
<td>.4086186</td>
<td>0</td>
<td>1</td>
</tr>
<tr>
<td>p</td>
<td>48</td>
<td>.25</td>
<td>.1956984</td>
<td>.1</td>
<td>.5</td>
</tr>
</tbody>
</table>

Stata remembers any rules used to identify the model and sets predictions to missing for any excluded observations. In example 4 of [R] probit, probit dropped the variable `1.repair` from our model and excluded 10 observations. When we typed `predict p`, those same 10 observations were again excluded and their predictions set to missing.

`predict`'s `rules` option uses the rules in the prediction. During estimation, we were told, “1.repair != 0 predicts failure perfectly”, so the rule is that when 1.repair is not zero, we should predict 0 probability of success or a positive outcome:

```
predict p2, rules
(option pr assumed; Pr(foreign))
.summarize foreign p p2
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>foreign</td>
<td>58</td>
<td>.2068966</td>
<td>.4086186</td>
<td>0</td>
<td>1</td>
</tr>
<tr>
<td>p</td>
<td>48</td>
<td>.25</td>
<td>.1956984</td>
<td>.1</td>
<td>.5</td>
</tr>
<tr>
<td>p2</td>
<td>58</td>
<td>.2068966</td>
<td>.2016268</td>
<td>0</td>
<td>.5</td>
</tr>
</tbody>
</table>

`predict`'s `asif` option ignores the rules and the exclusion criteria and calculates predictions for all observations possible using the estimated parameters from the model:

```
predict p3, asif
(option pr assumed; Pr(foreign))
.summarize for p p2 p3
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>foreign</td>
<td>58</td>
<td>.2068966</td>
<td>.4086186</td>
<td>0</td>
<td>1</td>
</tr>
<tr>
<td>p</td>
<td>48</td>
<td>.25</td>
<td>.1956984</td>
<td>.1</td>
<td>.5</td>
</tr>
<tr>
<td>p2</td>
<td>58</td>
<td>.2068966</td>
<td>.2016268</td>
<td>0</td>
<td>.5</td>
</tr>
<tr>
<td>p3</td>
<td>58</td>
<td>.2931034</td>
<td>.2016268</td>
<td>.1</td>
<td>.5</td>
</tr>
</tbody>
</table>

Which is right? By default, `predict` uses the most conservative approach. If many observations had been excluded due to a simple rule, we could be reasonably certain that the `rules` prediction is correct. The `asif` prediction is correct only if the exclusion is a fluke and we would be willing to exclude the variable from the analysis, anyway. Then, however, we should refit the model to include the excluded observations.
Performing hypothesis tests

After estimation with `probit`, you can perform hypothesis tests by using the `test` or `testnl` command; see `[U] 20 Estimation and postestimation commands`.

Methods and formulas

Let index \( j \) be used to index observations. Define \( M_j \) for each observation as the total number of observations sharing \( j \)’s covariate pattern. Define \( Y_j \) as the total number of positive responses among observations sharing \( j \)’s covariate pattern. Define \( p_j \) as the predicted probability of a positive outcome for observation \( j \).

For \( M_j > 1 \), the deviance residual \( d_j \) is defined as

\[
d_j = \pm \left( 2 \left[ Y_j \ln\left( \frac{Y_j}{M_j p_j} \right) + (M_j - Y_j) \ln\left( \frac{M_j - Y_j}{M_j(1 - p_j)} \right) \right] \right)^{1/2}
\]

where the sign is the same as the sign of \( (Y_j - M_j p_j) \). In the limiting cases, the deviance residual is given by

\[
d_j = \begin{cases} 
-\sqrt{2M_j \ln(1 - p_j)} & \text{if } Y_j = 0 \\
\sqrt{2M_j \ln p_j} & \text{if } Y_j = M_j 
\end{cases}
\]

Also see

[R] `probit` — Probit regression

[R] `estat gof` — Pearson or Hosmer–Lemeshow goodness-of-fit test
[R] `lroc` — Compute area under ROC curve and graph the curve
[R] `lsens` — Graph sensitivity and specificity versus probability cutoff
[U] 20 Estimation and postestimation commands
proportion — Estimate proportions

Description

proportion produces estimates of proportions, along with standard errors, for the categories identified by the values in each variable of `varlist`.

Quick start

Proportions, standard errors, and 95% CIs for each level of `v1`

```
proportion v1
```

Also compute statistics for `v2`

```
proportion v1 v2
```

As above, for each subpopulation defined by the levels of `catvar`

```
proportion v1 v2, over(catvar)
```

Standardizing across strata defined by `svar` with stratum weight `wvar1`

```
proportion v1, stdize(svar) stdweight(wvar1)
```

Weighting by sampling weight `wvar2`

```
proportion v1 [pweight=wvar2]
```

Menu

Statistics > Summaries, tables, and tests > Summary and descriptive statistics > Proportions
1988  proportion — Estimate proportions

Syntax

    proportion varlist [if] [in] [weight] [, options]

options    Description

Model

stdize(varname)     variable identifying strata for standardization
stdweight(varname)  weight variable for standardization
nostdrescale        do not rescale the standard weight variable

if/in/over          group over subpopulations defined by varlist

SE/Cluster

vce(vcetype)        vcetype may be analytic, cluster clustvar, bootstrap, or jackknife

Reporting

level(#)            set confidence level; default is level(95)
citype(citype)      method to compute limits of confidence intervals; default is citype(logit)
percent             report estimated proportions as percentages
noheader            suppress table header
display_options     control column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling

coeflegend          display legend instead of statistics

varlist may contain factor variables; see [U] 11.4.3 Factor variables.
Only numeric, nonnegative, integer-valued variables are allowed in varlist.
bootstrap, jackknife, mi estimate, rolling, statsby, and svy are allowed; see [U] 11.1.10 Prefix commands.
vce(bootstrap) and vce(jackknife) are not allowed with the mi estimate prefix; see [MI] mi estimate.
Weights are not allowed with the bootstrap prefix; see [R] bootstrap.
vce() and weights are not allowed with the svy prefix; see [SVY] svy.
fweights, iweights, and pweights are allowed; see [U] 11.1.6 weight.
coeflegend does not appear in the dialog box.
See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

citype    Description

logit     calculate logit-transformed confidence intervals; the default
agresti   calculate Agresti–Coulb confidence intervals
exact     calculate exact (Clopper–Pearson) confidence intervals
jeffreys  calculate Jeffreys confidence intervals
normal    calculate normal (Wald) confidence intervals
wald      synonym for normal
wilson    calculate Wilson confidence intervals
Options

\texttt{stdize(\textit{varname})} specifies that the point estimates be adjusted by direct standardization across the strata identified by \textit{varname}. This option requires the \texttt{stdweight()} option.

\texttt{stdweight(\textit{varname})} specifies the weight variable associated with the standard strata identified in the \texttt{stdize()} option. The standardization weights must be constant within the standard strata.

\texttt{nostdrescale} prevents the standardization weights from being rescaled within the \texttt{over()} groups. This option requires \texttt{stdize()} but is ignored if the \texttt{over()} option is not specified.

\texttt{over(\textit{varlist}_o)} specifies that estimates be computed for multiple subpopulations, which are identified by the different values of the variables in \textit{varlist}_o. Only numeric, nonnegative, integer-valued variables are allowed in \texttt{over(\textit{varlist}_o)}.

\texttt{vce(\textit{vcetype})} specifies the type of standard error reported, which includes types that are derived from asymptotic theory (\texttt{analytic}), that allow for intragroup correlation (\texttt{cluster clustvar}), and that use bootstrap or jackknife methods (\texttt{bootstrap}, \texttt{jackknife}); see \texttt{[R] vce_option}.\texttt{vce(analytic)}, the default, uses the analytically derived variance estimator associated with the sample proportion.

\texttt{level(#)}; see \texttt{[R] Estimation options}.

\texttt{citype(\textit{citype})} specifies how to compute the limits of confidence intervals. \textit{citype} may be one of \texttt{logit} (default), \texttt{agresti}, \texttt{exact}, \texttt{jeffreys}, \texttt{normal}, \texttt{wald}, or \texttt{wilson}.

\texttt{percent} specifies that the proportions be reported as percentages.

\texttt{noheader} prevents the table header from being displayed.

\texttt{display_options}: \texttt{nomitted}, \texttt{vsquish}, \texttt{noemptycells}, \texttt{baselevels}, \texttt{allbaselevels}, \texttt{nofvlabel}, \texttt{fvwrap(#)}, \texttt{fvwrapon(style)}, \texttt{cformat(\%fmt)}, and \texttt{nolstretch}; see \texttt{[R] Estimation options}.

The following option is available with \texttt{proportion} but is not shown in the dialog box:
\texttt{coeflegend}; see \texttt{[R] Estimation options}. 

Remarks and examples

Example 1

We can estimate the proportion of each repair rating in auto2.dta:

```
. use https://www.stata-press.com/data/r16/auto2
(1978 Automobile Data)
. proportion rep78
Proportion estimation Number of obs = 69

                      Logit
                     Proportion Std. Err.  [95% Conf. Interval]
rep78                
  Poor                .0289855   .0201966    .0070794    .1110924
  Fair                .115942    .0385422    .058317    .2173648
  Average             .4347826   .0596787    .3214848    .5553295
  Good                .2608696   .0528625   .1695907    .3788629
  Excellent           .1594203   .0440694   .0895793    .267702
```

marginsplot will produce a graph of the results from proportion:

```
. marginsplot
Variables that uniquely identify proportions: rep78
```

Estimated Proportions of rep78 with 95% CIs
### Example 2

We can also estimate proportions over groups:

```
. proportion rep78, over(foreign)
```

<table>
<thead>
<tr>
<th></th>
<th>Proportion</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>rep78@foreign</td>
<td></td>
<td></td>
<td>Logit</td>
</tr>
<tr>
<td>Poor Domestic</td>
<td>.0416667</td>
<td>.0288424</td>
<td>.0101825 1552326</td>
</tr>
<tr>
<td>Poor Foreign</td>
<td>0 (no observations)</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Fair Domestic</td>
<td>.1666667</td>
<td>.0537914</td>
<td>.084534 3022522</td>
</tr>
<tr>
<td>Fair Foreign</td>
<td>0 (no observations)</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Average Domestic</td>
<td>.5625</td>
<td>.0716027</td>
<td>.4184154 6967587</td>
</tr>
<tr>
<td>Average Foreign</td>
<td>.1428571</td>
<td>.0763604</td>
<td>.0458191 3664757</td>
</tr>
<tr>
<td>Good Domestic</td>
<td>.1875</td>
<td>.0563367</td>
<td>.0993684 3255432</td>
</tr>
<tr>
<td>Good Foreign</td>
<td>.4285714</td>
<td>.1079898</td>
<td>.2372889 6438783</td>
</tr>
<tr>
<td>Excellent Domestic</td>
<td>.0416667</td>
<td>.0288424</td>
<td>.0101825 1552326</td>
</tr>
<tr>
<td>Excellent Foreign</td>
<td>.4285714</td>
<td>.1079898</td>
<td>.2372889 6438783</td>
</tr>
</tbody>
</table>

To see the results as percentages instead of proportions, we add the `percent` option:

```
. proportion rep78, over(foreign) percent
```

<table>
<thead>
<tr>
<th></th>
<th>Percent</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>

<td>4.17</td>
<td>2.88</td>
<td>1.02 15.52</td>
</tr>
<tr>
<td>Excellent Foreign</td>
<td>42.86</td>
<td>10.80</td>
<td>23.73 64.39</td>
</tr>
</tbody>
</table>

We can now use `marginsplot` to graph the percentages for each group. We add the `bydimension(foreign)` option to plot the groups in separate graph panels. The `xlabel(, angle(30))` option prevents the x-axis labels from running into each other.
We estimate that only 19% of domestic cars have good repair records and only 4% have excellent repair records. For foreign cars, however, we find that 43% have good repair records and 43% have excellent repair records.

### Example 3

Instead of estimating percentages within the foreign and domestic groupings, we might want to know overall percentages. For instance, what percentage of all cars are foreign and have excellent repair records? What percentage are domestic and have average records? We can obtain all such percentages by specifying an interaction between `rep78` and `foreign`.

```
. proportion rep78#foreign, percent
```

<table>
<thead>
<tr>
<th>Percent estimation</th>
<th>Number of obs = 69</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Percent</td>
</tr>
<tr>
<td>rep78#foreign</td>
<td></td>
</tr>
<tr>
<td>Poor#Domestic</td>
<td>2.90</td>
</tr>
<tr>
<td>Poor#Foreign</td>
<td>0.00</td>
</tr>
<tr>
<td>Fair#Domestic</td>
<td>11.59</td>
</tr>
<tr>
<td>Fair#Foreign</td>
<td>0.00</td>
</tr>
<tr>
<td>Average#Domestic</td>
<td>39.13</td>
</tr>
<tr>
<td>Average#Foreign</td>
<td>4.35</td>
</tr>
<tr>
<td>Good#Domestic</td>
<td>13.04</td>
</tr>
<tr>
<td>Good#Foreign</td>
<td>13.04</td>
</tr>
<tr>
<td>Excellent#Domestic</td>
<td>2.90</td>
</tr>
<tr>
<td>Excellent#Foreign</td>
<td>13.04</td>
</tr>
</tbody>
</table>

Looking at the last line of this output, we estimate that 13% of all cars are foreign with excellent repair records.
Methods and formulas

Proportions are means of indicator variables; see [R] mean.

Confidence intervals

For an overview of confidence interval methods for binomial proportions, see Dean and Pagano (2015).

Given $k$ successes of $n$ trials, the estimated proportion (probability of a success) is $\hat{p} = k/n$ with estimated standard error $\hat{s} = \sqrt{\frac{\hat{p}(1-\hat{p})}{n}}$.

The logit-transformed confidence interval is given by

$$\log \left( \frac{\hat{p}}{1-\hat{p}} \right) \pm t_{1-\alpha/2,\nu} \frac{\hat{s}}{\hat{p}(1-\hat{p})}$$

where $t_{p,\nu}$ is the $p$th quantile of Student’s $t$ distribution with $\nu$ degrees of freedom.
The endpoints of this confidence interval are transformed back to the proportion metric by using the inverse of the logit transform

$$f^{-1}(y) = \frac{e^y}{1 + e^y}$$

Hence, the displayed confidence intervals for proportions are

$$f^{-1}\left\{ \ln \left( \frac{\hat{p}}{1 - \hat{p}} \right) \pm t_{1-\alpha/2,\nu} \frac{\hat{s}}{\hat{p}(1 - \hat{p})} \right\}$$

The Wald-type 100(1 − α)% confidence interval is given by

$$\hat{p} \pm t_{1-\alpha/2,\nu} \hat{s}$$

The Wilson interval is given by

$$\frac{\hat{p} + z^2_{1-\alpha/2}/2n \pm z_{1-\alpha/2} \sqrt{\hat{s} + z^2_{1-\alpha/2}/4n^2}}{1 + z^2_{1-\alpha/2}/n}$$

where $z_p$ is the $p$th quantile of the standard normal distribution.

The exact (Clopper–Pearson) interval is given by

$$\left\{ \hat{p} - \frac{\nu_1 F_{\alpha/2,\nu_1,\nu_2}}{\nu_2 + \nu_1 F_{\alpha/2,\nu_1,\nu_2}}; \hat{p} + \frac{\nu_3 F_{\alpha/2,\nu_3,\nu_4}}{\nu_4 + \nu_3 F_{\alpha/2,\nu_3,\nu_4}} \right\}$$

where $\nu_1 = 2k$, $\nu_2 = 2(n - k + 1)$, $\nu_3 = 2(k + 1)$, $\nu_4 = 2(n - k)$, and $F_{p,\nu_1,\nu_2}$ is the $p$th quantile of an $F$ distribution with $\nu_1$ and $\nu_2$ degrees of freedom.

The Jeffreys interval is given by

$$\left\{ \hat{p} - \text{Beta}_{\alpha/2,\alpha_1,\beta_2}; \hat{p} + \text{Beta}_{1-\alpha/2,\alpha_1,\beta_2} \right\}$$

where $\alpha_1 = k + 0.5$, $\beta_1 = n - k + 0.5$, and $\text{Beta}_{p,\alpha_1,\beta_2}$ is the $p$th quantile of a Beta distribution with $\alpha_1$ and $\beta_1$ degrees of freedom.

The Agresti–Coull interval is given by

$$\hat{p} \pm z_{1-\alpha/2} \sqrt{\hat{p}(1 - \hat{p})/\hat{n}}$$

where $\tilde{k} = k + z^2_{1-\alpha/2}/2$, $\tilde{n} = n + z^2_{1-\alpha/2}$, and $\tilde{p} = \tilde{k}/\tilde{n}$.

When degrees of freedom $\nu$ are posted to $\text{e(df, r)}$, the Wilson, exact, Jeffreys, and Agresti–Coull intervals use $n^*$ in place of $n$, where

$$n^* = \frac{\hat{p}(1 - \hat{p})}{\hat{s}^2} \left\{ \frac{z_{1-\alpha/2}}{t_{1-\alpha/2,\nu}} \right\}^2$$

Remarks and examples

Example 1

In example 2 of [R] `proportion`, we computed the proportions of cars with different repair records for each group, foreign or domestic. We use `test` to test whether the proportion of cars with repair record equal to 4 is the same for domestic and foreign cars.

```
. use https://www.stata-press.com/data/r16/auto
     (1978 Automobile Data)
. proportion rep78, over(foreign)
     (output omitted)
. test 4.rep78@0.foreign=4.rep78@1.foreign
     ( 1) 4.rep78@0bn.foreign - 4.rep78@1.foreign = 0
          F( 1,  68) =    3.92
          Prob > F =    0.0518
```

There is not a significant difference between those proportions at the 5% level.
Example 2

Continuing with auto.dta from example 1, we generate a new variable, highprice, that indicates if the price is larger than $5,000 and then use proportion to see the proportion of cars with high price among domestic and foreign cars separately.

```
. generate highprice = price>5000
. proportion highprice, over(foreign)
```

<table>
<thead>
<tr>
<th>highprice@foreign</th>
<th>Proportion</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
<th>Logit</th>
</tr>
</thead>
<tbody>
<tr>
<td>0 Domestic</td>
<td>.5576923</td>
<td>.0688744</td>
<td>.4195373 .6874611</td>
<td></td>
</tr>
<tr>
<td>0 Foreign</td>
<td>.3636364</td>
<td>.1025593</td>
<td>.191094 .5802222</td>
<td></td>
</tr>
<tr>
<td>1 Domestic</td>
<td>.4423077</td>
<td>.0688744</td>
<td>.3125389 .5804627</td>
<td></td>
</tr>
<tr>
<td>1 Foreign</td>
<td>.6363636</td>
<td>.1025593</td>
<td>.4197778 .808906</td>
<td></td>
</tr>
</tbody>
</table>

We will compute the odds ratio of having a high price in group Foreign to having a high price in group Domestic. Usually, odds ratios are computed by using the logistic command, but here we will perform the computation by using nlcom after proportion.

```
. nlcom OR: (_b[1.highprice@1.foreign]/_b[0.highprice@1.foreign])/(_b[1.highprice@0.foreign]/_b[0.highprice@0.foreign])
```

```
OR: (_b[1.highprice@1.foreign]/_b[0.highprice@1.foreign])/(_b[1.highprice@0.foreign]/_b[0.highprice@0.foreign])
```

| Proportion | Coef. | Std. Err. | z     | P>|z|  | [95% Conf. Interval] |
|------------|-------|-----------|-------|------|---------------------|
| OR         | 2.206522 | 1.155825   | 1.91  | 0.056| -.0588533 4.471897 |

This is the same odds ratio that we would obtain from
```
. logistic highprice foreign
```

The odds ratio is slightly larger than 2, which means that the odds of having a high price among foreign cars are more than twice that of having a high price among domestic cars.

Also see

[R] proportion — Estimate proportions
[U] 20 Estimation and postestimation commands
prtest — Tests of proportions

**Description**

prtest performs tests on the equality of proportions using large-sample statistics. The test can be performed for one sample against a hypothesized population value or for no difference in population proportions estimated from two samples. Clustered data are supported.

prtesti is the immediate form of prtest; see [U] 19 Immediate commands.

**Quick start**

One-sample test that the proportion of 1s in v is equal to 0.1

```
prtest v == 0.1
```

As above, but using the 90% confidence level and adjusting for clustering with clusters defined by cvar and an intraclass correlation of 0.5

```
prtest v == 0.1, level(90) cluster(cvar) rho(0.5)
```

Test that the proportion of 1s in v is equal between two groups defined by catvar

```
prtest v, by(catvar)
```

As above, and adjust for clustering with clusters defined by cvar and an intraclass correlation of 0.5 in the two groups

```
prtest v, by(catvar) cluster(cvar) rho(0.5)
```

Test equality of proportions between v1 and v2

```
prtest v1 == v2
```

Test \( p_1 = p_2 \) if \( \hat{p}_1 = 0.10, \hat{p}_2 = 0.17, n_1 = 29, \) and \( n_2 = 36 \)

```
prtesti 29 0.10 36 0.17
```

</tbody>
</table>

*by(groupvar) is required.

by is allowed with `prtest`; see [D] by.

Options for prtest

- `by(groupvar)` specifies a numeric variable that contains the group information for a given observation. This variable must have only two values. Do not confuse the `by()` option with the by prefix; both may be specified.
level(#) specifies the confidence level, as a percentage, for confidence intervals. The default is level(95) or as set by set level; see [U] 20.8 Specifying the width of confidence intervals.

cluster(varname) specifies the variable that identifies clusters. The cluster() option is required to adjust the computation for clustering.

rho(#) specifies the intraclass correlation for a one-sample test or the common intraclass correlation for a two-sample test. The rho() option is required to adjust the computation for clustering for a one-sample test.

rho1(#) specifies the intraclass correlation of the first group for a two-sample test using groups. The rho() option or both rho1() and rho2() options are required to adjust the computation for clustering.

rho2(#) specifies the intraclass correlation of the second group for a two-sample test using groups. The rho() option or both rho1() and rho2() options are required to adjust the computation for clustering.

Options for prtesti

level(#) specifies the confidence level, as a percentage, for confidence intervals. The default is level(95) or as set by set level; see [U] 20.8 Specifying the width of confidence intervals.

count specifies that integer counts instead of proportions be used in the immediate forms of prtest. In the first syntax, prtesti expects that #obs1 and #p1 are counts—#p1 ≤ #obs1—and #p2 is a proportion. In the second syntax, prtesti expects that all four numbers are integer counts, that #obs1 ≥ #p1, and that #obs2 ≥ #p2.

Remarks and examples

Remarks are presented under the following headings:

Tests of proportions
Adjust for clustering
Immediate form

Tests of proportions

The prtest output follows the output of ttest in providing a lot of information. Each proportion is presented along with a confidence interval. The appropriate one- or two-sample test is performed, and the two-sided and both one-sided results are included at the bottom of the output. For a two-sample test, the calculated difference is also presented with its confidence interval. This command may be used for both large-sample testing and large-sample interval estimation. For one-sample tests of proportions with small-sample sizes and to obtain exact p-values, researchers should use bitest; see [R] bitest.

Example 1: One-sample test of proportion

In the first form, prtest tests whether the mean of the sample is equal to a known constant. Assume that we have a sample of 74 automobiles. We wish to test whether the proportion of automobiles that are foreign is different from 40%.

. use https://www.stata-press.com/data/r16/auto
(1978 Automobile Data)
The test indicates that we cannot reject the hypothesis that the proportion of foreign automobiles is 0.40 at the 5% significance level.

Example 2: Two-sample test of proportions

We have two headache remedies that we give to patients. Each remedy’s effect is recorded as 0 for failing to relieve the headache and 1 for relieving the headache. We wish to test the equality of the proportion of people relieved by the two treatments.

We find that the proportions are statistically different from each other at any level greater than 3.9%.

Adjust for clustering

When observations are not independent and can be grouped into clusters, we need to adjust for clustering in a proportion test. For example, in a cluster randomized design, groups of individuals are randomized instead of individuals. To adjust for clustering, we need to specify the cluster identifier variable in the cluster() option. In the case of a one-sample proportion test, we need to also specify the intraclass correlation in the rho() option. In the case of a two sample proportions test, we need to also specify the common population intraclass correlation in the rho() option or group-specific population intraclass correlations in the rho1() and rho2() options.
Example 3: One-sample test of proportion, adjusting for clusters

Consider data from Hujoel, Moulton, and Loesche (1990) on the accuracy of an enzymatic diagnostic test (EDT) of bacterial infections for 29 patients with multiple sites. The EDT was conducted on each site, a specific area in a patient’s mouth, to determine infection by two strings of bacteria. A separate reference test was also conducted on each site with an antibody assay against the two strings of bacteria. The data record whether there was a positive EDT result at each infected site, a true positive result.

We want to test whether the proportion of infected sites that were correctly diagnosed by the EDT is different from 0.6. Because we have multiple infections per patient, we cluster by the patient-identifier subject and use a value of 0.2 from Ahn, Heo, and Zhang (2015, 33) for the intrapatient correlation.

To perform the test, we specify the cluster(subject) and rho(0.2) options:

```stata
use https://www.stata-press.com/data/r16/infection
(prtest infect == 0.6, cluster(subject) rho(0.2))
```

One-sample test of proportion

<table>
<thead>
<tr>
<th>Variable</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>infection</td>
<td>.6619718</td>
<td>.0537974</td>
<td>.5565308 .7674129</td>
</tr>
</tbody>
</table>

\( p = \text{proportion(infection)} \)
\( z = 1.1123 \)

Ho: \( p = 0.6 \)

Ha: \( p < 0.6 \) \( Ha: p \neq 0.6 \) \( Ha: p > 0.6 \)

\( Pr(Z < z) = 0.8670 \) \( Pr(|Z| > |z|) = 0.2660 \) \( Pr(Z > z) = 0.1330 \)

We do not find statistical evidence to reject the null hypothesis of \( H_0: P_{\text{infection}} = 0.6 \) versus the two-sided alternative \( H_a: P_{\text{infection}} \neq 0.6 \) at the 5% significance level; the \( p \)-value = 0.2660 > 0.05.

Example 4: Two-sample test of proportions using groups, adjusting for clusters

Consider a dataset provided by Hayes and Moulton (2009), which contains a random subsample of the original participants in a cluster randomized trial of a pneumococcal conjugate vaccine in American Indian populations in the southwestern United States. There are two groups of infants with 18 clusters in each group. The control group received a meningococcal C conjugate vaccine (MnCC), and the experimental group received the seven-valent pneumococcal conjugate vaccine (PnCRM7). The two groups are identified by the vaccine variable, and the pneumonia variable records 1 if an infant had at least one bacterial pneumonia episode and 0 otherwise. These data are originally from O’Brien et al. (2003).

We want to test the equality of the proportion of cases of pneumonia in the two vaccine groups. We assume a common known intraclass correlation of 0.02. To perform the test, we type
. use https://www.stata-press.com/data/r16/pneumoniacrt
(Bacterial pneumonia episodes data from CRT (Hayes and Moulton, 2009))
. prtest pneumonia, by(vaccine) cluster(cluster) rho(0.02)

Two-sample test of proportions
Cluster variable: cluster

| Group        | Mean   | Std. Err. | z    | P>|z|    | [95% Conf. Interval] |
|--------------|--------|-----------|------|--------|---------------------|
| MnCC         | 0.2226 | 0.0329    | 1.582| 0.1171 | 0.1582 - 0.2872     |
| PnCRM7       | 0.1659 | 0.0299    | 1.073| 0.2840 | 0.1073 - 0.2245     |
| diff         | 0.0568 | 0.0444    | 1.27 | 0.2044 | -0.0303 - 0.1439    |

We do not find statistical evidence to reject the null hypothesis of $H_0: \hat{p}_d = 0$ versus the two-sided alternative $H_a: \hat{p}_d \neq 0$ at the 5% significance level; the $p$-value = 0.2044 > 0.05.

Immediate form

Example 5: Immediate form of one-sample test of proportion

prtesti is like prtest, except that you specify summary statistics rather than variables as arguments. For instance, we are reading an article that reports the proportion of registered voters among 50 randomly selected eligible voters as 0.52. We wish to test whether the proportion is 0.7:

. prtesti 50 0.52 0.70

one-sample test of proportion x: Number of obs = 50

<table>
<thead>
<tr>
<th>x</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>x</td>
<td>0.52</td>
<td>0.0706</td>
<td>0.3815 - 0.6585</td>
</tr>
</tbody>
</table>

$z = -2.7775$ 
Ho: $p = 0.7$

Ha: $p < 0.7$ Ha: $p = 0.7$ Ha: $p > 0.7$

Pr(Z < z) = 0.0027 Pr(|Z| > |z|) = 0.0055 Pr(Z > z) = 0.9973
Example 6: Immediate form of two-sample test of proportions

To judge teacher effectiveness, we wish to test whether the same proportion of people from two classes will answer an advanced question correctly. In the first classroom of 30 students, 40% answered the question correctly, whereas in the second classroom of 45 students, 67% answered the question correctly.

```
. prtesti 30 0.4 45 0.67
```

Stored results

One-sample `prtest` and `prtesti` store the following in `r()`:

Scalars

- `r(N)` sample size
- `r(P)` sample proportion
- `r(se)` standard error of sample proportion
- `r(lb)` lower confidence bound of sample proportion
- `r(ub)` upper confidence bound of sample proportion
- `r(z)` z statistic
- `r(p_{-l})` lower one-sided p-value
- `r(p)` two-sided p-value
- `r(p_{-u})` upper one-sided p-value
- `r(level)` confidence level

Cluster-adjusted one-sample `prtest` also stores the following in `r()`:

Scalars

- `r(K)` number of clusters K
- `r(M)` cluster size M
- `r(rho)` intraclass correlation
- `r(CV_cluster)` coefficient of variation for cluster sizes

Two-sample `prtest` and two-sample `prtesti` store the following in `r()`:

Scalars

- `r(N1)` sample size of population one
- `r(N2)` sample size of population two
- `r(P1)` sample proportion for population one
- `r(P2)` sample proportion for population two
- `r(P_{diff})` difference of proportions
- `r(se1)` standard error of population-one sample proportion
- `r(se2)` standard error of population-two sample proportion
Cluster-adjusted two-sample *prtest* using the by() option also stores the following in *r()*:

Scalars

- `r(K1)` population-one number of clusters $K_1$
- `r(K2)` population-two number of clusters $K_2$
- `r(M1)` population-one cluster size $M_1$
- `r(M2)` population-two cluster size $M_2$
- `r(rho)` common intraclass correlation
- `r(rho1)` population-one intraclass correlation
- `r(rho2)` population-two intraclass correlation
- `r(CV_cluster1)` population-one coefficient of variation for cluster sizes
- `r(CV_cluster2)` population-two coefficient of variation for cluster sizes

### Methods and formulas

Remarks are presented under the following headings:

- **One-sample test**
- **Two-sample test**

For all the tests below, the test statistic $z$ has an asymptotic standard normal distribution, and the $p$-value is computed as

$$
p = \begin{cases} 
1 - \Phi(z) & \text{for an upper one-sided test} \\
\Phi(z) & \text{for a lower one-sided test} \\
2 \{1 - \Phi(|z|)\} & \text{for a two-sided test}
\end{cases}
$$

where $\Phi(\cdot)$ is the cdf of a standard normal distribution and $|z|$ is an absolute value of $z$.

See Acock (2018, 157–163) for additional examples of tests of proportions using Stata.

### One-sample test

Let $n$ be the number of observations, $\hat{p}$ be the observed proportion, and $\hat{q} = 1 - \hat{p}$.

The one-tailed and two-tailed tests of a population proportion use an asymptotically normally distributed test statistic calculated as

$$
z = \frac{\hat{p} - p_0}{s_0}
$$

where $p_0$ is the hypothesized proportion, $q_0 = 1 - p_0$, and $s_0 = \sqrt{p_0 q_0 / n}$ is the standard error of $\hat{p}$ under the null hypothesis of $p = p_0$. 

A large-sample 100\((1 - \alpha)\)% confidence interval for a proportion \(p\) is

\[
\hat{p} \pm z_{1-\alpha/2} s
\]

where \(s = \sqrt{\hat{p} \hat{q}/n}\) and \(z_{1-\alpha/2}\) is the \((1 - \alpha/2)\)th quantile of the standard normal distribution.

With clustered data, suppose that there are \(K\) clusters, each of size \(M_i\) such that \(n = \sum_{i=1}^{K} M_i\). Let \(\rho\) be the intraclass correlation. Following Ahn, Heo, and Zhang (2015), we assume that the cluster sizes \(M_i\) are independent and identically distributed. Let \(C_{\text{adj}}\) be the adjustment to the standard error for clustered data,

\[
C_{\text{adj}} = \sqrt{\sum_{i=1}^{K} M_i \{1 + \rho(M_i - 1)\} / n}
\]

such that \(s_{0,\text{cl}} = C_{\text{adj}} s_0\) and \(s_{\text{cl}} = C_{\text{adj}} s\).

\(C_{\text{adj}}\) can be equivalently written as

\[
C_{\text{adj}} = \sqrt{1 + \rho(M - 1) + \rho MC_{\text{cv}}^2_{\text{cl}}}
\]

where \(M = \sum_{i=1}^{K} M_i / K\) is the average cluster size and \(CV_{\text{cl}}\) is the coefficient of variation for cluster sizes:

\[
CV_{\text{cl}} = \sqrt{\frac{\sum_{i=1}^{K} (M_i - M)^2 / K}{M}}
\]

To adjust the test statistic \(z\) and the confidence interval for clustering, replace \(s_0\) with \(s_{0,\text{cl}}\) and \(s\) with \(s_{\text{cl}}\) in the corresponding formulas. In the presence of clustering, the test statistic \(z\) is asymptotically normally distributed conditional on the empirical distribution of \(M_i\)’s.

**Two-sample test**

Let \(n_1\) be the number of observations in population one and \(n_2\) be the number of observations in population two, \(\hat{p}_1\) be the observed proportion in population one and \(\hat{p}_2\) be the observed proportion in population two, and \(\hat{q}_1 = 1 - \hat{p}_1\) and \(\hat{q}_2 = 1 - \hat{p}_2\). Let \(x_1\) and \(x_2\) be the total number of successes in the two populations.

A test of the difference of two proportions uses an asymptotically normally distributed test statistic calculated as

\[
z = \frac{\hat{p}_1 - \hat{p}_2}{s_{d0}}
\]

where \(s_{d0} = \sqrt{\hat{p}_p \hat{q}_p (1/n_1 + 1/n_2)}\) is the standard error of \(\hat{p}_1 - \hat{p}_2\) under the null hypothesis of \(p_1 = p_2\), with \(\hat{p}_p = (x_1 + x_2)/(n_1 + n_2)\) and \(\hat{q}_p = 1 - \hat{p}_p\).

The 100\((1 - \alpha)\)% confidence interval for the difference of two proportions is given by

\[
(\hat{p}_1 - \hat{p}_2) \pm z_{1-\alpha/2} \sqrt{s_1^2 + s_2^2}
\]
where \( s_1 = \sqrt{\hat{p}_1 \hat{q}_1 / n_1} \) and \( s_2 = \sqrt{\hat{p}_2 \hat{q}_2 / n_2} \) are the standard errors of the two sample proportions and \( z_{1-\alpha/2} \) is the \((1 - \alpha/2)\)th quantile of the standard normal distribution.

With clustered data, suppose that there are \( K_1 \) and \( K_2 \) clusters in population one and population two with the corresponding average cluster sizes of \( \overline{M}_1 \) and \( \overline{M}_2 \). Let \( \rho_1 \) and \( \rho_2 \) be the intraclass correlations and \( CV_{cl,1} \) and \( CV_{cl,2} \) be the coefficients of variation for cluster sizes for population one and population two. Let \( C_{adj,1} \) and \( C_{adj,2} \) be the adjustments to standard errors of the two sample proportions for clustered data, defined analogously to \( C_{adj} \) in One-sample test for each population.

Let \( s_{d0,cl} = \sqrt{\hat{p} \hat{q} \left( C_{adj,1}^2 / n_1 + C_{adj,2}^2 / n_2 \right)} \) be the standard error of \( \hat{p}_1 - \hat{p}_2 \) under the null hypothesis of \( p_1 = p_2 \) adjusted for clustered data. Also, let \( s_{1,cl} = C_{adj,1}s_1 \) and \( s_{2,cl} = C_{adj,2}s_2 \) be the standard errors of \( \hat{p}_1 \) and \( \hat{p}_2 \) adjusted for clustered data. To adjust the two-sample test statistic and the confidence interval for clustering, replace \( s_{d0} \) with \( s_{d0,cl} \), \( s_1 \) with \( s_{1,cl} \), and \( s_2 \) with \( s_{2,cl} \) in the corresponding formulas.

Description

`pwcompare` performs pairwise comparisons across the levels of factor variables from the most recently fit model. `pwcompare` can compare estimated cell means, marginal means, intercepts, marginal intercepts, slopes, or marginal slopes—collectively called margins. `pwcompare` reports the comparisons as contrasts (differences) of margins along with significance tests or confidence intervals for the contrasts. The tests and confidence intervals can be adjusted for multiple comparisons.

`pwcompare` can be used with `svy` estimation results; see `[SVY] svy postestimation`.

See `[R] margins`, `pwcompare` for performing pairwise comparisons of margins of linear and nonlinear predictions.

Quick start

All pairwise comparisons of the means of y across levels of a after `regress y i.a`
   `pwcompare a`

As above, and report test statistics and p-values for tests of differences in means
   `pwcompare a, effects`

Adjust p-values and confidence intervals for multiple comparisons using Tukey’s method
   `pwcompare a, effects mcompare(tukey)`

As above, but adjust for multiple comparisons using Bonferroni’s method
   `pwcompare a, effects mcompare(bonferroni)`

Report means for the levels of a, and group those that are not significantly different
   `pwcompare a, groups`

Pairwise comparisons of cell means after `regress y1 a##b`
   `pwcompare a#b`

Pairwise comparisons of the marginal means of a
   `pwcompare a`

Pairwise comparisons of slopes for continuous x after `regress y1 a##c.x`
   `pwcompare a#c.x`

Pairwise comparisons of log odds after `logit y2 i.a`
   `pwcompare a`

Pairwise comparisons of the means of y2 across levels of a after `mvreg y1 y2 y3 = i.a`
   `pwcompare a, equation(y2)`
As above, but report pairwise comparisons of \( a \) for each equation

\texttt{pwcompare a, atequations}

Pairwise comparisons of overall margins of \( y_1, y_2, \) and \( y_3 \)

\texttt{pwcompare _eqns}

**Menu**

Statistics \( \Rightarrow \) Postestimation
Syntax

```
pwcompare marginlist [, options]
```

where `marginlist` is a list of factor variables or interactions that appear in the current estimation results or `_eqns` to reference equations. The variables may be typed with or without the `i.` prefix, and you may use any factor-variable syntax:

```
. pwcompare i.sex i.group i.sex*i.group
. pwcompare sex group sex#group
. pwcompare sex##group
```

* tukey, snk, duncan, and dunnett are only allowed with results from `anova`, `manova`, `regress`, and `mvreg`. tukey, snk, duncan, and dunnett are not allowed with results from `svy`.

Time-series operators are allowed if they were used in the estimation.

### Options

- `mcompare(method)` specifies the method for computing p-values and confidence intervals that account for multiple comparisons within a factor-variable term.

  Most methods adjust the comparisonwise error rate, \( \alpha_c \), to achieve a prespecified experimentwise error rate, \( \alpha_e \).

  - `mcompare(noadjust)` is the default; it specifies no adjustment.
    \[
    \alpha_c = \alpha_e
    \]

  - `mcompare(bonferroni)` adjusts the comparisonwise error rate based on the upper limit of the Bonferroni inequality:
    \[
    \alpha_e \leq m \alpha_c
    \]
    where \( m \) is the number of comparisons within the term.

    The adjusted comparisonwise error rate is
    \[
    \alpha_c = \frac{\alpha_e}{m}
    \]

  - `mcompare(sidak)` adjusts the comparisonwise error rate based on the upper limit of the probability inequality
    \[
    \alpha_e \leq 1 - (1 - \alpha_c)^m
    \]
    where \( m \) is the number of comparisons within the term.

    The adjusted comparisonwise error rate is
    \[
    \alpha_c = 1 - (1 - \alpha_e)^{1/m}
    \]

    This adjustment is exact when the \( m \) comparisons are independent.

  - `mcompare(scheffe)` controls the experimentwise error rate using the \( F \) (or \( \chi^2 \)) distribution with degrees of freedom equal to the rank of the term.

For results from `anova`, `regress`, `manova`, and `mvreg` (see [R] `anova`, [R] `regress`, [MV] `manova`, and [MV] `mvreg`), `pwcompare` allows the following additional methods. These methods are not allowed with results that used `vce(robust)` or `vce(cluster clustvar)`. 
mcompare(tukey) uses what is commonly referred to as Tukey’s honestly significant difference. This method uses the Studentized range distribution instead of the $t$ distribution.

mcompare(snk) is a variation on mcompare(tukey) that counts only the number of margins in the range for a given comparison instead of the full number of margins.

mcompare(duncan) is a variation on mcompare(snk) with additional adjustment to the significance probabilities.

mcompare(dunnett) uses Dunnett’s method for making comparisons with a reference category.

mcompare(method adjustall) specifies that the multiple-comparison adjustments count all comparisons across all terms rather than performing multiple comparisons term by term. This leads to more conservative adjustments when multiple variables or terms are specified in marginlist. This option is compatible only with the bonferroni and sidak methods.

asobserved specifies that factor covariates be evaluated using the cell frequencies observed when the model was fit. The default is to treat all factor covariates as though there were an equal number of observations at each level.

--- Equations ---

equation(eqspec) specifies the equation from which margins are to be computed. The default is to compute margins from the first equation.

atequations specifies that the margins be computed within each equation.

--- Advanced ---

emptycells(empspec) specifies how empty cells are handled in interactions involving factor variables that are being treated as balanced.

emptycells(strict) is the default; it specifies that margins involving empty cells be treated as not estimable.

emptycells(reweight) specifies that the effects of the observed cells be increased to accommodate any missing cells. This makes the margins estimable but changes their interpretation.

noestimcheck specifies that pwcompare not check for estimability. By default, the requested margins are checked and those found not estimable are reported as such. Nonestimability is usually caused by empty cells. If noestimcheck is specified, estimates are computed in the usual way and reported even though the resulting estimates are manipulable, which is to say they can differ across equivalent models having different parameterizations.

--- Reporting ---

level(#) specifies the confidence level, as a percentage, for confidence intervals. The default is level(95) or as set by set level; see [U] 20.8 Specifying the width of confidence intervals. The significance level used by the groups option is $100 - \#$, expressed as a percentage.

cieffects specifies that a table of the pairwise comparisons with their standard errors and confidence intervals be reported. This is the default.

pveffects specifies that a table of the pairwise comparisons with their standard errors, test statistics, and $p$-values be reported.

effects specifies that a table of the pairwise comparisons with their standard errors, test statistics, $p$-values, and confidence intervals be reported.

cimargins specifies that a table of the margins with their standard errors and confidence intervals be reported.
groups specifies that a table of the margins with their standard errors and group codes be reported. Margins with the same letter in the group code are not significantly different at the specified significance level.

sort specifies that the reported tables be sorted on the margins or differences in each term.

post causes pwcompare to behave like a Stata estimation (e-class) command. pwcompare posts the vector of estimated margins along with the estimated variance–covariance matrix to \texttt{e()}, so you can treat the estimated margins just as you would results from any other estimation command. For example, you could use \texttt{test} to perform simultaneous tests of hypotheses on the margins, or you could use \texttt{lincom} to create linear combinations.

display_options: \texttt{vsquish}, \texttt{nofvlabel}, \texttt{fvwrap(#)}, \texttt{fvwrapon(style)}, \texttt{cformat(\%fmt)}, \texttt{pformat(\%fmt)}, \texttt{sformat(\%fmt)}, and \texttt{nolstretch}.

\texttt{vsquish} specifies that the blank space separating factor-variable terms or time-series–operated variables from other variables in the model be suppressed.

\texttt{nofvlabel} displays factor-variable level values rather than attached value labels. This option overrides the \texttt{fvlabel} setting; see \texttt{[R] set showbaselevels}.

\texttt{fvwrap(#)} specifies how many lines to allow when long value labels must be wrapped. Labels requiring more than \# lines are truncated. This option overrides the \texttt{fvwrap} setting; see \texttt{[R] set showbaselevels}.

\texttt{fvwrapon(style)} specifies whether value labels that wrap will break at word boundaries or break based on available space.

\texttt{fvwrapon(word)}, the default, specifies that value labels break at word boundaries.

\texttt{fvwrapon(width)} specifies that value labels break based on available space.

This option overrides the \texttt{fvwrapon} setting; see \texttt{[R] set showbaselevels}.

\texttt{cformat(\%fmt)} specifies how to format contrasts or margins, standard errors, and confidence limits in the table of pairwise comparisons.

\texttt{pformat(\%fmt)} specifies how to format $p$-values in the table of pairwise comparisons.

\texttt{sformat(\%fmt)} specifies how to format test statistics in the table of pairwise comparisons.

\texttt{nolstretch} specifies that the width of the table of pairwise comparisons not be automatically widened to accommodate longer variable names. The default, \texttt{lstretch}, is to automatically widen the table of pairwise comparisons up to the width of the Results window. To change the default, use \texttt{set lstretch off}. \texttt{nolstretch} is not shown in the dialog box.

\texttt{eform_option} specifies that the contrasts table be displayed in exponentiated form. $e^{\text{contrast}}$ is displayed rather than contrast. Standard errors and confidence intervals are also transformed. See \texttt{[R] eform_option} for the list of available options.

The following option is available with \texttt{pwcompare} but is not shown in the dialog box:

\texttt{df(#)} specifies that the $t$ distribution with \# degrees of freedom be used for computing $p$-values and confidence intervals. The default is to use $e(\text{df}_r)$ degrees of freedom or the standard normal distribution if $e(\text{df}_r)$ is missing.

\section*{Remarks and examples}

\texttt{pwcompare} performs pairwise comparisons of margins across the levels of factor variables from the most recently fit model. The margins can be estimated cell means, marginal means, intercepts,
marginal intercepts, slopes, or marginal slopes. With the exception of slopes, we can also consider these margins to be marginal linear predictions.

The margins are calculated as linear combinations of the coefficients. Let \( k \) be the number of levels for a factor term in our model; then there are \( k \) margins for that term, and

\[
m = \binom{k}{2} = \frac{k(k - 1)}{2}
\]

unique pairwise comparisons of those margins.

The confidence intervals and \( p \)-values for these pairwise comparisons can be adjusted to account for multiple comparisons. Bonferroni’s, Šidák’s, and Scheffé’s adjustments can be made for multiple comparisons after fitting any type of model. In addition, Tukey’s, Student–Newman–Keuls’s, Duncan’s, and Dunnett’s adjustments are available when fitting ANOVA, linear regression, MANOVA, or multivariate regression models.

Remarks are presented under the following headings:

Pairwise comparisons of means
Marginal means
All pairwise comparisons
Overview of multiple-comparison methods
Fisher’s protected least-significant difference (LSD)
Bonferroni’s adjustment
Šidák’s adjustment
Scheffé’s adjustment
Tukey’s HSD adjustment
Student–Newman–Keuls’s adjustment
Duncan’s adjustment
Dunnett’s adjustment
Example adjustments using one-way models
Fisher’s protected LSD
Tukey’s HSD
Dunnett’s method for comparisons to a control
Two-way models
Pairwise comparisons of slopes
Nonlinear models
Multiple-equation models
Unbalanced data
Empty cells

Pairwise comparisons of means

Suppose we are interested in the effects of five different fertilizers on wheat yield. We could estimate the following linear regression model to determine the effect of each type of fertilizer on the yield.
. use https://www.stata-press.com/data/r16/yield
(Artificial wheat yield dataset)
. regress yield i.fertilizer

In this simple case, the coefficients for fertilizers 10-08-22, 16-04-08, 18-24-06, and 29-03-04 indicate the difference in the mean yield for that fertilizer versus the mean yield for fertilizer 10-10-10. That the standard errors of all four coefficients are identical results from having perfectly balanced data.

Marginal means

We can use `pwcompare` with the `cimargins` option to compute the mean yield for each of the fertilizers.

. pwcompare fertilizer, cimargins

Pairwise comparisons of marginal linear predictions

</tr>
</tbody>
</table>

Looking at the confidence intervals for fertilizers 10-10-10 and 10-08-22 in the table above, we might be tempted to conclude that these means are not significantly different because the intervals overlap. However, as discussed in Interaction plots of R `marginsplot`, we cannot draw conclusions about the differences in means by looking at confidence intervals for the means themselves. Instead, we would need to look at confidence intervals for the difference in means.
All pairwise comparisons

By default, \texttt{pwcompare} calculates all pairwise differences of the margins, in this case pairwise differences of the mean yields.

\begin{verbatim}
. pwcompare fertilizer
Pairwise comparisons of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>

<td>1.589997</td>
</tr>
<tr>
<td>29-03-04 vs 18-24-06</td>
<td>-6.161132</td>
<td>1.589997</td>
</tr>
</tbody>
</table>
\end{verbatim}

If a confidence interval does not include zero, the means for the compared fertilizers are significantly different. Therefore, at the 5% significance level, we would reject the hypothesis that the means for fertilizers 10-10-10 and 10-08-22 are equivalent—as we would do for 18-24-06 vs 10-10-10, 29-03-04 vs 10-08-22, 18-24-06 vs 16-04-08, and 29-03-04 vs 18-24-06.

We may prefer to see the \textit{p}-values instead of looking at confidence intervals to determine whether the pairwise differences are significantly different from zero. We could use the \texttt{pveffects} option to see the differences with standard errors and \textit{p}-values, or we could use the \texttt{effects} option to see both \textit{p}-values and confidence intervals in the same table. Here we specify \texttt{effects} as well as the \texttt{sort} option so that the differences are sorted from smallest to largest.
We find that 5 of the 10 pairs of means are significantly different at the 5% significance level.

We can use the *groups* option to obtain a table that identifies groups whose means are not significantly different by assigning them the same letter.
. pwcompare fertilizer, groups sort

</tr>
</tbody>
</table>

Note: Margins sharing a letter in the group label are not significantly different at the 5% level.

The letter A that is assigned to fertilizers 29-03-04, 10-10-10, and 16-04-08 designates that the mean yields for these fertilizers are not different at the 5% level.

**Overview of multiple-comparison methods**

For a single test, if we choose a 5% significance level, we would have a 5% chance of concluding that two margins are different when the population values are actually equal. This is known as making a type I error. When we perform \( m = \frac{k(k - 1)}{2} \) pairwise comparisons of the \( k \) margins, we have \( m \) opportunities to make a type I error.

`pwcompare` with the `mcompare()` option allows us to adjust the confidence intervals and \( p \)-values for each comparison to account for the increased probability of making a type I error when making multiple comparisons. Bonferroni’s adjustment, Šidák’s adjustment, and Scheffé’s adjustment can be used when making pairwise comparisons of the margins after any estimation command. Tukey’s honestly significant difference, Student–Newman–Keuls’s method, Duncan’s method, and Dunnett’s method are only available when fitting linear models after `anova`, `manova`, `regress`, or `mvreg`.

**Fisher’s protected least-significant difference (LSD)**

`pwcompare` does not offer an `mcompare()` option specifically for Fisher’s protected least-significant difference (LSD). In this methodology, no adjustment is made to the confidence intervals or \( p \)-values. However, it is protected in the sense that no pairwise comparisons are tested unless the joint test for the corresponding term in the model is significant. Therefore, the default `mcompare(noadjust)` corresponds to Fisher’s protected LSD assuming that the corresponding joint test was performed before using `pwcompare`.

Milliken and Johnson (2009) recommend using this methodology for planned comparisons, assuming the corresponding joint test is significant.

**Bonferroni’s adjustment**

`mcompare(bonferroni)` adjusts significance levels based on the Bonferroni inequality, which, in the case of multiple testing, tells us that the maximum error rate for all comparisons is the sum of the error rates for the individual comparisons. Assuming that we are using the same significance level for all tests, the experimentwise error rate is the error rate for a single test multiplied by the
number of comparisons. Therefore, a $p$-value for each comparison can be computed by multiplying the unadjusted $p$-value by the total number of comparisons. If the adjusted $p$-value is greater than 1, then `pwcompare` will report a $p$-value of 1.

Bonferroni’s adjustment is popular because it is easy to compute manually and because it can be applied to any set of tests, not only the pairwise comparisons available in `pwcompare`. In addition, this method does not require equal sample sizes.

Because Bonferroni’s adjustment is so general, it is more conservative than many of the other adjustments. It is especially conservative when a large number of tests is being performed.

**Šidák’s adjustment**

`mcompare(sidak)` performs an adjustment using Šidák’s method. This adjustment, like Bonferroni’s adjustment, is derived from an inequality. However, in this case, the inequality is based on the probability of not making a type I error. For a single test, the probability that we do not make a type I error is $1 - \alpha$. For two independent tests, both using $\alpha$ as a significance level, the probability is $(1 - \alpha)(1 - \alpha)$. Likewise, for $m$ independent tests, the probability of not making a type I error is $(1 - \alpha)^m$. Therefore, the probability of making one or more type I errors is $1 - (1 - \alpha)^m$. When tests are not independent, the probability of making at least one error is less than $1 - (1 - \alpha)^m$. Therefore, we can compute an adjusted $p$-value as $1 - (1 - uP)^m$, where $uP$ is the unadjusted $p$-value for a single comparison.

Šidák’s method is also conservative although slightly less so than Bonferroni’s method. Like Bonferroni’s method, this method does not require equal sample sizes.

**Scheffé’s adjustment**

Scheffé’s adjustment is used when `mcompare(scheffe)` is specified. This adjustment is derived from the joint $F$ test and its correspondence to the maximum normalized comparison. To adjust for multiple comparisons, the absolute value of the $t$ statistic for a particular comparison can be compared with a critical value of $\sqrt{(k - 1)F_{k-1,\nu}}$, where $\nu$ is the residual degrees of freedom. $F_{k-1,\nu}$ is the distribution of the joint $F$ test for the corresponding term in a one-way ANOVA model. Winer, Brown, and Michels (1991, 191–195) discuss this in detail. For estimation commands that report $z$ statistics instead of $t$ statistics for the tests on coefficients, a $\chi^2$ distribution is used instead of an $F$ distribution.

Scheffé’s method allows for making all possible comparisons of the $k$ margins, not just the pairwise comparisons. Unlike the methods described above, it does not take into account the number of comparisons that are currently being made. Therefore, this method is even more conservative than the others. Because this method adjusts for all possible comparisons of the levels of the term, Milliken and Johnson (2009) recommend using this procedure when making unplanned contrasts that are suggested by the data. As Winer, Brown, and Michels (1991, 191) put it, this method is often used to adjust for “unfettered data snooping”. When using this adjustment, a contrast will never be significant if the joint $F$ or $\chi^2$ test for the term is not also significant.

This is another method that does not require equal sample sizes.
Tukey’s HSD adjustment

Tukey’s adjustment is also referred to as Tukey’s honestly significant difference (HSD) and is used when `mcompare(tukey)` is specified. It is often applied to all pairwise comparisons of means. Tukey’s HSD is commonly used as a post hoc test although this is not a requirement.

To adjust for multiple comparisons, Tukey’s method compares the absolute value of the $t$ statistic from the individual comparison with a critical value based on a Studentized range distribution with parameter equal to the number of levels in the term. When applied to pairwise comparisons of means,

$$q = \frac{\text{mean}_{\text{max}} - \text{mean}_{\text{min}}}{s}$$

follows a Studentized range distribution with parameter $k$ and $\nu$ degrees of freedom. Here $\text{mean}_{\text{max}}$ and $\text{mean}_{\text{min}}$ are the largest and smallest marginal means, and $s$ is an estimate of the standard error of the means.

Now for the comparison of the smallest and largest means, we can say that the probability of not making a type I error is

$$\Pr\left(\frac{\text{mean}_{\text{max}} - \text{mean}_{\text{min}}}{s} \leq q_{k,\nu}\right) = 1 - \alpha$$

Then the following inequality holds for all pairs of means simultaneously:

$$\Pr\left(\frac{|\text{mean}_i - \text{mean}_j|}{s} \leq q_{k,\nu}\right) \geq 1 - \alpha$$

Based on this procedure, Tukey’s HSD computes the $p$-value for each of the individual comparisons using the Studentized range distribution. However, because the equality holds only for the difference in the largest and smallest means, this procedure produces conservative tests for the remaining comparisons. Winer, Brown, and Michels (1991, 172–182) discuss this in further detail.

With unequal sample sizes, `mcompare(tukey)` produces the Tukey–Kramer adjustment (Tukey 1953; Kramer 1956).

Student–Newman–Keuls’s adjustment

The Student–Newman–Keuls (SNK) method is used when `mcompare(snk)` is specified. It is a modification to Tukey’s method and is less conservative. In this procedure, we first order the means. We then test the difference in the smallest and largest means using a critical value from the Studentized range distribution with parameter $k$, where $k$ is the number of levels in the term. This step uses the same methodology as in Tukey’s procedure. However, in the next step, we will then test for differences in the two sets of means that are the endpoints of the two ranges including $k - 1$ means. Specifically, we test the difference in the smallest mean and the second-largest mean using a critical value from the Studentized range distribution with parameter $k - 1$. We would also test the difference in the second-smallest mean and the largest mean using this critical value. Likewise, the means that are the endpoints of ranges including $k - 2$ means when ordered are tested using the Studentized range distribution with parameter $k - 2$, and so on.

Equal sample sizes are required for this method.
Duncan’s adjustment

When \texttt{mcompare(duncan)} is specified, tests are adjusted for multiple comparisons using Duncan’s method, which is sometimes referred to as Duncan’s new multiple range method. This adjustment produces tests that are less conservative than both Tukey’s HSD and SNK. This procedure is performed in the same manner as SNK except that the \textit{p}-values for the individual comparisons are adjusted as \((1 - \text{snk}_P)^{1/(r+1)}\), where \text{snk}_P is the \textit{p}-value computed using the SNK method and \(r\) represents the number of means that, when ordered, fall between the two that are being compared.

Again equal sample sizes are required for this adjustment.

Dunnett’s adjustment

Dunnett’s adjustment is obtained by specifying \texttt{mcompare(dunnett)}. It is used when one of the levels of a factor can be considered a control or reference level with which each of the other levels is being compared. When Dunnett’s adjustment is requested, \((k - 1)\) instead of \(k(k - 1)/2\) pairwise comparisons are made. Dunnett (1955, 1964) developed tables of critical values for what Miller (1981, 76) refers to as the “many-one \textit{t} statistic”. The \textit{t} statistics for individual comparisons are compared with these critical values when making many comparisons to a single reference level.

This method also requires equal sample sizes.

Example adjustments using one-way models

Fisher’s protected LSD

Fisher’s protected LSD requires that we first verify that the joint test for a term in our model is significant before proceeding with pairwise comparisons. Using our previous example, we could have first used the \texttt{contrast} command to obtain a joint test for the effects of fertilizer.

```
. contrast fertilizer
Contrasts of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th></th>
<th>df</th>
<th>F</th>
<th>P&gt;F</th>
</tr>
</thead>
<tbody>
<tr>
<td>fertilizer</td>
<td>4</td>
<td>5.33</td>
<td>0.0004</td>
</tr>
<tr>
<td>Denominator</td>
<td>195</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
```

This test for the effects of fertilizer is highly significant. Now we can say we are using Fisher’s protected LSD when looking at the unadjusted \textit{p}-values that were obtained from our previous command,

```
. pwcompare fertilizer, effects sort
```
Tukey’s HSD

Because we fit a linear regression model and are interested in all pairwise comparisons of the marginal means, we may instead choose to use Tukey’s HSD.

```
pwcompare fertilizer, effects sort mcompare(tukey)

```

This time, our $p$-values have been modified, and we find that only four of the pairwise differences are considered significantly different from zero at the 5% level.

If we only are interested in performing pairwise comparisons of a subset of our means, we can use factor-variable operators to select the levels of the factor that we want to compare. Here we exclude all comparisons involving fertilizer 10-10-10.
. pwcompare i(2/5).fertilizer, effects sort mcompare(tukey)

The adjusted \( p \)-values and confidence intervals differ from those in the previous output because Tukey's adjustment takes into account the total number of comparisons being made when determining the appropriate degrees of freedom to use for the Studentized range distribution.

**Dunnett's method for comparisons to a control**

If one of our five fertilizer groups represents fields where no fertilizer was applied, we may want to use Dunnett’s method to compare each of the four fertilizers with the control group. In this case, we make only \( k - 1 \) comparisons for \( k \) groups.

| 29-03-04   | -1.238328 | 1.589997 | -0.78 | 0.852 | -5.152881 | 2.676225 |
| vs 10-10-10|           |        |       |          |           |          |

In our previous *regress* command, fertilizer 10-10-10 was treated as the base. Therefore, by default, it was treated as the control when using Dunnett’s adjustment, and the pairwise comparisons are equivalent to the coefficients reported by *regress*. Based on our *regress* output, we would conclude that fertilizers 10-08-22 and 18-24-06 are different from fertilizer 10-10-10 at the 5% level. However, using Dunnett’s adjustment, we find only fertilizer 18-24-06 to be different from fertilizer 10-10-10 at this same significance level.

If the model is fit without a base level for a factor variable, then *pwcompare* will choose the first level as the reference level. If we want to make comparisons with a different level than the one *mcompare(dunnett)* chooses by default, we can use the `b.` operator to override the default. Here we use fertilizer 5 (29-03-04) as the reference level.

</table>

Note: Margins sharing a letter in the group label are not significantly different at the 5% level.

Based on Tukey’s HSD and a 5% significance level, we would conclude that the mean yield for fertilizer 29-03-04 without irrigation is not significantly different from the mean yields for fertilizers 10-10-10, 10-08-22, and 16-04-08 when used without irrigation but is significantly different from the remaining means.

Up to this point, most of the pairwise comparisons that we have performed could have also been obtained with `pwmean` (see `[R] pwmean`) if we had not been interested in examining the results from the estimation command before making pairwise comparisons of the means. For instance, we could reproduce the results from the above `pwcompare` command by typing

```
pwmean yield, over(fertilizer irrigation) sort group mcompare(tukey)
```

However, `pwcompare` extends the capabilities of `pwmean` in many ways. For instance, `pwmean` only allows for pairwise comparisons of the cell means determined by the highest level interaction of the variables specified in the `over()` option. However, `pwcompare` allows us to fit a single model, such as the two-way model that we fit above,

```
regress yield fertilizer##irrigation
```
and compute pairwise comparisons of the marginal means for only one of the variables in the model:

```
. pwcompare fertilizer, sort effects mcompare(tukey)
```

Pairwise comparisons of marginal linear predictions

Here the standard errors for the differences in marginal means and the residual degrees of freedom are based on the full model. Therefore, the results will differ from those obtained from `pwcompare` after fitting the one-way model with only `fertilizer` (or equivalently using `pwmean`).

**Pairwise comparisons of slopes**

If we fit a model with a factor variable that is interacted with a continuous variable, `pwcompare` will even allow us to make pairwise comparisons of the slopes of the continuous variable for the levels of the factor variable.

In this case, we have a continuous variable, `N03_N`, indicating the amount of nitrate nitrogen already existing in the soil, based on a sample taken from each field.
These are the pairwise differences of the slopes of \( \text{NO3}_N \) for each pair of fertilizers:

Using Scheffé’s adjustment, we find that five of the pairs have significantly different slopes at the 5% level.
pwcompare — Pairwise comparisons

Nonlinear models

pwcompare can also perform pairwise comparisons of the marginal linear predictions after fitting a nonlinear model. For instance, we can use the dataset from *Beyond linear models* in [R] contrast and fit the following logistic regression model of patient satisfaction on hospital:

```stata
. use https://www.stata-press.com/data/r16/hospital
(Artificial hospital satisfaction data)
. logit satisfied i.hospital
```

```
Iteration 0: log likelihood = -393.72216
Iteration 1: log likelihood = -387.55736
Iteration 2: log likelihood = -387.47680
Iteration 3: log likelihood = -387.476789

Logistic regression Number of obs = 802
LR chi2(2) = 12.49
Prob > chi2 = 0.0019
Log likelihood = -387.476789 Pseudo R2 = 0.0159

satisfied Coef. Std. Err. z P>|z| [95% Conf. Interval]
hospital 2 .5348129 .2136021 2.50 0.012 .1161604 .9534654
3 .7354519 .2221929 3.31 0.001 .2999618 1.170942
_cons 1.034708 .1391469 7.44 0.000 .7619855 1.307431
```

For this model, the marginal linear predictions are the predicted log odds for each hospital and can be obtained with the cimargins option:

```stata
. pwcompare hospital, cimargins
```

```
P pairwise comparisons of marginal linear predictions
Margins : asbalanced

| satisfied | Coef. Std. Err. z P>|z| [95% Conf. Interval] |
|-----------|-----------------|-----------------|-----------------|-----------------|
| hospital 2| .5348129 .2136021 2.50 0.012 .1161604 .9534654 |
| 3         | .7354519 .2221929 3.31 0.001 .2999618 1.170942 |
| _cons     | 1.034708 .1391469 7.44 0.000 .7619855 1.307431 |
```

The pairwise comparisons are, therefore, differences in the log odds. We can specify mcompare(bonferroni) and effects to request Bonferroni-adjusted $p$-values and confidence intervals.

```stata
. pwcompare hospital, effects mcompare(bonferroni)
```

```
P pairwise comparisons of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th>satisfied</th>
<th>Number of</th>
</tr>
</thead>
<tbody>
<tr>
<td>hospital</td>
<td>3</td>
</tr>
</tbody>
</table>
```

For this model, the marginal linear predictions are the predicted log odds for each hospital and can be obtained with the cimargins option:
For nonlinear models, only Bonferroni’s adjustment, Šidák’s adjustment, and Scheffé’s adjustment are available.

If we want pairwise comparisons reported as odds ratios, we can specify the \texttt{or} option.

\begin{verbatim}
. pwcompare hospital, effects mcompare(bonferroni) or
Pairwise comparisons of marginal linear predictions
Margins : asbalanced

|        | Odds Ratio | Std. Err. | z       | P>|z|   | [95% Conf. Interval] |
|--------|------------|-----------|---------|-------|---------------------|
| satisfied hospital | | | | | |
| 2 vs 1 | 1.707129   | .3646464 | 2.50    | 0.037 | 1.023731 2.846733   |
| 3 vs 1 | 2.086425   | .4635888 | 3.31    | 0.003 | 1.225718 3.551525   |
| 3 vs 2 | 1.222183   | .2899226 | 0.85    | 1.000 | .6926341 2.156597   |
\end{verbatim}

Notice that these tests are still performed on the marginal linear predictions. The odds ratios reported here are the exponentiated versions of the pairwise differences of log odds in the previous output. For further discussion, see [R] \texttt{contrast}.

### Multiple-equation models

\texttt{pwcompare} works with models containing multiple equations. Commands such as \texttt{intreg} and \texttt{gnbreg} allow their ancillary parameters to be modeled as a function of independent variables, and \texttt{pwcompare} can compare the margins within these equations. The \texttt{equation()} option can be used to specify the equation for which pairwise comparisons of the margins should be made. The \texttt{ateqations} option specifies that pairwise comparisons be computed for each equation. In addition, \texttt{pwcompare} allows a special pseudofactor for equation—called \texttt{eqns}—when working with results from \texttt{manova}, \texttt{mvreg}, \texttt{mlogit}, and \texttt{mprobit}.

Here we use the jaw fracture dataset described in example 4 of [MV] \texttt{manova}. We fit a multivariate regression model including one independent factor variable, \texttt{fracture}.
```
use https://www.stata-press.com/data/r16/jaw
(Table 4.6 Two-Way Unbalanced Data for Fractures of the Jaw -- Rencher (1998))

`mvreg y1 y2 y3 = i.fracture`

| _cons    | 58.57143 | 2.259083 | 25.93 | 0.000     | 53.90891  | 63.23395  |
```
`pwcompare` performs pairwise comparisons of the margins using the coefficients from the first equation by default:

```
pwcompare fracture, mcompare(bonferroni)
Pairwise comparisons of marginal linear predictions
Margins : asbalanced
```

<table>
<thead>
<tr>
<th></th>
<th>Number of Comparisons</th>
</tr>
</thead>
<tbody>
<tr>
<td>y1 fracture</td>
<td>3</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th></th>
<th>Bonferroni</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Contrast</td>
</tr>
<tr>
<td>y1 fracture</td>
<td></td>
</tr>
<tr>
<td>two compound fractures vs one compound fracture</td>
<td>-8.833333</td>
</tr>
<tr>
<td>one simple fracture vs one compound fracture</td>
<td>6</td>
</tr>
<tr>
<td>two compound fractures vs one simple fracture</td>
<td>14.83333</td>
</tr>
</tbody>
</table>

We can use the `equation()` option to get `pwcompare` to perform comparisons in the `y2` equation:

```
pwcompare fracture, equation(y2) mcompare(bonferroni)
Pairwise comparisons of marginal linear predictions
Margins : asbalanced
```

<table>
<thead>
<tr>
<th></th>
<th>Number of Comparisons</th>
</tr>
</thead>
<tbody>
<tr>
<td>y2 fracture</td>
<td>3</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th></th>
<th>Bonferroni</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Contrast</td>
</tr>
<tr>
<td>y2 fracture</td>
<td></td>
</tr>
<tr>
<td>two compound fractures vs one compound fracture</td>
<td>-5.761905</td>
</tr>
<tr>
<td>one simple fracture vs one compound fracture</td>
<td>-3.053571</td>
</tr>
<tr>
<td>two compound fractures vs one simple fracture</td>
<td>2.708333</td>
</tr>
</tbody>
</table>
Because we are working with \texttt{mvreg} results, we can use the \_eqns pseudofactor to compare the margins between the three dependent variables. The levels of \_eqns index the equations: 1 for the first equation, 2 for the second, and 3 for the third.

\begin{verbatim}
. pwcompare \_eqns, mcompare(bonferroni)
Pairwise comparisons of marginal linear predictions
Margins : asbalanced

<table>
<thead>
<tr>
<th></th>
<th>Number of Comparisons</th>
</tr>
</thead>
<tbody>
<tr>
<td>_eqns</td>
<td>3</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th></th>
<th>Contrast</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>_eqns</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>2 vs 1</td>
<td>-.5654762</td>
<td>2.545923</td>

</tr>
<tr>
<td>3 vs 1</td>
<td>24.24603</td>
<td>2.320677</td>
<td>18.27344 30.21862</td>
</tr>
<tr>
<td>3 vs 2</td>
<td>24.81151</td>
<td>2.368188</td>
<td>18.71664 30.90637</td>
</tr>
</tbody>
</table>
\end{verbatim}

For the previous command, the only methods available are \texttt{mcompare(bonferroni)}, \texttt{mcompare(sidak)}, or \texttt{mcompare(scheffe)}. Methods that use the Studentized range are not appropriate for making comparisons across equations.

**Unbalanced data**

\texttt{pwcompare} treats all factors as balanced when it computes the marginal means. By “balanced”, we mean that the number of observations in each combination of factor levels (in each cell mean) is equal. We can alternatively specify the \texttt{asobserved} option when we have unbalanced data to obtain marginal means that are based on the observed cell frequencies from the model fit. For more details on the difference in these two types of marginal means and a discussion of when each may be appropriate, see \texttt{[R] margins} and \texttt{[R] contrast}.

In addition, when our data are not balanced, some of the multiple-comparison adjustments are no longer appropriate. Student–Newman–Keuls’s method, Duncan’s method, and Dunnett’s method assume equal numbers of observations per group.

Here we use an unbalanced dataset and fit a two-way ANOVA model for cholesterol levels on race and age group. Then we perform pairwise comparisons of the mean cholesterol levels for each race, requesting Šidák’s adjustment as well as marginal means that are computed using the observed cell frequencies.

Empty cells

An empty cell is a combination of the levels of factor variables that is not observed in the estimation sample. When we have empty cells in our data, the marginal means involving those empty cells are not estimable as described in [R] margins. In addition, all pairwise comparisons involving a marginal mean that is not estimable are themselves not estimable. Here we use a dataset where we do not have any observations for white individuals in the 20–29 age group. We can use the emptycells(reweight) option to reweight the nonempty cells so that we can estimate the marginal mean for whites and compute pairwise comparisons involving that marginal mean.

Stored results

`pwcompare` stores the following in `r()`:

Scalars
- `r(df_r)`: variance degrees of freedom
- `r(k_terms)`: number of terms in `marginlist`
- `r(level)`: confidence level of confidence intervals
- `r(balanced)`: 1 if fully balanced data, 0 otherwise

Macros
- `r(cmd)`
- `r(cmdline)`
- `r(est_cmd)`
- `r(est_cmdline)`
- `r(title)`
- `r(emptycells)`
- `r(groups#)`
- `r(mcmethod_vs)`
- `r(mctitle_vs)`
- `r(margin_method)`
- `r(vce)`

Matrices
- `r(b)`
- `r(V)`

- \( e(error\_vs) \) margin difference estimability codes;
  - 0 means estimable,
  - 8 means not estimable
- \( e(L) \) matrix that produces the margin differences from the model coefficients

Methods and formulas

Methods and formulas are presented under the following headings:

- Notation
- Unadjusted comparisons
- Bonferroni’s method
- Šidák’s method
- Scheffé’s method
- Tukey’s method
- Student–Newman–Keuls’s method
- Duncan’s method
- Dunnett’s method

Notation

`pwcompare` performs comparisons of margins; see _Methods and formulas_ in [R] _contrast_.

If there are \( k \) margins for a given factor term, then there are

\[
m = \binom{k}{2} = \frac{k(k - 1)}{2}
\]

unique pairwise comparisons. Let the \( i \)th pairwise comparison be denoted by
\[ \hat{\delta}_i = l'_i b \]

where \( b \) is a column vector of coefficients from the fitted model and \( l_i \) is a column vector that forms the corresponding linear combination. If \( \hat{V} \) denotes the estimated variance matrix for \( b \), then the standard error for \( \hat{\delta}_i \) is given by

\[ \hat{se}(\hat{\delta}_i) = \sqrt{l'_i \hat{V} l_i} \]

The corresponding test statistic is then

\[ t_i = \frac{\hat{\delta}_i}{\hat{se}(\hat{\delta}_i)} \]

and the limits for a \( 100(1 - \alpha)\% \) confidence interval for the expected value of \( \hat{\delta}_i \) are

\[ \hat{\delta}_i \pm c_i(\alpha) \hat{se}(\hat{\delta}_i) \]

where \( c_i(\alpha) \) is the critical value corresponding to the chosen multiple-comparison method.

**Unadjusted comparisons**

`pwcompare` computes unadjusted \( p \)-values and confidence intervals by default. `pwcompare` uses the \( t \) distribution with \( \nu = e(df_r) \) degrees of freedom when \( e(df_r) \) is posted by the estimation command. The unadjusted two-sided \( p \)-value is

\[ u_{p_i} = 2 \Pr(t_\nu > |t_i|) \]

and the unadjusted critical value \( u_{c_i}(\alpha) \) satisfies the following probability statement:

\[ \alpha = 2 \Pr \{t_\nu > u_{c_i}(\alpha)\} \]

`pwcompare` uses the standard normal distribution when \( e(df_r) \) is not posted.

**Bonferroni’s method**

For `mcompare(bonferroni)`, the adjusted \( p \)-value is

\[ b_{p_i} = \min(1, m_{u_{p_i}}) \]

and the adjusted critical value is

\[ b_{c_i}(\alpha) = u_{c_i}(\alpha/m) \]
Šidák’s method

For \texttt{mcompare(sidak)}, the adjusted \( p \)-value is

\[
sp_i = 1 - (1 - up_i)^m
\]

and the adjusted critical value is

\[
sic_i(\alpha) = uc_i\left\{1 - (1 - \alpha)^{1/m}\right\}
\]

Scheffé’s method

For \texttt{mcompare(scheffe)}, the adjusted \( p \)-value is

\[
scp_i = \Pr\left(F_{d,\nu} > t_i^2/d\right)
\]

where \( F_{d,\nu} \) is distributed as an \( F \) with \( d \) numerator and \( \nu \) denominator degrees of freedom and \( d \) is the rank of the VCE for the term. The adjusted critical value satisfies the following probability statement:

\[
\alpha = \Pr\left[F_{d,\nu} > \{sc_i(\alpha)\}^2/d\right]
\]

\texttt{pwcompare} uses the \( \chi^2 \) distribution when \texttt{e(df_r)} is not posted.

Tukey’s method

For \texttt{mcompare(tukey)}, the adjusted \( p \)-value is

\[
tp_i = \Pr\left(q_{k,\nu} > |t_i|\sqrt{2}\right)
\]

where \( q_{k,\nu} \) is distributed as the Studentized range statistic for \( k \) means and \( \nu \) residual degrees of freedom (Miller 1981). The adjusted critical value satisfies the following probability statement:

\[
\alpha = \Pr\left\{q_{k,\nu} > tc_i(\alpha)\sqrt{2}\right\}
\]

Student–Newman–Keuls’s method

For \texttt{mcompare(snk)}, suppose \( t_i \) is comparing two margins that have \( r \) other margins between them. Then the adjusted \( p \)-value is

\[
snp_i = \Pr\left(q_{r+2,\nu} > |t_i|\sqrt{2}\right)
\]

where \( r \) ranges from 0 to \( k - 2 \). The adjusted critical value \( snk_c_i(\alpha) \) satisfies the following probability statement:

\[
\alpha = \Pr\left\{q_{r+2,\nu} > snk_c_i(\alpha)\sqrt{2}\right\}
\]
Duncan’s method

For mcompare(duncan), the adjusted $p$-value is

$$duncp_i = 1 - (1 - snkp_i)^{1/(r+1)}$$

and the adjusted critical value is

$$dunc_c_i(\alpha) = snkc_i \{1 - (1 - \alpha)^{r+1}\}$$

Dunnett’s method

For mcompare(dunnett), the margins are compared with a reference category, resulting in only $k - 1$ pairwise comparisons. The adjusted $p$-value is

$$dunn_p_i = \Pr(d_{k-1,\nu} > |t_i|)$$

where $d_{k-1,\nu}$ is distributed as the many-one $t$ statistic (Miller 1981, 76). The adjusted critical value $dunn_c_i(\alpha)$ satisfies the following probability statement:

$$\alpha = \Pr\{d_{k-1,\nu} > dunn_c_i(\alpha)\}$$

The multiple-comparison methods for mcompare(tukey), mcompare(snk), mcompare(duncan), and mcompare(dunnett) assume the normal distribution with equal variance; thus these methods are allowed only with results from anova, regress, manova, and mvreg. mcompare(snk), mcompare(duncan), and mcompare(dunnett) assume equal sample size for each marginal mean. These options will cause pwcompare to report a footnote if unbalanced factors are detected.

[U] 20 Estimation and postestimation commands
Postestimation commands

The following postestimation commands are available after `pwcompare, post`:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>estat vce</code></td>
<td>variance–covariance matrix of the estimators (VCE)</td>
</tr>
<tr>
<td><code>estat (svy)</code></td>
<td>postestimation statistics for survey data</td>
</tr>
<tr>
<td><code>estimates</code></td>
<td>cataloging estimation results</td>
</tr>
<tr>
<td><code>lincom</code></td>
<td>point estimates, standard errors, testing, and inference for linear combinations of coefficients</td>
</tr>
<tr>
<td><code>nlcom</code></td>
<td>point estimates, standard errors, testing, and inference for nonlinear combinations of coefficients</td>
</tr>
<tr>
<td><code>test</code></td>
<td>Wald tests of simple and composite linear hypotheses</td>
</tr>
<tr>
<td><code>testnl</code></td>
<td>Wald tests of nonlinear hypotheses</td>
</tr>
</tbody>
</table>

Remarks and examples

When we use the `post` option with `pwcompare`, the marginal linear predictions are posted as estimation results, and we can use postestimation commands to perform further analysis on them.

In *Pairwise comparisons of means* of [R] `pwcompare`, we fit a regression of wheat yield on types of fertilizers.

```
. use https://www.stata-press.com/data/r16/yield
(Artificial wheat yield dataset)
. regress yield i.fertilizer
(output omitted)
```

We also used `pwcompare` with the `cimargins` option to obtain the marginal mean yield for each fertilizer. We can add the `post` option to this command to post these marginal means and their VCEs as estimation results.
. pwcompare fertilizer, cimargins post

Pairwise comparisons of marginal linear predictions

Margins : asbalanced

<table>
<thead>
<tr>
<th>fertilizer</th>
<th>Margin</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>10-10-10</td>

<td>1.124298</td>
<td>44.06789 48.50258</td>
</tr>
<tr>
<td>29-03-04</td>
<td>40.1241</td>
<td>1.124298</td>
<td>37.90676 42.34145</td>
</tr>
</tbody>
</table>

Now we can use nlcom to compute a percentage improvement in the mean yield for fertilizer 2 when compared with fertilizer 1.

. nlcom (pct_chg: 100*(_b[2.fertilizer] - _b[1.fertilizer])/_b[1.fertilizer])

| Coef.       | Std. Err. | z   | P>|z| | [95% Conf. Interval] |
|-------------|-----------|-----|------|----------------------|
| pct_chg     | 8.758479  | 4.015932 | 2.18 | 0.029 | 0.8873982 16.62956 |

The mean yield for fertilizer 2 is about 9% higher than that of fertilizer 1, with a standard error of 4%.

Also see

[R] pwcompare — Pairwise comparisons

[U] 20 Estimation and postestimation commands
**Description**

`pwmean` performs pairwise comparisons of means. It computes all pairwise differences of the means of `varname` over the combination of the levels of the variables in `varlist`. The tests and confidence intervals for the pairwise comparisons assume equal variances across groups. `pwmean` also allows for adjusting the confidence intervals and `p`-values to account for multiple comparisons using Bonferroni’s method, Scheffé’s method, Tukey’s method, Dunnett’s method, and others.

See [R] `pwcompare` for performing pairwise comparisons of means, estimated marginal means, and other types of marginal linear predictions after `anova`, `regress`, and most other estimation commands.

**Quick start**

All pairwise differences in the means of `y` over levels of categorical variable `catvar`
```
pwmean y, over(catvar)
```

As above, and report test statistics and `p`-values for tests that differences equal zero
```
pwmean y, over(catvar) effects
```

Adjust `p`-values and confidence intervals for multiple comparisons using Tukey’s method
```
pwmean y, over(catvar) effects mcompare(tukey)
```

As above, but adjust for multiple comparisons using Bonferroni’s method
```
pwmean y, over(catvar) effects mcompare(bonferroni)
```

Report mean of `y` for each level of `catvar`, grouping means that are not significantly different
```
pwmean y, over(catvar) groups
```

**Menu**

Statistics > Summaries, tables, and tests > Summary and descriptive statistics > Pairwise comparisons of means
Syntax

```
pwmean varname, over(varlist) [options]
```

Options

over(varlist) is required and specifies that means are computed for each combination of the levels of the variables in varlist.

mcompare(method) specifies the method for computing \( p \)-values and confidence intervals that account for multiple comparisons.

Most methods adjust the comparisonwise error rate, \( \alpha_c \), to achieve a prespecified experimentwise error rate, \( \alpha_e \).

mcompare(noadjust) is the default; it specifies no adjustment.

\[
\alpha_c = \alpha_e
\]
**mcompare(bonferroni)** adjusts the comparisonwise error rate based on the upper limit of the Bonferroni inequality:

\[ \alpha_e \leq m \alpha_c \]

where \( m \) is the number of comparisons within the term.

The adjusted comparisonwise error rate is

\[ \alpha_c = \frac{\alpha_e}{m} \]

**mcompare(sidak)** adjusts the comparisonwise error rate based on the upper limit of the probability inequality

\[ \alpha_e \leq 1 - (1 - \alpha_c)^m \]

where \( m \) is the number of comparisons within the term.

The adjusted comparisonwise error rate is

\[ \alpha_c = 1 - (1 - \alpha_e)^{1/m} \]

This adjustment is exact when the \( m \) comparisons are independent.

**mcompare(scheffe)** controls the experimentwise error rate using the \( F \) (or \( \chi^2 \)) distribution with degrees of freedom equal to \( k - 1 \) where \( k \) is the number of means being compared.

**mcompare(tukey)** uses what is commonly referred to as Tukey’s honestly significant difference.

This method uses the Studentized range distribution instead of the \( t \) distribution.

**mcompare(snk)** is a variation on **mcompare(tukey)** that counts only the number of means participating in the range for a given comparison instead of the full number of means.

**mcompare(duncan)** is a variation on **mcompare(snk)** with additional adjustment to the significance probabilities.

**mcompare(dunnett)** uses Dunnett’s method for making comparisons with a reference category.

---

**Reporting**

level(#) specifies the confidence level, as a percentage, for confidence intervals. The default is level(95) or as set by set level; see [U] 20.8 Specifying the width of confidence intervals. The significance level used by the **groups** option is \( 100 - # \), expressed as a percentage.

cieffects specifies that a table of the pairwise comparisons of means with their standard errors and confidence intervals be reported. This is the default.

pveffects specifies that a table of the pairwise comparisons of means with their standard errors, test statistics, and \( p \)-values be reported.

effects specifies that a table of the pairwise comparisons of means with their standard errors, test statistics, \( p \)-values, and confidence intervals be reported.

cimeans specifies that a table of the means with their standard errors and confidence intervals be reported.

groups specifies that a table of the means with their standard errors and group codes be reported. Means with the same letter in the group code are not significantly different at the specified significance level.

sort specifies that the reported tables be sorted by the mean or difference that is displayed in the table.

display options: nofvlbl, fvwrap(#), fvwrapon(style), cformat(\%,fmt), pformat(\%,fmt), sformat(\%,fmt), and nolstretch.
nofvlabel displays factor-variable level values rather than attached value labels. This option overrides the fvlabel setting; see [R] set showbaselevels.

fvwrap(#) specifies how many lines to allow when long value labels must be wrapped. Labels requiring more than # lines are truncated. This option overrides the fvwrap setting; see [R] set showbaselevels.

displays factor-variable level values rather than attached value labels. This option overrides the fvlabel setting; see [R] set showbaselevels.

fvwrapon(style) specifies whether value labels that wrap will break at word boundaries or break based on available space.

fvwrapon(word), the default, specifies that value labels break at word boundaries. fvwrapon(width) specifies that value labels break based on available space.

This option overrides the fvwrapon setting; see [R] set showbaselevels.

cformat(%,fmt) specifies how to format means, standard errors, and confidence limits in the table of pairwise comparison of means.

pformat(%,fmt) specifies how to format p-values in the table of pairwise comparison of means.

sformat(%,fmt) specifies how to format test statistics in the table of pairwise comparison of means.

nolstretch specifies that the width of the table of pairwise comparisons not be automatically widened to accommodate longer variable names. The default, lstretch, is to automatically widen the table of pairwise comparisons up to the width of the Results window. To change the default, use set lstretch off. nolstretch is not shown in the dialog box.

Remarks and examples

pwmean performs pairwise comparisons (differences) of means, assuming a common variance among groups. It can easily adjust the p-values and confidence intervals for the differences to account for the elevated type I error rate due to multiple comparisons. Adjustments for multiple comparisons can be made using Bonferroni’s method, Scheffé’s method, Tukey’s method, Dunnett’s method, and others.

See [R] margins, pwcompare for performing pairwise comparisons of marginal probabilities and other linear and nonlinear predictions after estimation commands.

Remarks are presented under the following headings:

Group means
Pairwise differences of means
Group output
Adjusting for multiple comparisons
Tukey’s method
Dunnett’s method
Multiple over() variables
Equal variance assumption

Group means

Suppose we have data on the wheat yield of fields that were each randomly assigned an application of one of five types of fertilizers. Let’s first look at the mean yield for each type of fertilizer.
. use https://www.stata-press.com/data/r16/yield
(Artificial wheat yield dataset)

The contrast in the row labeled (10-08-22 vs 10-10-10) is the difference in the mean wheat yield for fertilizer 10-08-22 and fertilizer 10-10-10. At a 5% significance level, we conclude that there is a difference in the means for these two fertilizers. Likewise, the rows labeled (18-24-06 vs 10-10-10), (29-03-04 vs 10-08-22), (18-24-06 vs 16-04-08) and (29-03-04 vs 18-24-06) show differences in these pairs of means. In all, we find that 5 of the 10 mean differences are significantly different from zero at a 5% significance level.

We can specify the sort option to order the differences from smallest to largest in the table.

```
    . pwmean yield, over(fertilizer) effects sort
```

```

```

Ordering the pairwise differences is particularly convenient when we are comparing means for a large number of groups.

**Group output**

We can use the group option to see the mean of each group and a visual representation of the tests for differences.
. pwmean yield, over(fertilizer) group sort
Pairwise comparisons of means with equal variances
over : fertilizer

<table>
<thead>

</tbody>
</table>

Note: Means sharing a letter in the group label are not significantly different at the 5% level.

Fertilizers 29-03-04, 10-10-10, and 16-04-08 are all in group A. This means that at our 5% level of significance, we have insufficient information to distinguish their means. Likewise, fertilizers 16-04-08 and 10-08-22 are in group B and cannot be distinguished at the 5% level. The same is true for fertilizers 10-08-22 and 18-24-06 in group C.

Fertilizer 29-03-04 and fertilizer 10-08-22 have no letters in common, indicating that the mean yields of these two groups are significantly different at the 5% level. We can conclude that any other fertilizers without a letter in common have significantly different means as well.

**Adjusting for multiple comparisons**

The statistics in the examples above take no account that we are performing 10 comparisons. With our 5% significance level and assuming the comparisons are independent, we expect 1 in 20 tests of comparisons to be significant, even if all the population means are truly the same. If we are performing many comparisons, then we should account for the fact that some tests will be found significant by chance alone. More formally, the test for each pairwise comparison is made without adjusting for the elevated type I experimentwise error rate that is introduced when performing multiple tests. We can use the mcompare() option to adjust the confidence intervals and p-values for multiple comparisons.

**Tukey’s method**

Of the available adjustments for multiple comparisons, Tukey’s honestly significant difference, Student–Newman–Keuls’s method, and Duncan’s method are most often used when performing all pairwise comparisons of means. Of these, Tukey’s method is the most conservative and Duncan’s method is the least conservative. For further discussion of each of the multiple-comparison adjustments, see [R] pwcompare.

Here we use Tukey’s adjustment to compute p-values and confidence intervals for the pairwise differences.
. `pwmean yield, over(fertilizer) effects sort mcompare(tukey)`

Pairwise comparisons of means with equal variances

| 10-08-22 10-08-22 vs 10-10-10 18-24-06 | 1.300083  | 1.589997  | 0.82  | 0.925 | -3.077928 5.678095  |
| 10-10-10 18-24-06 vs 18-24-06    | 3.62272   | 1.589997  | 2.28  | 0.156 | -.7552913 8.000731  |
| 16-04-08 18-24-06 vs 18-24-06    | 4.432173  | 1.589997  | 2.79  | 0.046 | .0541623 8.810185   |
| 10-10-10                                        | 4.922803  | 1.589997  | 3.10  | 0.019 | .5447922 9.300815   |

When using a 5% significance level, Tukey’s adjustment indicates that four pairs of means are different. With the adjustment, we no longer conclude that the difference in the mean yields for fertilizers 10-08-22 and 10-10-10 is significantly different from zero.
Dunnett’s method

Now let’s suppose that fertilizer 10-10-10 actually represents fields on which no fertilizer was applied. In this case, we can use Dunnett’s method for comparing each of the fertilizers to the control.

```
. pwmean yield, over(fertilizer) effects mcompare(dunnett)
Pairwise comparisons of means with equal variances
over : fertilizer

<table>
<thead>
<tr>
<th>Number of Comparisons</th>
</tr>
</thead>
<tbody>
<tr>
<td>fertilizer</td>
</tr>
<tr>
<td>4</td>
</tr>
</tbody>
</table>
```

| yield | Contrast | Std. Err. | Dunnett t | P>|t| | Dunnett [95% Conf. Interval] |
|-------|----------|-----------|-----------|-----|-----------------------------|
| fertilizer 10-08-22 vs 10-10-10 | 3.62272 | 1.589997 | 2.28 | 0.079 | -0.2918331 7.537273 |
| 10-10-10 vs 18-24-06 | 0.4906299 | 1.589997 | 0.31 | 0.994 | -3.423923 4.405183 |
| 10-10-10 vs 29-03-04 | 4.922803 | 1.589997 | 3.10 | 0.008 | 1.00825 8.837356 |
| 10-10-10 vs 10-10-10 | -1.238328 | 1.589997 | -0.78 | 0.852 | -5.152881 2.676225 |

Using Dunnett’s adjustment, we conclude that only fertilizer 4 (18-24-06) produces a mean yield that is significantly different from the mean yield of the field with no fertilizer applied.

By default, `pwmean` treats the lowest level of the group variable as the control. If, for instance, fertilizer 3 (16-04-08) was our control group, we could type

```
. pwmean yield, over(b3.fertilizer) effects mcompare(dunnett)
```

using the `b3.` factor-variable operator to specify this level as the reference level.
Multiple over() variables

When we specify more than one variable in the `over()` option, pairwise comparisons are performed for the means defined by each combination of levels of these variables.

```
. pwmean yield, over(fertilizer irrigation) group
```

Pairwise comparisons of means with equal variances

```
over       : fertilizer irrigation
```

<table>
<thead>
<tr>
<th>fertilizer#irrigation</th>
<th>yield</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>Unadjusted Groups</th>
</tr>
</thead>
<tbody>
<tr>
<td>10-10-10#0</td>

<td>44.55</td>
<td>1.12</td>
<td>B D</td>
<td></td>
</tr>
</tbody>
</table>

Note: Means sharing a letter in the group label are not significantly different at the 5% level.

Here the row labeled 10-10-10#0 is the mean for the fields treated with fertilizer 10-10-10 and without irrigation. This mean is significantly different from the mean of all fertilizer/irrigation pairings that do not have an A in the “Unadjusted Groups” column. These include all pairings where the fields were irrigated as well as the fields treated with fertilizer 18-24-06 but without irrigation.

Equal variance assumption

`pwmean` performs multiple comparisons assuming that there is a common variance for all groups. In the case of two groups, this is equivalent to performing the familiar two-sample $t$ test when equal variances are assumed.
. ttest yield, by(irrigation)

Two-sample t test with equal variances

. pwmean yield, over(irrigation) effects

Pairwise comparisons of means with equal variances
over : irrigation

| yield | Contrast | Std. Err. | t   | P>|t| | [95% Conf. Interval] |
|-------|----------|-----------|-----|-----|----------------------|
| irrigation | 1 vs 0 | 10.01844 | .7732872 | 12.96 | 0.000 | 8.493509 | 11.54338 |

The signs for the difference, the test statistic, and the confidence intervals are reversed because the difference is taken in the opposite direction. The \( p \)-value from \texttt{pwmean} is equivalent to the one for the two-sided test in the \texttt{ttest} output.

\texttt{pwmean} extends the capabilities of \texttt{ttest} to allow for simultaneously comparing all pairs of means and to allow for using one common variance estimate for all the tests instead of computing a separate pooled variance for each pair of means when using multiple \texttt{ttest} commands. In addition, \texttt{pwmean} allows adjustments for multiple comparisons, many of which rely on an assumption of equal variances among groups.
Stored results

\texttt{pwmean} stores the following in \texttt{e()}: 

Scalars
\begin{itemize}
  \item \texttt{e(df_r)} variance degrees of freedom
  \item \texttt{e(balanced)} 1 if fully balanced data, 0 otherwise
\end{itemize}

Macros
\begin{itemize}
  \item \texttt{e(cmd)} \texttt{pwmean}
  \item \texttt{e(cmdline)} command as typed
  \item \texttt{e(title)} title in output
  \item \texttt{e(depvar)} name of variable from which the means are computed
  \item \texttt{e(over)} \texttt{varlist} from \texttt{over()}
  \item \texttt{e(properties)} \texttt{b V}
\end{itemize}

Matrices
\begin{itemize}
  \item \texttt{e(b)} mean estimates
  \item \texttt{e(V)} variance–covariance matrix of the mean estimates
  \item \texttt{e(error)} mean estimability codes;
    \begin{itemize}
      \item 0 means estimable,
      \item 8 means not estimable
    \end{itemize}
  \item \texttt{e(b_vs)} mean difference estimates
  \item \texttt{e(V_vs)} variance–covariance matrix of the mean difference estimates
  \item \texttt{e(error_vs)} mean difference estimability codes;
    \begin{itemize}
      \item 0 means estimable,
      \item 8 means not estimable
    \end{itemize}
\end{itemize}

Methods and formulas

\texttt{pwmean} is a convenience command that uses \texttt{pwcompare} after fitting a fully factorial linear model. See Methods and formulas described in [R] \texttt{pwcompare}.

</tbody>
</table>
```

After `pwmean`, we can use `testnl` to test whether the improvement in mean wheat yield when using fertilizer 18-24-06 instead of fertilizer 29-03-04 is significantly different from 10%.
. testnl (_b[4.fertilizer] - _b[5.fertilizer])/_b[5.fertilizer] = 0.1
(1) (_b[4.fertilizer] - _b[5.fertilizer])/_b[5.fertilizer] = 0.1
    chi2(1) = 1.57
    Prob > chi2 = 0.2106

The improvement is not significantly different from 10%.

[R] pmean — Pairwise comparisons of means

[U] 20 Estimation and postestimation commands
Description

These commands provide standard quality-control charts. `cchart` draws a c chart; `pchart`, a p (fraction-defective) chart; `rchart`, an R (range or dispersion) chart; `xchart`, an $\bar{X}$ (control line) chart; and `shewhart`, vertically aligned $\bar{X}$ and R charts.

Quick start

c chart for `dvar` defects per unit identified by `uvar`
   `cchart dvar uvar`
   
p chart for `dvar` defective items out of `nvar` items inspected from each unit identified by `uvar`
   `pchart dvar uvar nvar`
   
As above, but stabilize the p chart for unequal numbers of items inspected per unit
   `pchart dvar uvar nvar, stabilized`
   
R chart for the range of measurements `m1`, `m2`, `m3`, and `m4`
   `rchart m1 m2 m3 m4, connect(1)`
   
As above, but use known process standard deviation of 0.5 for control limits
   `rchart m1 m2 m3 m4, connect(1) std(.5)`
   
$\bar{X}$ chart for measurements `m1`, `m2`, `m3`, and `m4`
   `xchart m1 m2 m3 m4, connect(1)`
   
As above, but use known process standard deviation of 0.5 and grand mean of 10 for control limits
   `xchart m1 m2 m3 m4, connect(1) std(.5) mean(10)`
   
Shewhart chart with vertically aligned R and $\bar{X}$ charts
   `shewhart m1 m2 m3 m4, connect(1) std(.5) mean(10)`

### Options

- stabilized stabilizes the p chart when sample sizes are unequal.
- std(#) specifies the standard deviation of the process. The R chart is calculated (based on the range) if this option is not specified.
- mean(#) specifies the grand mean, which is calculated if not specified.
lower(#) and upper(#) must be specified together or not at all. They specify the lower and upper limits of the $\bar{X}$ chart. Calculations based on the mean and standard deviation (whether specified by option or calculated) are used otherwise.

nograph suppresses the graph.

generate(newvar f newvar lcl newvar ucl) stores the plotted values in the p chart. newvar f will contain the fractions of defective elements; newvar lcl and newvar ucl will contain the lower and upper control limits, respectively.

connect_options affect whether lines connect the plotted points and the rendition of those lines; see [G-3] connect_options.

marker_options affect the rendition of markers drawn at the plotted points, including their shape, size, color, and outline; see [G-3] marker_options.

marker_label_options specify if and how the markers are to be labeled; see [G-3] marker_label_options.

clopts(cline_options) affects the rendition of the control limits; see [G-3] cline_options.

addplot(plot) provides a way to add other plots to the generated graph. See [G-3] addplot_option.

twoway_options are any of the options documented in [G-3] twoway_options, excluding by(). These include options for titling the graph (see [G-3] title_options) and for saving the graph to disk (see [G-3] saving_option).

combine_options (shewhart only) are any of the options documented in [G-2] graph combine. These include options for titling the graph (see [G-3] title_options) and for saving the graph to disk (see [G-3] saving_option).

Remarks and examples

Control charts may be used to define the goal of a repetitive process, to control that process, and to determine if the goal has been achieved. Walter A. Shewhart of Bell Telephone Laboratories devised the first control chart in 1924. In 1931, Shewhart published Economic Control of Quality of Manufactured Product. According to Burr, “Few fields of knowledge have ever been so completely explored and charted in the first exposition” (1976, 29). Shewhart states that “a phenomenon will be said to be controlled when, through the use of past experience, we can predict, at least within limits, how the phenomenon may be expected to vary in the future. Here it is understood that prediction within limits means that we can state, at least approximately, the probability that the observed phenomenon will fall within given limits” (1931, 6).

For more information on quality-control charts, see Burr (1976), Duncan (1986), Harris (1999), or Ryan (2011).
Example 1: cchart

cchart graphs a c chart showing the number of nonconformities in a unit, where `defect_var` records the number of defects in each inspection unit and `unit_var` records the unit number. The unit numbers need not be in order. For instance, consider the following example dataset from Ryan (2011, 186):

```stata
use https://www.stata-press.com/data/r16/ncu
describe
Contains data from https://www.stata-press.com/data/r16/ncu.dta
obs: 30
vars: 2 2 Dec 2018 15:15

<table>

<td>3</td>
</tr>
<tr>
<td>4.</td>
<td>4</td>
</tr>
<tr>
<td>5.</td>
<td>5</td>
</tr>
</tbody>
</table>
```

```stata
cchart defects day, title(c Chart for Nonconforming Transistors)
```

The expected number of defects is 10.6, with lower and upper control limits of 0.8327 and 20.37, respectively. No units are out of control.
Example 2: pchart

*pchart* graphs a p chart, which shows the fraction of nonconforming items in a subgroup, where *reject_var* records the number rejected in each inspection unit, *unit_var* records the inspection unit number, and *ssize_var* records the number inspected in each unit.

Consider the example dataset from *Ryan* (2011, 186) of the number of nonconforming transistors out of 1,000 inspected each day during the month of April:

```
. use https://www.stata-press.com/data/r16/ncu2
. describe
Contains data from https://www.stata-press.com/data/r16/ncu2.dta
    obs: 30                          2 Dec 2018 15:16
    vars: 3
  variable name   type     format value
      storage          display label          variable label
       day          byte   %9.0g      Day in April
      rejects        byte   %9.0g       Number of nonconforming units
        ssize        int    %9.0g       Sample size
```

Sorted by:
```
. list in 1/5
    +-----------------+-----------------+----------+
    | day | rejects | ssize |
    +-----------------+-----------------+----------+
    |  1.  |   7     | 1000   |
    |  2.  |   5     | 1000   |
    |  3.  |  11     | 1000   |
    |  4.  |  13     | 1000   |
    |  5.  |   9     | 1000   |
    +-----------------+-----------------+----------+
```

```
. pchart rejects day ssize
```

All the points are within the control limits, which are 0.0009 for the lower limit and 0.0203 for the upper limit.

Here the sample sizes are fixed at 1,000, so the *ssize* variable contains 1,000 for each observation. Sample sizes need not be fixed, however. Say that our data were slightly different:
. use https://www.stata-press.com/data/r16/ncu3
. list in 1/5

<table>
<thead>
<tr>
<th>day</th>
<th>rejects</th>
<th>ssize</th>
</tr>
</thead>
<tbody>
<tr>
<td>1.</td>
<td>1</td>
<td>7</td>
</tr>
<tr>
<td>2.</td>
<td>2</td>
<td>5</td>
</tr>
<tr>
<td>3.</td>
<td>3</td>
<td>11</td>
</tr>
<tr>
<td>4.</td>
<td>4</td>
<td>13</td>
</tr>
<tr>
<td>5.</td>
<td>5</td>
<td>9</td>
</tr>
</tbody>
</table>

. pchart rejects day ssize

Here the control limits are, like the sample size, no longer constant. The `stabilize` option will stabilize the control chart:

. pchart rejects day ssize, stabilize
Example 3: rchart

rchart displays an R chart showing the range for repeated measurements at various times. Variables within observations record measurements. Observations represent different samples.

For instance, say that we take five samples of 5 observations each. In our first sample, our measurements are 10, 11, 10, 11, and 12. The data are

```
. list

   +----+----+----+----+----+
   | m1 | m2 | m3 | m4 | m5 |
   +----+----+----+----+----+
   | 10  | 11  | 10 | 11 | 12 |
   | 12  | 10  | 9  | 10 | 9  |
   | 10  | 11  | 10 | 12 | 10 |
   | 9   | 9   | 9  | 10 | 11 |
   | 12  | 12  | 12 | 12 | 13 |
   +----+----+----+----+----+
```

```
. rchart m1-m5, connect(l)
```

The expected range in each sample is 2 with lower and upper control limits of 0 and 4.23, respectively. If we know that the process standard deviation is 0.3, we could specify
Example 4: xchart

xchart graphs an $\overline{X}$ chart for repeated measurements at various times. Variables within observations record measurements, and observations represent different samples. Using the same data as in the previous example, we type

```
.xchart m1-m5, connect(1)
```

The average measurement in the sample is 10.64, and the lower and upper control limits are 9.486 and 11.794, respectively. Suppose that we knew from prior information that the mean of the process is 11. Then we would type
QC — Quality control charts 2069

. xchart m1-m5, connect(l) mean(11)

If we also know that the standard deviation of the process is 0.3, we could type

. xchart m1-m5, connect(l) mean(11) std(.3)

Finally, xchart allows us to specify our own control limits:
. xchart m1-m5, connect(l) mean(11) lower(10) upper(12)

Example 5: shewhart

shewhart displays a vertically aligned $\bar{X}$ and R chart in the same image. To produce the best-looking combined image possible, you will want to use the xchart and rchart commands separately and then combine the graphs. shewhart, however, is more convenient.

Using the same data as previously, but realizing that the standard deviation should have been 0.4, we type

. shewhart m1-m5, connect(l) mean(11) std(.4)
Walter Andrew Shewhart (1891–1967) was born in Illinois and educated as a physicist, with degrees from the Universities of Illinois and California. After a brief period teaching physics, he worked for the Western Electric Company and (from 1925) the Bell Telephone Laboratories. His name is most associated with control charts used in quality controls, but his many other interests ranged generally from quality assurance to the philosophy of science.

Stored results

**cchart** stores the following in \( r() \):  

Scalars  
- \( r(\text{cbar}) \): expected number of nonconformities  
- \( r(\text{lcl}_c) \): lower control limit  
- \( r(\text{ucl}_c) \): upper control limit  
- \( r(N) \): number of observations  
- \( r(\text{out}_c) \): number of units out of control  
- \( r(\text{below}_c) \): number of units below the lower limit  
- \( r(\text{above}_c) \): number of units above the upper limit

**pchart** stores the following in \( r() \):  

Scalars  
- \( r(\text{pbar}) \): average fraction of nonconformities  
- \( r(\text{lcl}_p) \): lower control limit  
- \( r(\text{ucl}_p) \): upper control limit  
- \( r(N) \): number of observations  
- \( r(\text{out}_p) \): number of units out of control  
- \( r(\text{below}_p) \): number of units below the lower limit  
- \( r(\text{above}_p) \): number of units above the upper limit

**rchart** stores the following in \( r() \):  

Scalars  
- \( r(\text{central_line}) \): ordinate of the central line  
- \( r(\text{lcl}_r) \): lower control limit  
- \( r(\text{ucl}_r) \): upper control limit  
- \( r(N) \): number of observations  
- \( r(\text{out}_r) \): number of units out of control  
- \( r(\text{below}_r) \): number of units below the lower limit  
- \( r(\text{above}_r) \): number of units above the upper limit

**xchart** stores the following in \( r() \):  

Scalars  
- \( r(\text{xbar}) \): grand mean  
- \( r(\text{lcl}_x) \): lower control limit  
- \( r(\text{ucl}_x) \): upper control limit  
- \( r(N) \): number of observations  
- \( r(\text{out}_x) \): number of units out of control  
- \( r(\text{below}_x) \): number of units below the lower limit  
- \( r(\text{above}_x) \): number of units above the upper limit

**shewhart** stores in \( r() \) the combination of stored results from **xchart** and **rchart**.
Methods and formulas

For the c chart, the number of defects per unit, \( C \), is taken to be a value of a random variable having a Poisson distribution. If \( k \) is the number of units available for estimating \( \lambda \), the parameter of the Poisson distribution, and if \( C_i \) is the number of defects in the \( i \)th unit, then \( \lambda \) is estimated by \( \bar{C} = \frac{\sum_i C_i}{k} \). Then

\[
\begin{align*}
\text{central line} & = \bar{C} \\
\text{UCL} & = \bar{C} + 3\sqrt{\bar{C}} \\
\text{LCL} & = \bar{C} - 3\sqrt{\bar{C}}
\end{align*}
\]

Control limits for the \( p \) chart are based on the sampling theory for proportions, using the normal approximation to the binomial. If \( k \) samples are taken, the estimator of \( p \) is given by \( \bar{p} = \frac{\sum_i \hat{p}_i}{k} \), where \( \hat{p}_i = \frac{x_i}{n_i} \), and \( x_i \) is the number of defects in the \( i \)th sample of size \( n_i \). The central line and the control limits are given by

\[
\begin{align*}
\text{central line} & = \bar{p} \\
\text{UCL} & = \bar{p} + 3\sqrt{\frac{\bar{p}(1-\bar{p})}{n_i}} \\
\text{LCL} & = \bar{p} - 3\sqrt{\frac{\bar{p}(1-\bar{p})}{n_i}}
\end{align*}
\]

Control limits for the \( R \) chart are based on the distribution of the range of samples of size \( n \) from a normal population. If the standard deviation of the process, \( \sigma \), is known,

\[
\begin{align*}
\text{central line} & = d_2\sigma \\
\text{UCL} & = D_2\sigma \\
\text{LCL} & = D_1\sigma
\end{align*}
\]

where \( d_2 \), \( D_1 \), and \( D_2 \) are functions of the number of observations in the sample and are obtained from the table published in Beyer (1976).

When \( \sigma \) is unknown,

\[
\begin{align*}
\text{central line} & = \bar{R} \\
\text{UCL} & = \frac{D_2}{d_2}\bar{R} \\
\text{LCL} & = \frac{D_1}{d_2}\bar{R}
\end{align*}
\]

where \( \bar{R} = \frac{\sum_i R_i}{k} \) is the range of the \( k \) sample ranges \( R_i \).

Control limits for the \( \bar{X} \) chart are given by

\[
\begin{align*}
\text{central line} & = \bar{x} \\
\text{UCL} & = \bar{x} + (3/\sqrt{n})\sigma \\
\text{LCL} & = \bar{x} - (3/\sqrt{n})\sigma
\end{align*}
\]
if \( \sigma \) is known. If \( \sigma \) is unknown,

\[
\text{central line} = \bar{x} \\
\text{UCL} = \bar{x} + A_2 \bar{R} \\
\text{LCL} = \bar{x} - A_2 \bar{R}
\]

where \( \bar{R} \) is the average range as defined above and \( A_2 \) is a function (op. cit.) of the number of observations in the sample.

Isobel Loutit (1909–2009) is known for her work during World War II to improve the accuracy of targeting for anti-aircraft guns and as a contributor to the field of quality control. Loutit was born in Selkirk Manitoba, Canada. She graduated from the University of Manitoba in 1929 with a degree in mathematics and was one of the first women to work as a professional statistician in Canada. After graduation, she obtained a job teaching French. However, because of her training, she served as a substitute math teacher when needed.

When World War II started, Loutit took a job as a quality control statistician at Northern Electric. Shortly after that, the Canadian government advertised for women with technical training to fill jobs that had been vacated by men who had gone to war. She took a position testing equipment for the military. This job eventually returned her to Northern Electric, this time as a government employee verifying the accuracy of Northern Electric’s Vickers anti-aircraft gun predictor, which was used to aim artillery at incoming planes. Recognizing the quality of her work, the CEO of Northern Electric rehired Loutit as an engineer, the only position for which her pay would not be capped as a woman. She later became the first female manager at Northern Electric and the first woman to chair the Montreal Section of the American Society for Quality Control.

**qreg — Quantile regression**

**Description**

qreg fits quantile (including median) regression models, also known as least–absolute-value models (LAV or MAD) and minimum L1-norm models. The quantile regression models fit by qreg express the quantiles of the conditional distribution as linear functions of the independent variables.

iqreg estimates interquantile range regressions, regressions of the difference in quantiles. The estimated variance–covariance matrix of the estimators (VCE) is obtained via bootstrapping.

sqreg estimates simultaneous-quantile regression. It produces the same coefficients as qreg for each quantile. Reported standard errors will be similar, but sqreg obtains an estimate of the VCE via bootstrapping, and the VCE includes between-quantile blocks. Thus you can test and construct confidence intervals comparing coefficients describing different quantiles.

bsqreg is equivalent to sqreg with one quantile.

**Quick start**

**Quantile regression**

Median regression of \(y\) on \(x_1\) and \(x_2\)

\[
\texttt{qreg \ y\ x1\ x2}
\]

Add categorical covariate \(a\) using factor-variable syntax

\[
\texttt{qreg \ y\ x1\ x2\ i.a}
\]

As above, but with standard errors using a biweight kernel for the nonparametric density estimator

\[
\texttt{qreg \ y\ x1\ x2\ i.a, vce(, kernel(biweight))}
\]

Quantile regression of the 75th percentile of \(y\) on \(x_1\), \(x_2\), and \(a\)

\[
\texttt{qreg \ y\ x1\ x2\ i.a, quantile(.75)}
\]

**Interquantile range regression**

Difference between the 90th and 10th quantiles of \(y\) on \(x_1\), \(x_2\), and \(a\) with bootstrap standard errors

\[
\texttt{iqreg \ y\ x1\ x2\ i.a, quantiles(.1 .9)}
\]
Simultaneous-quantile regression

Simultaneous estimation of quantile regressions for the 10th and 90th quantiles of $y$ with bootstrap standard errors

\[ \text{sqreg y x1 x2 i.a, quantiles(.1 .9)} \]

As above, but for the 25th, 50th, and 75th quantiles of $y$

\[ \text{sqreg y x1 x2 i.a, quantiles(.25 .5 .75)} \]

As above, but increase the number of bootstrap replications to 500

\[ \text{sqreg y x1 x2 i.a, quantiles(.25 .5 .75) reps(500)} \]

Bootstrapped quantile regression

Single quantile regression for the 25th quantile with bootstrap standard errors

\[ \text{bsqreg y x1 x2 i.a, quantile(.25)} \]

- \texttt{level(#)} set confidence level; default is \texttt{level(95)}
- \texttt{display\_options} control columns and column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling

\textit{indepvars} may contain factor variables; see [U] 11.4.3 Factor variables.

by, mi estimate, rolling, and statsby, are allowed by \texttt{qreg}, \texttt{iqreg}, \texttt{sqreg}, and \texttt{bsqreg}; \texttt{mfp}, \texttt{nestreg}, and \texttt{stepwise} are allowed only with \texttt{qreg}; see [U] 11.1.10 Prefix commands.

\texttt{qreg} allows \texttt{fweight}s, \texttt{iweight}s, and \texttt{pweight}s; see [U] 11.1.6 weight.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

\textbf{Options for qreg}

\texttt{Model}
- \texttt{quantile(#)} specifies the quantile to be estimated and should be a number between 0 and 1, exclusive. Numbers larger than 1 are interpreted as percentages. The default value of 0.5 corresponds to the median.

\texttt{SE/Robust}
- \texttt{vce([vcetype], [vceopts])} specifies the type of VCE to compute and the density estimation method to use in computing the VCE.
  - \texttt{vcetype} specifies the type of VCE to compute. Available types are \texttt{iid} and \texttt{robust}.
    - \texttt{vce(iid)}, the default, computes the VCE under the assumption that the residuals are independent and identically distributed (i.i.d.).
    - \texttt{vce(robust)} computes the robust VCE under the assumption that the residual density is continuous and bounded away from 0 and infinity at the specified \texttt{quantile()}; see Koenker (2005, sec. 4.2).
vceopts consists of available *denmethod* and *bwidth* options.

*denmethod* specifies the method to use for the nonparametric density estimator. Available methods are fitted, residual, or kernel([kernel]), where the optional *kernel* must be one of the kernel choices listed below.

fitted and residual specify that the nonparametric density estimator use some of the structure imposed by quantile regression. The default fitted uses a function of the fitted values and residual uses a function of the residuals. vce(robust, residual) is not allowed.

kernel() specifies that the nonparametric density estimator use a kernel method. The available kernel functions are epanechnikov, epan2, biweight, cosine, gaussian, parzen, rectangle, and triangle. The default is epanechnikov. See [R] kdensity for the kernel function forms.

*bwidth* specifies the bandwidth method to use by the nonparametric density estimator. Available methods are hsheather for the Hall–Sheather bandwidth, bofinger for the Bofinger bandwidth, and chamberlain for the Chamberlain bandwidth.

See Koenker (2005, sec. 3.4 and 4.10) for a description of the sparsity estimation techniques and the Hall–Sheather and Bofinger bandwidth formulas. See Chamberlain (1994, eq. 2.2) for the Chamberlain bandwidth.

### Reporting

level(#); see [R] Estimation options.

display_options: noci, nopvalues, noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(#), fvwraupon(style), cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch; see [R] Estimation options.

### Optimization

optimization_options: iterate(#), [no]log, trace. iterate() specifies the maximum number of iterations; log/nolog specifies whether to show the iteration log (see set iterlog in [R] set iter); and trace specifies that the iteration log should include the current parameter vector. These options are seldom used.

wlsiter(#) specifies the number of weighted least-squares iterations that will be attempted before the linear programming iterations are started. The default value is 1. If there are convergence problems, increasing this number should help.

### Options for iqreg

quantiles(##) specifies the quantiles to be compared. The first number must be less than the second, and both should be between 0 and 1, exclusive. Numbers larger than 1 are interpreted as percentages. Not specifying this option is equivalent to specifying quantiles(.25 .75), meaning the interquantile range.

reps(#) specifies the number of bootstrap replications to be used to obtain an estimate of the variance–covariance matrix of the estimators (standard errors). reps(20) is the default and is arguably too small. reps(100) would perform 100 bootstrap replications. reps(1000) would perform 1,000 replications.
Options for \texttt{sqreg}

\texttt{quantiles(#) [# [# ... ]])} specifies the quantiles to be estimated and should contain numbers between 0 and 1, exclusive. Numbers larger than 1 are interpreted as percentages. The default value of 0.5 corresponds to the median.

\texttt{reps(#)} specifies the number of bootstrap replications to be used to obtain an estimate of the variance–covariance matrix of the estimators (standard errors). \texttt{reps(20)} is the default and is arguably too small. \texttt{reps(100)} would perform 100 bootstrap replications. \texttt{reps(1000)} would perform 1,000 replications.

Options for \texttt{bsqreg}

\texttt{quantile(#)} specifies the quantile to be estimated and should be a number between 0 and 1, exclusive. Numbers larger than 1 are interpreted as percentages. The default value of 0.5 corresponds to the median.

\texttt{reps(#)} specifies the number of bootstrap replications to be used to obtain an estimate of the variance–covariance matrix of the estimators (standard errors). \texttt{reps(20)} is the default and is arguably too small. \texttt{reps(100)} would perform 100 bootstrap replications. \texttt{reps(1000)} would perform 1,000 replications.
Remarks and examples

Remarks are presented under the following headings:

- Median regression
- Quantile regression
- Estimated standard errors
- Interquantile and simultaneous-quantile regression
- What are the parameters?

Median regression

qreg fits quantile regression models. The default form is median regression, where the objective is to estimate the median of the dependent variable, conditional on the values of the independent variables. This method is similar to ordinary regression, where the objective is to estimate the conditional mean of the dependent variable. Simply put, median regression finds a line through the data that minimizes the sum of the absolute residuals rather than the sum of the squares of the residuals, as in ordinary regression. Equivalently, median regression expresses the median of the conditional distribution of the dependent variable as a linear function of the conditioning (independent) variables. Cameron and Trivedi (2010, chap. 7) provide a nice introduction to quantile regression using Stata.

Example 1: Estimating the conditional median

Consider a two-group experimental design with 5 observations per group:

```
. use https://www.stata-press.com/data/r16/twogrp
. list
```

```
We have estimated the equation 
\[ y_{\text{median}} = 3 + 17x \]

We look back at our data. \( x \) takes on the values 0 and 1, so the median for the \( x = 0 \) group is 3, whereas for \( x = 1 \) it is \( 3 + 17 = 20 \). The output reports that the raw sum of absolute deviations about 14 is 78.5; that is, the sum of \( |y - 14| \) is 78.5. Fourteen is the unconditional median of \( y \), although in these data, any value between 14 and 19 could also be considered an unconditional median (we have an even number of observations, so the median is bracketed by those two values). In any case, the raw sum of deviations of \( y \) about the median would be the same no matter what number we choose between 14 and 19. (With a “median” of 14, the raw sum of deviations is 78.5. Now think of choosing a slightly larger number for the median and recalculating the sum. Half the observations will have larger negative residuals, but the other half will have smaller positive residuals, resulting in no net change.)

We turn now to the actual estimated equation. The sum of the absolute deviations about the solution \( y_{\text{median}} = 3 + 17x \) is 55. The pseudo-\( R^2 \) is calculated as \( 1 - 55/78.5 \approx 0.2994 \). This result is based on the idea that the median regression is the maximum likelihood estimate for the double-exponential distribution.

Technical note

qreg is an alternative to regular regression or robust regression—see \[R\] regress and \[R\] rreg. Let’s compare the results:

```
. regress y x
```

```

Unlike qreg, regress fits ordinary linear regression and is concerned with predicting the mean rather than the median, so both results are, in a technical sense, correct. Putting aside those technicalities, however, we tend to use either regression to describe the central tendency of the data, of which the mean is one measure and the median another. Thus we can ask, “which method better describes the central tendency of these data?”

Means—and therefore ordinary linear regression—are sensitive to outliers, and our data were purposely designed to contain two such outliers: 95 for \( x = 0 \) and 14 for \( x = 1 \). These two outliers dominated the ordinary regression and produced results that do not reflect the central tendency well—you are invited to enter the data and graph \( y \) against \( x \).
Robust regression attempts to correct the outlier-sensitivity deficiency in ordinary regression:

```
. rreg y x, genwt(wt)
```

| Huber iteration 1: maximum difference in weights = .7311828 |
| Huber iteration 2: maximum difference in weights = .17695779 |
| Huber iteration 3: maximum difference in weights = .03149585 |
| Biweight iteration 4: maximum difference in weights = .1979335 |
| Biweight iteration 5: maximum difference in weights = .2332905 |
| Biweight iteration 6: maximum difference in weights = .09960067 |
| Biweight iteration 7: maximum difference in weights = .02691458 |
| Biweight iteration 8: maximum difference in weights = .0009113 |

Robust regression

| y | Coef. | Std. Err. | t | P>|t| | [95% Conf. Interval] |
|---|-------|-----------|---|------|-----------------|
| x | 18.16597 | 2.023114 | 8.98 | 0.000 | 13.50066 | 22.83128 |
| _cons | 2.000003 | 1.430558 | 1.40 | 0.200 | -1.298869 | 5.298875 |

Here `rreg` discarded the first outlier completely. (We know this because we included the `genwt()` option on `rreg` and, after fitting the robust regression, examined the weights.) For the other “outlier”, `rreg` produced a weight of 0.47.

In any case, the answers produced by `qreg` and `rreg` to describe the central tendency are similar, but the standard errors are different. In general, robust regression will have smaller standard errors because it is not as sensitive to the exact placement of observations near the median. You are welcome to try removing the first outlier in the `qreg` estimation to observe an improvement in the standard errors by typing

```
. qreg y x if _n!=5
```

Also, some authors (Rousseeuw and Leroy 1987, 11) have noted that quantile regression, unlike the unconditional median, may be sensitive to even one outlier if its leverage is high enough. Rousseeuw and Leroy (1987) discuss estimators that are more robust to perturbations to the data than either mean regression or quantile regression.

In the end, quantile regression may be more useful for the interpretation of the parameters that it estimates than for its robustness to perturbations to the data.

Example 2: Median regression

Let’s now consider a less artificial example using the automobile data described in [U] 1.2.2 Example datasets. Using median regression, we will regress each car’s price on its weight and length and whether it is of foreign manufacture:
. use https://www.stata-press.com/data/r16/auto, clear
(1978 Automobile Data)
. qreg price weight length foreign
Iteration 1: WLS sum of weighted deviations = 56397.829
Iteration 1: sum of abs. weighted deviations = 55950.5
Iteration 2: sum of abs. weighted deviations = 55264.718
Iteration 3: sum of abs. weighted deviations = 54762.283
Iteration 4: sum of abs. weighted deviations = 54734.152
Iteration 5: sum of abs. weighted deviations = 54552.638
note: alternate solutions exist
Iteration 6: sum of abs. weighted deviations = 54465.511
Iteration 7: sum of abs. weighted deviations = 54443.699
Iteration 8: sum of abs. weighted deviations = 54411.294
Median regression Number of obs = 74
Raw sum of deviations 71102.5 (about 4934)
Min sum of deviations 54411.29 Pseudo R2 = 0.2347

| price      | Coef.  | Std. Err. | t     | P>|t| | [95% Conf. Interval] |
|------------|--------|-----------|-------|------|----------------------|
| weight     | 3.933588 | 1.328718  | 2.96  | 0.004 | 1.283543 – 6.583632  |
| length     | -41.25191 | 45.46469  | -0.91 | 0.367 | -131.9284 – 49.42456 |
| foreign    | 3377.771  | 885.4198  | 3.81  | 0.000 | 1611.857 – 5143.685  |
| _cons      | 344.6489  | 5182.394  | 0.07  | 0.947 | -9991.31 – 10680.61  |

The estimated equation is

\[
\text{price}_{\text{median}} = 3.93 \text{weight} - 41.25 \text{length} + 3377.8 \text{foreign} + 344.65
\]

The output may be interpreted in the same way as linear regression output; see \[\text{[R] regress}\]. The variables weight and foreign are significant, but length is not significant. The median price of the cars in these data is $4,934. This value is a median (one of the two center observations), not the median, which would typically be defined as the midpoint of the two center observations.

\[
\text{Quantile regression}
\]

Quantile regression is similar to median regression in that it estimates an equation expressing a quantile of the conditional distribution, albeit one that generally differs from the 0.5 quantile that is the median. For example, specifying `quantile(.25)` estimates the parameters that describe the 25th percentile (first quartile) of the conditional distribution.

Quantile regression allows for effects of the independent variables to differ over the quantiles. For example, Chamberlain (1994) finds that union membership has a larger effect on the lower quantiles than on the higher quantiles of the conditional distribution of U.S. wages. That the effects of the independent variables may vary over quantiles of the conditional distribution is an important advantage of quantile regression over mean regression.
Example 3: Estimating quantiles other than the median

Returning to real data, the equation for the 25th percentile of price conditional on weight, length, and foreign in our automobile data is

```
use https://www.stata-press.com/data/r16/auto
(1978 Automobile Data)
.qreg price weight length foreign, quantile(.25)
```

|                | Coef.  | Std. Err. | t     | P>|t| | 95% Conf. Interval |
|----------------|--------|-----------|-------|-----|-------------------|
| weight         | 1.831789 | 0.6328903 | 2.89  | 0.005 | 0.5695289 - 3.094049 |
| length         | 2.84556  | 21.65558  | 0.13  | 0.896 | -40.34514 - 46.03626 |
| foreign        | 2209.925 | 421.7401  | 5.24  | 0.000 | 1368.791 - 3051.059 |
| _cons          | -1879.775 | 2468.46   | -0.76 | 0.449 | -6802.963 - 3043.413 |

Compared with our previous median regression, the coefficient on length now has a positive sign, and the coefficients on foreign and weight are reduced. The actual lower quantile is $4,187, substantially less than the median $4,934.
We can also estimate the upper quartile as a function of the same three variables:

```
. qreg price weight length foreign, quantile(.75)
Iteration 1: WLS sum of weighted deviations = 55465.741
Iteration 1: sum of abs. weighted deviations = 55652.957
Iteration 2: sum of abs. weighted deviations = 52994.785
Iteration 3: sum of abs. weighted deviations = 50189.446
Iteration 4: sum of abs. weighted deviations = 49898.245
Iteration 5: sum of abs. weighted deviations = 49398.106
Iteration 6: sum of abs. weighted deviations = 49241.835
Iteration 7: sum of abs. weighted deviations = 49197.967
```

.75 Quantile regression
Number of obs = 74
Raw sum of deviations 79860.75 (about 6342)
Min sum of deviations 49197.97 Pseudo R2 = 0.3840

|    | Coef.  | Std. Err. | t     | P>|t| | 95% Conf. Interval |
|----|--------|-----------|-------|-----|-------------------|
| price |      |           |       |     |                   |
| weight | 9.22291 | 1.785767  | 5.16  | 0.000 | 5.66131 - 12.78451 |
| length | -220.7833 | 61.10352 | -3.61 | 0.001 | -342.6504 - -98.91616 |
| foreign | 3595.133 | 1189.984 | 3.02  | 0.004 | 1221.785 - 5968.482 |
| _cons | 20242.9 | 6965.02  | 2.91  | 0.005 | 6351.61 - 34134.2 |

This result tells a different story: weight is much more important, and length is now significant—with a negative coefficient! The prices of high-priced cars seem to be determined by factors different from those affecting the prices of low-priced cars.

Technical note

One explanation for having substantially different regression functions for different quantiles is that the data are heteroskedastic, as we will demonstrate below. The following statements create a sharply heteroskedastic set of data:

```
. drop _all
. set obs 10000
   number of observations (_N) was 0, now 10,000
. set seed 50550
. generate x = .1 + .9 * runiform()
. generate y = x * runiform()^2
```
Let’s now fit the regressions for the 5th and 95th quantiles:

```
.qreg y x, quantile(.05)
Iteration 1: WLS sum of weighted deviations = 555.44181
Iteration 1: sum of abs. weighted deviations = 555.25622
Iteration 2: sum of abs. weighted deviations = 115.02628
Iteration 3: sum of abs. weighted deviations = 89.617883
Iteration 4: sum of abs. weighted deviations = 89.616799

.05 Quantile regression
Number of obs = 10,000
Raw sum of deviations 89.68001 (about .00105493)
Min sum of deviations 89.61679
Pseudo R2 = 0.0007

| Coef. Std. Err. t P>|t| [95% Conf. Interval] |
|---|---|---|---|---|---|
| y  | x | .0028667 | .0004395 | 6.52 0.000 | .0020052 .0037283 |
| _cons | -.0001135 | .0002661 | -0.43 0.670 | -.0006352 .0004081 |
```

```
.qreg y x, quantile(.95)
Iteration 1: WLS sum of weighted deviations = 624.91903
Iteration 1: sum of abs. weighted deviations = 621.88928
Iteration 2: sum of abs. weighted deviations = 182.03243
Iteration 3: sum of abs. weighted deviations = 170.42588
Iteration 4: sum of abs. weighted deviations = 169.05915
Iteration 5: sum of abs. weighted deviations = 169.05911

.95 Quantile regression
Number of obs = 10,000
Raw sum of deviations 275.9779 (about .60579139)
Min sum of deviations 169.0591
Pseudo R2 = 0.3874

| Coef. Std. Err. t P>|t| [95% Conf. Interval] |
|---|---|---|---|---|---|
| y  | x | .9010814 | .008758 | 102.89 0.000 | .883914 .9182488 |
| _cons | -.0004053 | .0053028 | -0.08 0.939 | -.0107999 .0099893 |
```

The coefficient on \( x \), in particular, differs markedly between the two estimates. For the mathematically inclined, it is not too difficult to show that the theoretical lines are \( y = 0.0025x \) for the 5th percentile and \( y = 0.9025x \) for the 95th, numbers in close agreement with our numerical results.

The estimator for the standard errors computed by `qreg` assumes that the sample is independent and identically distributed (i.i.d.); see Estimated standard errors and Methods and formulas for details. Because the data are conditionally heteroskedastic, we should have used `bsqreg` to consistently estimate the standard errors using a bootstrap method.

---

**Estimated standard errors**

The variance–covariance matrix of the estimator (VCE) depends on the reciprocal of the density of the dependent variable evaluated at the quantile of interest. This function, known as the “sparsity function”, is hard to estimate.

The default method, which uses the fitted values for the predicted quantiles, generally performs well, but other methods may be preferred in larger samples. The `vce()` suboptions `denmethod` and `bwidth` provide other estimators of the sparsity function, the details of which are described in Methods and formulas.
For models with heteroskedastic errors, option vce(robust) computes a Huber (1967) form of sandwich estimate (Koenker 2005). Alternatively, Gould (1992, 1997b) introduced generalized versions of \texttt{qreg} that obtain estimates of the standard errors by using bootstrap resampling (see Efron and Tibshirani [1993] or Wu [1986] for an introduction to bootstrap standard errors). The \texttt{iqreg}, \texttt{sqreg}, and \texttt{bsqreg} commands provide a bootstrapped estimate of the entire variance–covariance matrix of the estimators.

Example 4: Obtaining robust standard errors

Example 2 of \texttt{qreg} on real data above was a median regression of \texttt{price} on \texttt{weight}, \texttt{length}, and \texttt{foreign} using \texttt{auto.dta}. Suppose, after investigation, we are convinced that car price observations are not independent. We decide that standard errors robust to non-i.i.d. errors would be appropriate and use the option vce(robust).

```
use https://www.stata-press.com/data/r16/auto, clear
(1978 Automobile Data)
qreg price weight length foreign, vce(robust)
```

```
 Iteration 1: WLS sum of weighted deviations = 56397.829
 Iteration 1: sum of abs. weighted deviations = 55950.5
 Iteration 2: sum of abs. weighted deviations = 55264.718
 Iteration 3: sum of abs. weighted deviations = 54762.283
 Iteration 4: sum of abs. weighted deviations = 54734.152
 Iteration 5: sum of abs. weighted deviations = 54552.638
   note: alternate solutions exist
 Iteration 6: sum of abs. weighted deviations = 54465.511
 Iteration 7: sum of abs. weighted deviations = 54443.699
 Iteration 8: sum of abs. weighted deviations = 54411.294

Median regression  Number of obs = 74
Raw sum of deviations 71102.5 (about 4934)
Min sum of deviations 54411.29  Pseudo R2 = 0.2347

| price | Coef. | Std. Err. | t   | P>|t|  | [95% Conf. Interval] |
|-------|-------|-----------|-----|------|---------------------|
| weight|  3.933588 | 1.694477  | 2.32| 0.023 | 0.55406 7.313116 |
| length| -41.25191 | 51.73571 | -0.80| 0.428 | -144.4355 61.93171 |
| foreign| 3377.771 | 728.5115 | 4.64| 0.000 | 1924.801 4830.741 |
| _cons |  344.6489 | 5096.528 | 0.07| 0.946 | -9820.055 10509.35 |
```

We see that the robust standard error for \texttt{weight} increases making it less significant in modifying the median automobile price. The standard error for \texttt{length} also increases, but the standard error for the \texttt{foreign} indicator decreases.
For comparison, we repeat the estimation using bootstrap standard errors:

```
. use https://www.stata-press.com/data/r16/auto, clear
(1978 Automobile Data)
. set seed 1001
. bsqreg price weight length foreign
   (fitting base model)
```

Bootstrap replications (20)

```
....................
```

```
Median regression, bootstrap(20) SEs
Number of obs = 74
Raw sum of deviations  71102.5 (about 4934)
Min sum of deviations  54411.29  Pseudo R2 = 0.2347
```

|     | Coef.    | Std. Err. | t    | P>|t|  | [95% Conf. Interval] |
|-----|----------|-----------|------|-----|---------------------|
| price |          |           |      |     |                     |
| weight| 3.933588 | 2.941839  | 1.34 | 0.186 | -1.933726 9.800901  |
| length| -41.25191| 73.47105  | -0.56| 0.576 | -187.7853 105.2815 |
| foreign| 3377.771 | 1352.518  | 2.50 | 0.015 | 680.2582 6075.284  |
| _cons | 344.6489 | 5927.045  | 0.06 | 0.954 | -11476.47 12165.77  |

The coefficient estimates are the same—indeed, they are obtained using the same technique. Only the standard errors differ. Therefore, the \( t \) statistics, significance levels, and confidence intervals also differ.

Because `bsqreg` (as well as `sqreg` and `iqreg`) obtains standard errors by randomly resampling the data, the standard errors it produces will not be the same from run to run unless we first set the random-number seed to the same number; see \[R\] `set seed`. 

By default, bsqreg, sqreg, and iqreg use 20 replications. We can control the number of replications by specifying the `reps()` option:

```
.bsqreg price weight length i.foreign, reps(1000)
(fitting base model)
```

The results shown above are typical for models with heteroskedastic errors. (Our dependent variable is `price`; if our model had been in terms of `ln(price)`, the standard errors estimated by `qreg` and `bsqreg` would have been nearly identical.) Also, even for heteroskedastic errors, 20 replications is generally sufficient for hypothesis tests against 0.
Interquantile and simultaneous-quantile regression

Consider a quantile regression model where the $q$th quantile is given by

$$Q_q(y) = a_q + b_{q,1}x_1 + b_{q,2}x_2$$

For instance, the 75th and 25th quantiles are given by

$$Q_{0.75}(y) = a_{0.75} + b_{0.75,1}x_1 + b_{0.75,2}x_2$$
$$Q_{0.25}(y) = a_{0.25} + b_{0.25,1}x_1 + b_{0.25,2}x_2$$

The difference in the quantiles is then

$$Q_{0.75}(y) - Q_{0.25}(y) = (a_{0.75} - a_{0.25}) + (b_{0.75,1} - b_{0.25,1})x_1 + (b_{0.75,2} - b_{0.25,2})x_2$$

$qreg$ fits models such as $Q_{0.75}(y)$ and $Q_{0.25}(y)$. $iqreg$ fits interquantile models, such as $Q_{0.75}(y) - Q_{0.25}(y)$. The relationships of the coefficients estimated by $qreg$ and $iqreg$ are exactly as shown: $iqreg$ reports coefficients that are the difference in coefficients of two $qreg$ models, and, of course, $iqreg$ reports the appropriate standard errors, which it obtains by bootstrapping.

$sqreg$ is like $qreg$ in that it estimates the equations for the quantiles

$$Q_{0.75}(y) = a_{0.75} + b_{0.75,1}x_1 + b_{0.75,2}x_2$$
$$Q_{0.25}(y) = a_{0.25} + b_{0.25,1}x_1 + b_{0.25,2}x_2$$

The coefficients it obtains are the same that would be obtained by estimating each equation separately using $qreg$. $sqreg$ differs from $qreg$ in that it estimates the equations simultaneously and obtains an estimate of the entire variance–covariance matrix of the estimators by bootstrapping. Thus you can perform hypothesis tests concerning coefficients both within and across equations.

For example, to fit the above model, you could type

```
  . qreg y x1 x2, quantile(.25)
  . qreg y x1 x2, quantile(.75)
```

By doing this, you would obtain estimates of the parameters, but you could not test whether $b_{0.25,1} = b_{0.75,1}$ or, equivalently, $b_{0.75,1} - b_{0.25,1} = 0$. If your interest really is in the difference of coefficients, you could type

```
  . iqreg y x1 x2, quantiles(.25 .75)
```

The “coefficients” reported would be the difference in quantile coefficients. You could also estimate both quantiles simultaneously and then test the equality of the coefficients:

```
  . sqreg y x1 x2, quantiles(.25 .75)
  . test [q25]x1 = [q75]x1
```

Whether you use $iqreg$ or $sqreg$ makes no difference for this test. $sqreg$, however, because it estimates the quantiles simultaneously, allows you to test other hypotheses. $iqreg$, by focusing on quantile differences, presents results in a way that is easier to read.

Finally, $sqreg$ can estimate quantiles singly,

```
  . sqreg y x1 x2, quantiles(.5)
```

and can thereby be used as a substitute for the slower $bsqreg$. (Gould [1997b] presents timings demonstrating that $sqreg$ is faster than $bsqreg$.) $sqreg$ can also estimate more than two quantiles simultaneously:

```
  . sqreg y x1 x2, quantiles(.25 .5 .75)
```
Example 5: Simultaneous quantile estimation

In demonstrating \texttt{qreg}, we performed quantile regressions using \texttt{auto.dta}. We discovered that the regression of \texttt{price} on \texttt{weight}, \texttt{length}, and \texttt{foreign} produced vastly different coefficients for the 0.25, 0.5, and 0.75 quantile regressions. Here are the coefficients that we obtained:

<table>
<thead>
<tr>
<th>Variable</th>
<th>25th percentile</th>
<th>50th percentile</th>
<th>75th percentile</th>
</tr>
</thead>
<tbody>
<tr>
<td>weight</td>
<td>1.83</td>
<td>3.93</td>
<td>9.22</td>
</tr>
<tr>
<td>length</td>
<td>2.85</td>
<td>-41.25</td>
<td>-220.8</td>
</tr>
<tr>
<td>foreign</td>
<td>2209.9</td>
<td>3377.8</td>
<td>3595.1</td>
</tr>
<tr>
<td>_cons</td>
<td>-1879.8</td>
<td>344.6</td>
<td>20242.9</td>
</tr>
</tbody>
</table>

All we can say, having estimated these equations separately, is that \texttt{price} seems to depend differently on the \texttt{weight}, \texttt{length}, and \texttt{foreign} variables depending on the portion of the \texttt{price} distribution we examine. We cannot be more precise because the estimates have been made separately. With \texttt{sqreg}, however, we can estimate all the effects simultaneously:

```stata
. use https://www.stata-press.com/data/r16/auto, clear
  (1978 Automobile Data)
. set seed 1001
. sqreg price weight length foreign, q(.25 .5 .75) reps(100)
  (fitting base model)
```

Simultaneous quantile regression

<table>
<thead>
<tr>
<th></th>
<th>25th percentile</th>
<th>50th percentile</th>
<th>75th percentile</th>
</tr>
</thead>
<tbody>
<tr>
<td>weight</td>
<td>1.831789</td>
<td>3.933588</td>
<td>9.22291</td>
</tr>
<tr>
<td>length</td>
<td>2.84556</td>
<td>-41.25191</td>
<td>-220.7833</td>
</tr>
<tr>
<td>foreign</td>
<td>2209.925</td>
<td>3377.771</td>
<td>3595.133</td>
</tr>
<tr>
<td>_cons</td>
<td>-1879.775</td>
<td>344.6489</td>
<td>20242.994</td>
</tr>
</tbody>
</table>

The coefficient estimates above are the same as those previously estimated, although the standard error estimates are a little different. \texttt{sqreg} obtains estimates of variance by bootstrapping. The important thing here, however, is that the full covariance matrix of the estimators has been estimated and stored, and thus it is now possible to perform hypothesis tests. Are the effects of \texttt{weight} the same at the 25th and 75th percentiles?
It appears that they are not. We can obtain a confidence interval for the difference by using `lincom`:

```
. lincom [q75]weight-[q25]weight
( 1) - [q25]weight + [q75]weight = 0
```

|       | Coef.       | Std. Err. | t     | P>|t|   | [95% Conf. Interval] |
|-------|-------------|-----------|-------|-------|----------------------|
| price | 7.391121    | 2.524626  | 2.93  | 0.005 | 2.355914 12.42633    |

Indeed, we could test whether the `weight` and `length` sets of coefficients are equal at the three quantiles estimated:

```
. quietly test [q25]weight = [q50]weight
. quietly test [q25]weight = [q75]weight, accumulate
. quietly test [q25]length = [q50]length, accumulate
. test [q25]length = [q75]length, accumulate
( 1) [q25]weight - [q50]weight = 0
( 2) [q25]weight - [q75]weight = 0
( 3) [q25]length - [q50]length = 0
( 4) [q25]length - [q75]length = 0
F( 4, 70) = 2.25
Prob > F = 0.0727
```

`iqreg` focuses on one quantile comparison but presents results that are more easily interpreted:

```
. set seed 1001
. iqreg price weight length foreign, q(.25 .75) reps(100) nolog
```

Looking only at the 0.25 and 0.75 quantiles (the interquartile range), the `iqreg` command output is easily interpreted. Increases in `weight` correspond significantly to increases in `price` dispersion. Increases in `length` correspond to decreases in `price` dispersion. The `foreign` variable does not significantly change `price` dispersion.

Do not make too much of these results; the purpose of this example is simply to illustrate the `sqreg` and `iqreg` commands and to do so in a context that suggests why analyzing dispersion might be of interest.
lincom after sqreg produced the same t statistic for the interquartile range of weight, as did the iqreg command above. In general, they will not agree exactly because of the randomness of bootstrapping, unless the random-number seed is set to the same value before estimation (as was done here).

Gould (1997a) presents simulation results showing that the coverage—the actual percentage of confidence intervals containing the true value—for iqreg is appropriate.

What are the parameters?

In this section, we use a specific data-generating process (DGP) to illustrate the interpretation of the parameters estimated by qreg. If simulation experiments are not intuitive to you, skip this section.

In general, quantile regression parameterizes the quantiles of the distribution of \( y \) conditional on the independent variables \( x \) as \( x \beta \), where \( \beta \) is a vector of estimated parameters. In our example, we include a constant term and a single independent variable, and we express quantiles of the distribution of \( y \) conditional on \( x \) as \( \beta_0 + \beta_1 x \).

We use simulated data to illustrate what we mean by a conditional distribution and how to interpret the parameters \( \beta \) estimated by qreg. We also note how we could change our example to illustrate a DGP for which the estimator in qreg would be misspecified.

We suppose that the distribution of \( y \) conditional on \( x \) has a Weibull form. If \( y \) has a Weibull distribution, the distribution function is

\[
F(y) = 1 - \exp\left\{-\frac{y}{\lambda}\right\}^k,
\]

where the scale parameter \( \lambda > 0 \) and the shape parameter \( k > 0 \). We can make \( y \) have a Weibull distribution function conditional on \( x \) by making the scale parameter or the shape parameter functions of \( x \). In our example, we specify a particular DGP by supposing that \( \lambda = (1 + \alpha x) \), \( \alpha = 1.5 \), \( x = 1 + \sqrt{\nu} \), and that \( \nu \) has a \( \chi^2(1) \) distribution. For the moment, we leave the parameter \( k \) as is so that we can discuss how this decision relates to model specification.

Plugging in for \( \lambda \) yields the functional form for the distribution of \( y \) conditional on \( x \), which is known as the conditional distribution function and is denoted \( F(y|x) \). \( F(y|x) \) is the distribution for \( y \) for each given value of \( x \).

Some algebra yields that \( F(y|x) = 1 - \exp\left(-\frac{y}{1 + \alpha x}\right)^k \). Letting \( \tau = F(y|x) \) implies that \( 0 \leq \tau \leq 1 \), because probabilities must be between 0 and 1.

To obtain the \( \tau \) quantile of the distribution of \( y \) conditional on \( x \), we solve

\[
\tau = 1 - \exp\left(-\frac{y}{1 + \alpha x}\right)^k
\]

for \( y \) as a function of \( \tau \), \( x \), \( \alpha \), and \( k \). The solution is

\[
y = (1 + \alpha x)\left\{-\ln(1 - \tau)\right\}^{(1/k)}
\]  

(1)

For any value of \( \tau \in (0, 1) \), expression (1) gives the \( \tau \) quantile of the distribution of \( y \) conditional on \( x \). To use qreg, we must rewrite (1) as a function of \( x \), \( \beta_0 \), and \( \beta_1 \). Some algebra yields that (1) can be rewritten as

\[
y = \beta_0 + \beta_1 * x
\]

where \( \beta_0 = \left\{-\ln(1 - \tau)\right\}^{(1/k)} \) and \( \beta_1 = \alpha\left\{-\ln(1 - \tau)\right\}^{(1/k)} \). We can express the conditional quantiles as linear combinations of \( x \), which is a property of the estimator implemented in qreg.
If we parameterize $k$ as a nontrivial function of $x$, the conditional quantiles will not be linear in $x$. If the conditional quantiles cannot be represented as linear functions of $x$, we cannot estimate the true parameters of the DGP. This restriction illustrates the limits of the estimator implemented in \texttt{qreg}.

We set $k = 2$ for our example.

Conditional quantile regression allows the coefficients to change with the specified quantile. For our DGP, the coefficients $\beta_0$ and $\beta_1$ increase as $\tau$ gets larger. Substituting in for $\alpha$ and $k$ yields that $\beta_0 = \sqrt{-\ln(1 - \tau)}$ and $\beta_1 = 1.5 \sqrt{-\ln(1 - \tau)}$. Table 1 presents the true values for $\beta_0$ and $\beta_1$ implied by our DGP when $\tau \in \{0.25, 0.5, 0.8\}$.

<table>
<thead>
<tr>
<th>$\tau$</th>
<th>$\beta_0$</th>
<th>$\beta_1$</th>
</tr>
</thead>
<tbody>
<tr>
<td>0.25</td>
<td>0.53636</td>
<td>0.80454</td>
</tr>
<tr>
<td>0.5</td>
<td>0.8325546</td>
<td>1.248832</td>
</tr>
<tr>
<td>0.8</td>
<td>1.268636</td>
<td>1.902954</td>
</tr>
</tbody>
</table>

We can also use (1) to generate data from the specified distribution of $y$ conditional on $x$ by plugging in random uniform numbers for $\tau$. Each random uniform number substituted in for $\tau$ in (1) yields a draw from the conditional distribution of $y$ given $x$.

**Example 6**

In this example, we generate 100,000 observations from our specified DGP by substituting random uniform numbers for $\tau$ in (1), with $\alpha = 1.5$, $k = 2$, $x = 1 + \sqrt{\nu}$, and $\nu$ coming from a $\chi^2(1)$ distribution.

We begin by executing the code that implements this method; below we discuss each line of the output produced.

```stata
.clear // drop existing variables
.set seed 1234571 // set random-number seed
.set obs 100000 // set number of observations
number of observations (_N) was 0, now 100,000
.generate double tau = runiform() // generate uniform variate
.generate double x = 1 + sqrt(rchi2(1)) // generate values for x
.generate double lambda = 1 + 1.5*x // lambda is 1 + alpha*x
.generate double k = 2 // fix value of k
.generate double y = lambda*((-ln(1-tau))^(1/k)) // generate random values for y

Although the comments at the end of each line briefly describe what each line is doing, we provide a more careful description. The first line drops any variables in memory. The second sets the seed of the random-number generator so that we will always get the same sequence of random uniform numbers. The third line sets the sample size to 100,000 observations, and the fourth line reports the change in sample size.

The fifth line substitutes random uniform numbers for $\tau$. This line is the key to the algorithm. This standard method, known as inverse-probability transforms, for computing random numbers is discussed by Cameron and Trivedi (2010, 126–127), among others.
Lines 6–8 generate $x$, $\lambda$, and $k$ per our specified DGP. Lines 9–11 implement (1) using the previously generated $\lambda$, $x$, and $k$.

At the end, we have 100,000 observations on $y$ and $x$, with $y$ coming from the conditional distribution that we specified above.

**Example 7**

In the example below, we use `qreg` to estimate $\beta_1$ and $\beta_0$, the parameters from the conditional quantile function, for the 0.5 quantile from our simulated data.

```
. qreg y x, quantile(.5)
```

Median regression

| Coef. Std. Err. | t                | P>|t| | [95% Conf. Interval] |
|-----------------|------------------|-----|----------------------|
| $x$             | 1.266062         | 0.0117759 | 107.51 | 0.000 | 1.242981 | 1.289143 |
| _cons           | 0.8083315        | 0.0222972 | 36.25 | 0.000 | 0.7646291 | 0.8520338 |

In the `qreg` output, the results for $x$ correspond to the estimate of $\beta_1$, and the results for _cons correspond to the estimate of $\beta_0$. The reported estimates are close to their true values of 1.248832 and 0.8325546, which are given in table 1.

The intuition in this example comes from the ability of `qreg` to recover the true parameters of our specified DGP. As we increase the number of observations in our sample size, the `qreg` estimates will get closer to the true values.
Example 8

In the example below, we estimate the parameters of the conditional quantile function for the 0.25 quantile and compare them with the true values.

```
. qreg y x, quantile(.25)
Iteration 1: WLS sum of weighted deviations = 65395.359
Iteration 1: sum of abs. weighted deviations = 65397.892
Iteration 2: sum of abs. weighted deviations = 52640.481
Iteration 3: sum of abs. weighted deviations = 50706.508
Iteration 4: sum of abs. weighted deviations = 49767.356
Iteration 5: sum of abs. weighted deviations = 49766.98
Iteration 6: sum of abs. weighted deviations = 49765.818
Iteration 7: sum of abs. weighted deviations = 49765.589
Iteration 8: sum of abs. weighted deviations = 49765.549
Iteration 9: sum of abs. weighted deviations = 49765.533
Iteration 10: sum of abs. weighted deviations = 49765.528
Iteration 11: sum of abs. weighted deviations = 49765.527
Iteration 12: sum of abs. weighted deviations = 49765.527
Iteration 13: sum of abs. weighted deviations = 49765.527

.25 Quantile regression
Number of obs = 100,000
Raw sum of deviations 51945.91 (about 1.8560913)
Min sum of deviations 49765.53 Pseudo R2 = 0.0420
```

|       | Coef.  | Std. Err. | t     | P>|t| | [95% Conf. Interval] |
|-------|--------|-----------|-------|------|----------------------|
| x     | .8207143 | .0106425  | 77.12 | 0.000 | .799855 -.8415735   |
| _cons | .5075988 | .0201512  | 25.19 | 0.000 | .4681026 .547095    |

As above, `qreg` reports the estimates of $\beta_1$ and $\beta_0$ in the output table for x and _cons, respectively. The reported estimates are close to their true values of 0.80454 and 0.53636, which are given in table 1. As expected, the estimates are close to their true values. Also as expected, the estimates for the 0.25 quantile are smaller than the estimates for the 0.5 quantile.
Example 9

We finish this section by estimating the parameters of the conditional quantile function for the 0.8 quantile and comparing them with the true values.

```
. qreg y x, quantile(.8)
Iteration 1: WLS sum of weighted deviations = 66126.751
Iteration 1: sum of abs. weighted deviations = 66130.001
Iteration 2: sum of abs. weighted deviations = 55084.287
Iteration 3: sum of abs. weighted deviations = 52914.276
Iteration 4: sum of abs. weighted deviations = 52101.59
Iteration 5: sum of abs. weighted deviations = 51899.426
Iteration 6: sum of abs. weighted deviations = 51898.269
Iteration 7: sum of abs. weighted deviations = 51898.268
Iteration 8: sum of abs. weighted deviations = 51898.267
```

```
.8 Quantile regression Number of obs = 100,000
Raw sum of deviations 60129.76 (about 4.7060381)
Min sum of deviations 51898.27 Pseudo R2 = 0.1369
```

```
|     | Coef.  | Std. Err. |    t  |    P>|t| | [95% Conf. Interval] |
|-----|--------|-----------|-------|-------|---------------------|
|   x | 1.911771 | 0.014834 | 128.88 | 0.000 | 1.882697, 1.940846  |
| _cons | 1.254583 | 0.0280877 | 44.67 | 0.000 | 1.199531, 1.309634  |
```

As above, `qreg` reports the estimates of $\beta_1$ and $\beta_0$ in the output table for `x` and `_cons`, respectively. The reported estimates are close to their true values of 1.902954 and 1.268636, which are given in table 1. As expected, the estimates are close to their true values. Also as expected, the estimates for the 0.8 quantile are larger than the estimates for the 0.5 quantile.
 Stored results

qreg stores the following in e():

Scalars
  e(N) number of observations
  e(df_m) model degrees of freedom
  e(df_r) residual degrees of freedom
  e(q) quantile requested
  e(q_val) value of the quantile
  e(sum_adev) sum of absolute deviations
  e(sum_rdev) sum of raw deviations
  e(sum_w) sum of weights
  e(f_r) density estimate
  e(sparsity) sparsity estimate
  e(bwidth) bandwidth
  e(kbwidth) kernel bandwidth
  e(rank) rank of e(V)
  e(convcode) 0 if converged; otherwise, return code for why nonconvergence

Macros
  e(cmd) qreg
  e(cmdline) command as typed
  e(depvar) name of dependent variable
  e(bwmethod) bandwidth method; hsheather, bofinger, or chamberlain
  e(demethod) density estimation method; fitted, residual, or kernel
  e(kernel) kernel function
  e(wtype) weight type
  e(wexp) weight expression
  e(vcetype) vcetyp specified in vce()
  e(properties) b V
  e(predict) program used to implement predict
  e(marginsnotok) predictions disallowed by margins
  e(asbalanced) factor variables fvset as asbalanced
  e(asobserved) factor variables fvset as asobserved

Matrices
  e(b) coefficient vector
  e(V) variance–covariance matrix of the estimators

Functions
  e(sample) marks estimation sample
iqreg stores the following in e():

Methods and formulas

Methods and formulas are presented under the following headings:

Introduction
Linear programming formulation of quantile regression
Standard errors when residuals are i.i.d.
Pseudo-\(R^2\)

Introduction

According to Stuart and Ord (1991, 1084), the method of minimum absolute deviations was first proposed by Boscovich in 1757 and was later developed by Laplace; Stigler (1986, 39–55) and Hald (1998, 97–103, 112–116) provide historical details. According to Bloomfield and Steiger (1980), Harris (1950) later observed that the problem of minimum absolute deviations could be turned into the linear programming problem that was first implemented by Wagner (1959). Interest has grown in this method because robust methods and extreme value modeling have become more popular. Statistical and computational properties of minimum absolute deviation estimators are surveyed by Narula and Wellington (1982). Cameron and Trivedi (2005), Hao and Naiman (2007), and Wooldridge (2010) provide excellent introductions to quantile regression methods, while Koenker (2005) gives an in-depth review of the topic.
Linear programming formulation of quantile regression

Define \( \tau \) as the quantile to be estimated; the median is \( \tau = 0.5 \). For each observation \( i \), let \( \varepsilon_i \) be the residual
\[
\varepsilon_i = y_i - x_i' \hat{\beta}_\tau
\]
The objective function to be minimized is
\[
c_\tau(\varepsilon_i) = (\tau \mathbf{1}\{ \varepsilon_i \geq 0 \} + (1 - \tau) \mathbf{1}\{ \varepsilon_i < 0 \}) |\varepsilon_i|
\]
\[
= (\tau \mathbf{1}\{ \varepsilon_i \geq 0 \} - (1 - \tau) \mathbf{1}\{ \varepsilon_i < 0 \}) \varepsilon_i
\]
\[
= (\tau - 1 \{ \varepsilon_i < 0 \}) \varepsilon_i
\]
where \( \mathbf{1}\{ \cdot \} \) is the indicator function. This function is sometimes referred to as the check function because it resembles a check mark (Wooldridge 2010, 450); the slope of \( c_\tau(\varepsilon_i) \) is \( \tau \) when \( \varepsilon_i > 0 \) and is \( \tau - 1 \) when \( \varepsilon_i < 0 \), but is undefined for \( \varepsilon_i = 0 \). Choosing the \( \hat{\beta}_\tau \) that minimize \( c_\tau(\varepsilon_i) \) is equivalent to finding the \( \hat{\beta}_\tau \) that make \( x \hat{\beta}_\tau \) best fit the quantiles of the distribution of \( y \) conditional on \( x \).

This minimization problem is set up as a linear programming problem and is solved with linear programming techniques, as suggested by Armstrong, Frome, and Kung (1979) and described in detail by Koenker (2005). Here \( 2n \) slack variables, \( u_{n \times 1} \) and \( v_{n \times 1} \), are introduced, where \( u_i \geq 0, v_i \geq 0, \) and \( u_i \times v_i = 0 \), reformulating the problem as
\[
\min_{\beta, u, v} \{ \tau \mathbf{1}_n^t u + (1 - \tau) \mathbf{1}_n^t v \mid y - X\beta = u - v \}
\]
where \( \mathbf{1}_n \) is a vector of 1s. This is a linear objective function on a polyhedral constraint set with \( \binom{n}{k} \) vertices, and our goal is to find the vertex that minimizes (2). Each step in the search is described by a set of \( k \) observations through which the regression plane passes, called the basis. A step is taken by replacing a point in the basis if the linear objective function can be improved. If this occurs, a line is printed in the iteration log. The definition of convergence is exact in the sense that no amount of added iterations could improve the objective function.

A series of weighted least-squares (WLS) regressions is used to identify a set of observations as a starting basis. The WLS algorithm for \( \tau = 0.5 \) is taken from Schlossmacher (1973) with a generalization for \( 0 < \tau < 1 \) implied from Hunter and Lange (2000).

Standard errors when residuals are i.i.d.

The estimator for the VCE implemented in \texttt{qreg} assumes that the errors of the model are independent and identically distributed (i.i.d.). When the errors are i.i.d., the large-sample VCE is
\[
\text{cov}(\beta_\tau) = \frac{\tau(1 - \tau)}{F_Y^{-1}(\xi_\tau)^2} \{E(x_i x_i')\}^{-1}
\]
where \( \xi_\tau = F_Y^{-1}(\tau) \) and \( F_Y(y) \) is the distribution function of \( Y \) with density \( f_Y(y) \). See Koenker (2005, 73) for this result. From (3), we see that the regression precision depends on the inverse of the density function, termed the sparsity function, \( s_\tau = 1/f_Y(\xi_\tau) \).

While \( 1/n \sum_{i=1}^n x_i x_i' \) estimates \( E(x_i x_i') \), estimating the sparsity function is more difficult. \texttt{qreg} provides several methods to estimate the sparsity function. The different estimators are specified through the suboptions of \texttt{vce(iid, denmethod bwidth)}. The suboption \texttt{denmethod} specifies the functional form for the sparsity estimator. The default is fitted.
Here we outline the logic underlying the fitted estimator. Because \( F_Y(y) \) is the distribution function for \( Y \), we have \( f_Y(y) = \{dF_Y(y)\}/dy \), \( \tau = F_Y(\xi_\tau) \), and \( \xi_\tau = F_Y^{-1}(\tau) \). When differentiating the identity \( F_Y\{F_Y^{-1}(\tau)\} = \tau \), the sparsity function can be written as \( s_\tau = \{F_Y^{-1}(\tau)\}/dt \).

Numerically, we can approximate the derivative using the centered difference,

\[
\frac{F_Y^{-1}(\tau)}{dt} \approx \frac{F_Y^{-1}(\tau + h) - F_Y^{-1}(\tau - h)}{2h} = \frac{\xi_{\tau+h} - \xi_{\tau-h}}{2h} = \hat{s}_\tau
\]

(4)

where \( h \) is the bandwidth.

The empirical quantile function is computed by first estimating \( \beta_{\tau+h} \) and \( \beta_{\tau-h} \), and then computing \( \hat{F}_\epsilon^{-1}(\tau + h) = \bar{x}'\hat{\beta}_{\tau+h} \) and \( \hat{F}_\epsilon^{-1}(\tau - h) = \bar{x}'\hat{\beta}_{\tau-h} \), where \( \bar{x} \) is the sample mean of the independent variables \( x \). These quantities are then substituted into (4).

Alternatively, as the option suggests, vce(iid, residual) specifies that qreg use the empirical quantile function of the residuals to estimate the sparsity. Here we substitute \( \hat{F}_\epsilon \), the distribution of the residuals, for \( F_Y \), which only differ by their first moments.

The \( k \) residuals associated with the linear programming basis will be zero, where \( k \) is the number of regression coefficients. These zero residuals are removed before computing the \( \tau + h \) and \( \tau - h \) quantiles, \( \varepsilon_{(\tau+h)} = \hat{F}_\epsilon^{-1}(\tau + h) \) and \( \varepsilon_{(\tau-h)} = \hat{F}_\epsilon^{-1}(\tau - h) \). The \( \hat{F}_\epsilon^{-1} \) estimates are then substituted for \( F_Y^{-1} \) in (4).

Each of the estimators for the sparsity function depends on a bandwidth. The vce() suboption bandwidth specifies the bandwidth method to use. The three bandwidth options and their citations are \( h.hsheather \) (Hall and Sheather 1988), \( h.bofinger \) (Bofinger 1975), and \( h.chamberlain \) (Chamberlain 1994).

Their formulas are

\[
h_s = n^{-1/3} \Phi^{-1} \left( 1 - \frac{\alpha}{2} \right)^{2/3} \left[ \frac{3}{2} \times \frac{\phi\{\Phi^{-1}(\tau)\}^4}{2\Phi^{-1}(\tau)^2 + 1} \right]^{1/3}
\]

\[
h_b = n^{-1/5} \left[ \frac{9}{2} \Phi\{2\Phi^{-1}(\tau)\}^4}{\{2\Phi^{-1}(\tau)^2 + 1\}^2} \right]^{1/5}
\]

\[
h_c = \Phi^{-1} \left( 1 - \frac{\alpha}{2} \right) \sqrt{\frac{\tau(1 - \tau)}{n}}
\]

where \( h_s \) is the Hall–Sheather bandwidth, \( h_b \) is the Bofinger bandwidth, \( h_c \) is the Chamberlain bandwidth, \( \Phi() \) and \( \phi() \) are the standard normal distribution and density functions, \( n \) is the sample size, and \( 100(1 - \alpha) \) is the confidence level set by the level() option. Koenker (2005) discusses the derivation of the Hall–Sheather and the Bofinger bandwidth formulas. You should avoid modifying the confidence level when replaying estimates that use the Hall–Sheather or Chamberlain bandwidths because these methods use the confidence level to estimate the coefficient standard errors.

Finally, the vce() suboption kernel(kernel) specifies that qreg use one of several kernel-density estimators to estimate the sparsity function. kernel allows you to choose which kernel function to use, where the default is the Epanechnikov kernel. See [R] kdensity for the functional form of the eight kernels.
The kernel bandwidth is computed using an adaptive estimate of scale

\[ h_k = \min \left( \hat{\sigma}, \frac{r_q}{1.34} \right) \times \left\{ \Phi^{-1}(\tau + h) - \Phi^{-1}(\tau - h) \right\} \]

where \( h \) is one of \( h_s, h_b, \) or \( h_c; \) \( r_q \) is the interquartile range; and \( \hat{\sigma} \) is the standard deviation of \( y; \) see Silverman (1986, 47) and Koenker (2005, 81) for discussions. Let \( \hat{f}_\epsilon(\varepsilon_i) \) be the kernel density estimate for the \( i \)th residual, and then the kernel estimator for the sparsity function is

\[ \hat{s}_\tau = \frac{nh_k}{\sum_{i=1}^{n} \hat{f}_\epsilon(\varepsilon_i)} \]

Finally, substituting your choice of sparsity estimate into (3) results in the i.i.d. variance–covariance matrix

\[ V_n = \hat{s}_\tau^2 (1 - \tau) \left( \sum_{i=1}^{n} x_i x_i' \right)^{-1} \]

Pseudo-\( R^2 \)

The pseudo-\( R^2 \) is calculated as

\[ 1 - \frac{\text{sum of weighted deviations about estimated quantile}}{\text{sum of weighted deviations about raw quantile}} \]

This is based on the likelihood for a double-exponential distribution \( e^{v_i |\varepsilon_i|} \), where \( v_i \) are multipliers

\[ v_i = \begin{cases} \tau & \text{if } \varepsilon_i > 0 \\ (1 - \tau) & \text{otherwise} \end{cases} \]

Minimizing the objective function (2) with respect to \( \beta_\tau \) also minimizes \( \sum_i |\varepsilon_i| v_i \), the sum of weighted least absolute deviations. For example, for the 50th percentile \( v_i = 1 \), for all \( i \), and we have median regression. If we want to estimate the 75th percentile, we weight the negative residuals by 0.25 and the positive residuals by 0.75. It can be shown that the criterion is minimized when 75% of the residuals are negative.

* `hausman` is not appropriate after `bsqreg`, `isqreg`, or `sqreg`.
† `forecast` is not appropriate with `mi` estimation results.
predict

Description for predict

predict creates a new variable containing predictions such as linear predictions, standard errors, and residuals.

Menu for predict

Statistics > Postestimation

Syntax for predict

For qreg, iqreg, and bsqreg

\texttt{predict [\textit{type}] newvar [\textit{if}] [\textit{in}], [\textit{xb|stdp|residuals}]}]

For sqreg

\texttt{predict [\textit{type}] newvar [\textit{if}] [\textit{in}], equation(eqno[,eqno]) statistic]}

statistic Description

Main
\texttt{xb} linear prediction; the default
\texttt{stdp} standard error of the linear prediction
\texttt{stddp} standard error of the difference in linear predictions
\texttt{residuals} residuals

These statistics are available both in and out of sample; type \texttt{predict ... if e(sample)} ... if wanted only for the estimation sample.

Options for predict

\texttt{xb}, the default, calculates the linear prediction.
\texttt{stdp} calculates the standard error of the linear prediction.
\texttt{stddp} is allowed only after you have fit a model using \texttt{sqreg}. The standard error of the difference in linear predictions (x_{1j} \cdot b - x_{2j} \cdot b) between equations 1 and 2 is calculated.
\texttt{residuals} calculates the residuals, that is, y_j - x_j \cdot b.

\texttt{equation(eqno[,eqno])} specifies the equation to which you are making the calculation.

\texttt{equation()} is filled in with one \textit{eqno} for the \texttt{xb}, \texttt{stdp}, and \texttt{residuals} options. \texttt{equation(#1)} would mean that the calculation is to be made for the first equation, \texttt{equation(#2)} would mean the second, and so on. You could also refer to the equations by their names. \texttt{equation(income)} would refer to the equation named income and \texttt{equation(hours)} to the equation named hours.

If you do not specify \texttt{equation()}, results are the same as if you had specified \texttt{equation(#1)}.

To use \texttt{stddp}, you must specify two equations. You might specify \texttt{equation(#1, #2)} or \texttt{equation(q80, q20)} to indicate the 80th and 20th quantiles.
margins

Description for margins

margins estimates margins of response for linear predictions.

Menu for margins

Statistics  >  Postestimation

Syntax for margins

margins [marginlist] [ , options ]
margins [marginlist] , predict(statistic ...) [options]

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>xb</td>
<td>linear prediction; the default</td>
</tr>
<tr>
<td>stdp</td>
<td>not allowed with margins</td>
</tr>
<tr>
<td>stddp</td>
<td>not allowed with margins</td>
</tr>
<tr>
<td>residuals</td>
<td>not allowed with margins</td>
</tr>
</tbody>
</table>

Statistics not allowed with margins are functions of stochastic quantities other than e(b).

For the full syntax, see [R] margins.

Remarks and examples

Example 1

In example 4 of [R] qreg, we fit regressions for the lower and the upper quartile of the price variable. The predict command can be used to obtain the linear prediction after each regression.

```
. use https://www.stata-press.com/data/r16/auto
(1978 Automobile Data)
. qreg price weight length foreign, quantile(.25)          (output omitted)
. predict q25                                               (option xb assumed; fitted values)
. qreg price weight length foreign, quantile(.75)          (output omitted)
. predict q75                                               (option xb assumed; fitted values)

. generate iqr1 = q75 - q25
```

We can use the variables generated by predict to compute the predicted interquartile range, that is,

```
. generate iqr1 = q75 - q25
```

If we directly perform the interquartile range regression with the iqreg command, we can predict the interquartile range and also the standard error for the prediction.
. iqreg price weight length foreign, quantile(.25 .75)
   (output omitted)
. predict iqr2
   (option xb assumed; fitted values)
. predict stdp, stdp

We now plot the predicted interquartile range versus variable length:

. scatter iqr2 length

As stated in example 5 of [R] qreg, the negative coefficient for the length variable means that increases in length imply decreases in the interquartile range and therefore in price dispersion. Consequently, we could have expected a downward trend in the plot, but there is not. This is because the regression output indicates that when we hold the rest of the variables constant, an increase in length leads to a decrease in iqr2. However, there is a high correlation between weight and length, which could be masking the effect of length on iqr2. We can achieve a better visualization by using a contour plot.
We can see the effect by setting a fixed value of length on the vertical axis, say, 3,000 lbs. When we move from left to right on the horizontal axis, we see that for small values of length, iqr2 values are shown in red, meaning high values, and when we move toward the right, the graph indicates transition into increasingly smaller values.

query — Display system parameters

Description
query displays the settings of various Stata parameters.

Syntax
```
query [ memory | output | interface | graphics | network |
       update | trace | mata | java | python | random | unicode | other ]
```

Remarks and examples
query provides more system information than you will ever want to know. You do not need to understand every line of output that query produces if all you need is one piece of information. Here is what happens when you type query:

```
. query

Memory settings
  set maxvar 5000 2048-32767; max. vars allowed
  set niceness 5 0-10
  set min_memory 0 0-1600g
  set max_memory . 32m-1600g or .
  set segmentsize 32m 1m-32g
  set adosize 1000 kilobytes
  set max_preservemem 1g 0-1600g

Output settings
  set more off
  set rmsg off
  set dp period may be period or comma
  set linesize 79 characters
  set pagesize 28 lines

  set iterlog on

  set level 95 percent confidence intervals
  set clevel 95 percent credible intervals

  set showbaselevels may be empty, off, on, or all
  set showemptycells may be empty, off, or on
  set showomitted may be empty, off, or on
  set fvlabel on
  set fvwrap 1
  set fvwrapon word may be word or width

  set lstretch may be empty, off, or on
```
set cformat may be empty or a numerical format
set pformat may be empty or a numerical format
set sformat may be empty or a numerical format

set coeftabresults on
set dots on

set logtype smcl may be smcl or text

---

Interface settings
set dockable on
set floatwindows off
set locksplitters off
set pinnable on
set doublebuffer on

set linegap 1 pixels
set scrollbufsize 200000 characters
set fastscroll on
set reventries 5000 lines

set maxdb 50 dialog boxes

---

Graphics settings
set graphics on
set autotabgraphs off
set scheme s2color
set printcolor automatic may be automatic, asis, gs1, gs2, gs3
set copycolor automatic may be automatic, asis, gs1, gs2, gs3

---

Network settings
set checksum off
set timeout1 30 seconds
set timeout2 180 seconds

set httpproxy off
set httpproxyhost
set httpproxyport 80

set httpproxyauth off
set httpproxyuser
set httpproxywpw

---

Update settings
set update_query on
set update_interval 7
set update_prompt on

---

Trace (programming debugging) settings
set trace off
set tracedepth 32000
set traceexpand on
set tracesep on
set traceindent on
set tracenumber off
set tracehilite

---

Mata settings
set matastrict off
set matalnum off
set mataoptimize on
set matafavor space may be space or speed
The output is broken into several divisions: memory, output, interface, graphics, network, update, trace, mata, random, unicode, and other settings. We will discuss each one in turn.

We generated the output above using Stata/MP for Windows. Here is what happens when we type `query` and we are running Stata/SE for Mac:

```
. query
```

copycolor [G-2] set printcolor
```

Network settings

Network settings determine how Stata interacts with the Internet.

For more information, see [R] netio.

Update settings

Update settings determine how Stata performs updates.

For more information, see [R] update.

Trace settings

Trace settings adjust Stata’s behavior and are particularly useful in debugging code.

For more information, see [P] trace.
Mata settings

Mata settings affect Mata’s system parameters.
For more information, see [M-3] mata set.

Java settings

Java settings control the Java Runtime Environment.
For more information, see [P] Java utilities.

Python settings

Python settings control the version and search paths of Python.
For more information, see [P] python.

Random settings

The random settings set Stata’s random number generators.
For more information, see [R] set rng, [R] set seed (set rngstate), and [R] set rngstream.

Unicode settings

Unicode settings affect Stata’s localization package for the user interface.
For more information, see [P] set locale_ui and [P] set locale_functions.

Other settings

The other settings are a miscellaneous collection.

[P] creturn — Return c-class values
**Description**

`ranksum` tests the hypothesis that two independent samples (that is, *unmatched* data) are from populations with the same distribution by using the Wilcoxon rank-sum test, which is also known as the Mann–Whitney two-sample statistic (*Wilcoxon* 1945; *Mann* and *Whitney* 1947).

`median` performs a nonparametric *k*-sample test on the equality of medians. It tests the null hypothesis that the *k* samples were drawn from populations with the same median. For two samples, the chi-squared test statistic is computed both with and without a continuity correction.

`ranksum` and `median` are for use with *unmatched* data. For equality tests on matched data, see [R] `signrank`.

**Quick start**

**Wilcoxon rank-sum test**

Test for equality of distributions of `v` over two groups defined by the levels of `catvar1`

```
ranksum v, by(catvar1)
```

Compute an exact *p*-value for the Wilcoxon rank-sum test

```
ranksum v, by(catvar1) exact
```

Estimate the probability that a case from the first level of `catvar1` has a greater value of `v` than a case from the second level of `catvar1`

```
ranksum v, by(catvar1) porder
```

**Nonparametric equality-of-medians test**

Equality of medians test for `v` over two or more groups defined by the levels of `catvar2`

```
median v, by(catvar2)
```

Also report Fisher’s exact test

```
median v, by(catvar2) exact
```

As above, but split cases at the median evenly between the above and below groups

```
median v, by(catvar2) exact medianties(split)
```

ranksum
Statistics > Nonparametric analysis > Tests of hypotheses > Wilcoxon rank-sum test

median
Statistics > Nonparametric analysis > Tests of hypotheses > K-sample equality-of-medians test

Syntax

Wilcoxon rank-sum test

\texttt{ranksum varname [if] [in], by(groupvar) [exact porder]}

Nonparametric equality-of-medians test

\texttt{median varname [if] [in] [weight], by(groupvar) [median_options]}

\begin{tabular}{ll}
\textbf{ranksum options} & \textbf{Description} \\
\hline
Main & \\
* \texttt{by(groupvar)} & grouping variable \\
exact & report exact \textit{p}-value for rank-sum test; by default, exact \textit{p}-value is computed when total sample size \leq 200 \\
porder & probability that variable for first group is larger than variable for second group \\
\hline
\textbf{median options} & \textbf{Description} \\
Main & \\
* \texttt{by(groupvar)} & grouping variable \\
exact & report \textit{p}-value from Fisher’s exact test \\
\texttt{medianties(below)} & assign values equal to the median to below group \\
\texttt{medianties(above)} & assign values equal to the median to above group \\
\texttt{medianties(drop)} & drop values equal to the median from the analysis \\
\texttt{medianties(split)} & split values equal to the median equally between the two groups \\
\hline
\end{tabular}

*\texttt{by(groupvar)} is required.

by is allowed with \texttt{ranksum} and \texttt{median}; see [D] by.

fweights are allowed with \texttt{median}; see [U] 11.1.6 weight.
Options for ranksum

by(groupvar) is required. It specifies the name of the grouping variable.

exact specifies that the exact $p$-value be computed in addition to the approximate $p$-value. The exact $p$-value is based on the actual randomization distribution of the test statistic. The approximate $p$-value is based on a normal approximation to the randomization distribution. By default, the exact $p$-value is computed for sample sizes $n = n_1 + n_2 \leq 200$ because the normal approximation may not be precise in small samples. The exact computation can be suppressed by specifying noexact. For sample sizes larger than 200, you must specify exact to compute the exact $p$-value. The exact computation is available for sample sizes $n \leq 1000$. As the sample size approaches 1,000, the computation takes significantly longer.

porder displays an estimate of the probability that a random draw from the first population is larger than a random draw from the second population.

Options for median

by(groupvar) is required. It specifies the name of the grouping variable.

exact displays the $p$-value calculated by Fisher’s exact test. For two samples, both one- and two-sided $p$-values are displayed.

medianties(below | above | drop | split) specifies how values equal to the overall median are to be handled. The median test computes the median for varname by using all observations and then divides the observations into those falling above the median and those falling below the median. When values for an observation are equal to the sample median, they can be dropped from the analysis by specifying medianties(drop); added to the group above or below the median by specifying medianties(above) or medianties(below), respectively; or if there is more than 1 observation with values equal to the median, they can be equally divided into the two groups by specifying medianties(split). If this option is not specified, medianties(below) is assumed.

Remarks and examples

Example 1

We are testing the effectiveness of a new fuel additive. We run an experiment with 24 cars: 12 cars with the fuel treatment and 12 cars without. We input these data by creating a dataset with 24 observations. mpg records the mileage rating, and treat records 0 if the mileage corresponds to untreated fuel and 1 if it corresponds to treated fuel.
. use https://www.stata-press.com/data/r16/fuel2
. ranksum mpg, by(treat)

Two-sample Wilcoxon rank-sum (Mann-Whitney) test

<table>
<thead>
<tr>
<th>treat</th>
<th>obs</th>
<th>rank sum</th>
<th>expected</th>
</tr>
</thead>
<tbody>
<tr>
<td>untreated</td>
<td>12</td>
<td>128</td>
<td>150</td>
</tr>
<tr>
<td>treated</td>
<td>12</td>
<td>172</td>
<td>150</td>
</tr>
<tr>
<td>combined</td>
<td>24</td>
<td>300</td>
<td>300</td>
</tr>
</tbody>
</table>

unadjusted variance 300.00
adjustment for ties -4.04

adjusted variance 295.96

Ho: mpg(treat==untreated) = mpg(treat==treated)
   z = -1.279
   Prob > |z| = 0.2010
   Exact Prob = 0.2117

Because the total sample is only 24 cars, the exact p-value is computed by default. If the sample size were greater than 200, we would have to specify the exact option if we wanted the exact p-value computed.

Despite the small sample size, the p-value computed using a normal approximation, 0.2010, is similar to the exact p-value, 0.2117. These results indicate that the distributions are not statistically different at a 0.05 significance level.

Similarly, the median test,

. median mpg, by(treat) exact

Median test

<table>
<thead>
<tr>
<th>Greater than the median</th>
<th>whether car received fuel additive</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>untreated</td>
<td>treated</td>
</tr>
<tr>
<td>no</td>
<td>7</td>
<td>5</td>
</tr>
<tr>
<td>yes</td>
<td>5</td>
<td>7</td>
</tr>
<tr>
<td>Total</td>
<td>12</td>
<td>12</td>
</tr>
</tbody>
</table>

Pearson ch2(1) = 0.6667 Pr = 0.414
Fisher’s exact = 0.684
1-sided Fisher’s exact = 0.342
Continuity corrected:
Pearson ch2(1) = 0.1667 Pr = 0.683

fails to reject the null hypothesis that there is no difference between the fuel with the additive and the fuel without the additive.

Compare these results from these two tests with those obtained from the signrank and signtest where we found significant differences; see [R] signrank. An experiment run on 24 different cars is not as powerful as a before-and-after comparison using the same 12 cars.
ranksum — Equality tests on unmatched data

Stored results

ranksum stores the following in r():

Scalars
- r(N) sample size
- r(N_1) sample size of first group
- r(N_2) sample size of second group
- r(z) z statistic
- r(Var_a) adjusted variance
- r(group1) value of variable for first group
- r(sum_obs) observed sum of ranks for first group
- r(sum_exp) expected sum of ranks for first group
- r(p) two-sided p-value from normal approximation
- r(p_l) lower one-sided p-value from normal approximation
- r(p_u) upper one-sided p-value from normal approximation
- r(p_exact) two-sided exact p-value
- r(p_l_exact) lower one-sided exact p-value
- r(p_u_exact) upper one-sided exact p-value
- r(porder) probability that draw from first population is larger than draw from second population

median stores the following in r():

Scalars
- r(N) sample size
- r(chi2) Pearson’s \( \chi^2 \)
- r(chi2_cc) continuity-corrected Pearson’s \( \chi^2 \)
- r(groups) number of groups compared
- r(p) p-value for Pearson’s \( \chi^2 \) test
- r(p_cc) continuity-corrected p-value
- r(p_exact) Fisher’s exact p-value
- r(p1_exact) one-sided Fisher’s exact p-value

Methods and formulas

For a practical introduction to these techniques with an emphasis on examples rather than theory, see Acock (2018), Bland (2015), or Sprent and Smeeton (2007). For a summary of these tests, see Snedecor and Cochran (1989).

Methods and formulas are presented under the following headings:

- ranksum
- median

ranksum

For the Wilcoxon rank-sum test, there are two independent random variables, \( X_1 \) and \( X_2 \), and we test the null hypothesis that \( X_1 \sim X_2 \). We have a sample of size \( n_1 \) from \( X_1 \) and another of size \( n_2 \) from \( X_2 \).

The data are then ranked without regard to the sample to which they belong. If the data are tied, averaged ranks are used. Wilcoxon’s test statistic (1945) is the sum of the ranks for the observations in the first sample:

\[
T = \sum_{i=1}^{n_1} R_{1i}
\]
Mann and Whitney’s $U$ statistic (1947) is the number of pairs $(X_{1i}, X_{2j})$ such that $X_{1i} > X_{2j}$. These statistics differ only by a constant:

$$U = T - \frac{n_1(n_1 + 1)}{2}$$

Fisher’s principle of randomization provides a method for calculating the distribution of the test statistic. The randomization distribution consists of all the possible values of $T$ resulting from the $\binom{n}{n_1}$ ways to choose $n_1$ ranks from the set of all $n = n_1 + n_2$ observed ranks (untied or tied) and assign them to the first sample. When the exact option is specified (or implied for $n \leq 200$), this distribution is computed using a recursive algorithm whose computational time is proportional to $n^4$. (See Fisher [1935] for the principle of randomization; Wilcoxon, Katti, and Wilcox [1970] for the computation with untied ranks; and Hill and Peto [1971] for the general recursive algorithm.)

$p$-values can also be computed using a normal approximation to the randomization distribution. It is a straightforward exercise to verify that

$$E(T) = \frac{n_1(n + 1)}{2} \quad \text{and} \quad \text{Var}(T) = \frac{n_1n_2s^2}{n}$$

where $s$ is the standard deviation of the combined ranks, $r_i$, for both groups:

$$s^2 = \frac{1}{n-1} \sum_{i=1}^{n} (r_i - \bar{r})^2$$

This formula for the variance is exact and holds both when there are no ties and when there are ties and we use averaged ranks. (Indeed, the variance formula holds for the randomization distribution of choosing $n_1$ numbers from any set of $n$ numbers.)

For the normal approximation, we calculate

$$z = \frac{T - E(T)}{\sqrt{\text{Var}(T)}}$$

When the porder option is specified, the probability

$$p = \frac{U}{n_1n_2}$$

is computed.

⚠️ Technical note

We follow the great majority of the literature in naming these tests for Wilcoxon, Mann, and Whitney. However, they were independently developed by several other researchers in the late 1940s and early 1950s. In addition to Wilcoxon, Mann, and Whitney, credit is due to Festinger (1946), Whitfield (1947), Haldane and Smith (1947), and Van der Reyden (1952). Leon Festinger (1919–1989), John Burdon Sanderson Haldane (1892–1964), and Cedric Austen Bardell Smith (1917–2002) are well known for other work, but little seems to be known about Whitfield or van der Reyden. For a detailed study, including information on these researchers, see Berry, Mielke, and Johnston (2012).
The median test examines whether it is likely that two or more samples came from populations with the same median. The null hypothesis is that the samples were drawn from populations with the same median. The alternative hypothesis is that at least one sample was drawn from a population with a different median. The test should be used only with ordinal or interval data.

Assume that there are score values for \( k \) independent samples to be compared. The median test is performed by first computing the median score for all observations combined, regardless of the sample group. Each score is compared with this computed grand median and is classified as being above the grand median, below the grand median, or equal to the grand median. Observations with scores equal to the grand median can be dropped, added to the “above” group, added to the “below” group, or split between the two groups.

Once all observations are classified, the data are cast into a \( 2 \times k \) contingency table, and a Pearson’s chi-squared test or Fisher’s exact test is performed.

Henry Berthold Mann (1905–2000) was born in Vienna, Austria, where he completed a doctorate in algebraic number theory. He moved to the United States in 1938 and for several years made his livelihood by tutoring in New York. During this time, he proved a celebrated conjecture in number theory and studied statistics at Columbia with Abraham Wald, with whom he wrote three papers. After the war, he taught at Ohio State and the Universities of Wisconsin and Arizona. In addition to his work in number theory and statistics, he made major contributions to algebra and combinatorics.

Donald Ransom Whitney (1915–2007) studied at Oberlin, Princeton, and Ohio State Universities and worked at the latter throughout his career. His PhD thesis under Henry Mann was on nonparametric statistics. It was this work that produced the test that bears their names.

[R] `signrank` — Equality tests on matched data

[R] `ttest` — *t* tests (mean-comparison tests)
ratio — Estimate ratios

Description

ratio produces estimates of ratios, along with standard errors.

Quick start

Estimate, standard error, and 95% confidence interval for the ratio of \( v_1 \) to \( v_2 \)
\[
\text{ratio } v_1/v_2
\]

With bootstrap standard errors
\[
\text{ratio } v_1/v_2, \ vce(\text{bootstrap})
\]

Ratios of \( v_1 \) to \( v_2 \) and \( v_3 \) to \( v_2 \)
\[
\text{ratio } (v_1/v_2) \ (v_3/v_2)
\]

As above, but name the ratios \( \text{ratio1} \) and \( \text{ratio2} \)
\[
\text{ratio } (\text{ratio1}: \ v_1/v_2) \ (\text{ratio2}: \ v_3/v_2)
\]

Test that \( \text{ratio1} \) is equal to \( \text{ratio2} \)
\[
\text{test } \text{ratio1} = \text{ratio2}
\]

Ratio of \( v_1 \) to \( v_2 \) over strata defined by levels of \( s\text{var} \)
\[
\text{ratio } v_1/v_2, \ over(s\text{var})
\]

Direct standardization across categories \( c\text{var} \), weighting by standardization weight \( w\text{var} \)
\[
\text{ratio } v_1/v_2, \ stdize(c\text{var}) \ stdweight(w\text{var})
\]

bootstrap, jackknife, mi estimate, rolling, statsby, and svy are allowed; see [U] 11.1.10 Prefix commands. vce(bootstrap) and vce(jackknife) are not allowed with the mi estimate prefix; see [MI] mi estimate. Weights are not allowed with the bootstrap prefix; see [R] bootstrap. vce() and weights are not allowed with the svy prefix; see [SVY] svy. fweights, iweights, and pweights are allowed; see [U] 11.1.6 weight. coeflegend does not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.
Options

\textbf{Model}

\texttt{stdize(varname)} specifies that the point estimates be adjusted by direct standardization across the strata identified by \textit{varname}. This option requires the \texttt{stdweight()} option.

\texttt{stdweight(varname)} specifies the weight variable associated with the standard strata identified in the \texttt{stdize()} option. The standardization weights must be constant within the standard strata.

\texttt{nostdrescale} prevents the standardization weights from being rescaled within the \texttt{over()} groups. This option requires \texttt{stdize()} but is ignored if the \texttt{over()} option is not specified.

\textbf{if/in/over}

\texttt{over(varlist)} specifies that estimates be computed for multiple subpopulations, which are identified by the different values of the variables in \textit{varlist}. Only numeric, nonnegative, integer-valued variables are allowed in \texttt{over(varlist)}.

\textbf{SE/Cluster}

\texttt{vce(vcetype)} specifies the type of standard error reported, which includes types that are derived from asymptotic theory (\texttt{linearized}), that allow for intragroup correlation (\texttt{cluster clustvar}), and that use bootstrap or jackknife methods (\texttt{bootstrap, jackknife}); see \texttt{[R] vce_option}.

\texttt{vce(linearized)}, the default, uses the linearized or sandwich estimator of variance.

\textbf{Reporting}

\texttt{level(#)}; see \texttt{[R] Estimation options}.

\texttt{noheader} prevents the table header from being displayed. This option implies \texttt{nolegend}.

\texttt{nolegend} prevents the table legend identifying the ratios from being displayed.

\textit{display_options}: \texttt{vsquish, noemptycells, nofylabel, fvwrap(#), fvwrapon(style), cformat(\%fmt), and nolstretch}; see \texttt{[R] Estimation options}.

The following option is available with \texttt{ratio} but is not shown in the dialog box: \texttt{coeflegend}; see \texttt{[R] Estimation options}. 

Remarks and examples

Example 1

Using the fuel data from example 3 of [R] ttest, we estimate the ratio of mileage for the cars without the fuel treatment (mpg1) to those with the fuel treatment (mpg2).

```
. use https://www.stata-press.com/data/r16/fuel
. ratio myratio: mpg1/mpg2
Ratio estimation Number of obs = 12

myratio: mpg1/mpg2

<table>
<thead>
<tr>
<th></th>
<th>Linearized</th>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Ratio</td>
<td>Std. Err.</td>
<td>[95% Conf. Interval]</td>
<td></td>
</tr>
<tr>
<td>myratio</td>
<td>.9230769</td>
<td>.032493</td>
<td>.8515603</td>
<td>.9945936</td>
</tr>
</tbody>
</table>
```

Using these results, we can test to see if this ratio is significantly different from one.

```
. test myratio = 1
( 1) myratio = 1
  F( 1, 11) = 5.60
  Prob > F = 0.0373
```

We find that the ratio is different from one at the 5% significance level but not at the 1% significance level.

Example 2

Using state-level census data, we want to test whether the marriage rate is equal to the death rate.

```
. use https://www.stata-press.com/data/r16/census2
(1980 Census data by state)
. ratio (deathrate: death/pop) (marrate: marriage/pop)
Ratio estimation Number of obs = 50

deathrate: death/pop
marrate: marriage/pop

<td>.0118005</td>
</tr>
</tbody>
</table>
```

```
. test deathrate = marrate
( 1) deathrate - marrate = 0
  F( 1, 49) = 6.93
  Prob > F = 0.0113
```

Stored results

`ratio` stores the following in `e()`:

Scalars
- `e(N)` number of observations
- `e(N_over)` number of subpopulations
- `e(N_stsize)` number of standard strata
- `e(N_clust)` number of clusters
- `e(k_eq)` number of equations in `e(b)`
- `e(df_r)` sample degrees of freedom
- `e(rank)` rank of `e(V)`

Macros
- `e(cmd)` `ratio`
- `e(cmdline)` command as typed
- `e(varlist)` `varlist`
- `e(stdize)` `varname` from `stdize()`
- `e(stdweight)` `varname` from `stdweight()`
- `e(wtype)` weight type
- `e(wexp)` weight expression
- `e(title)` title in estimation output
- `e(clustvar)` name of cluster variable
- `e(over)` `varlist` from `over()`
- `e(namelist)` ratio identifiers
- `e(vcexp)` `vcetype` specified in `vce()`
- `e(vcetype)` title used to label Std. Err.
- `e(properties)` `b` `V`
- `e(estat_cmd)` program used to implement `estat`
- `e(marginsnotok)` predictions disallowed by `margins`

Matrices
- `e(b)` vector of ratio estimates
- `e(V)` (co)variance estimates
- `e(_N)` vector of numbers of nonmissing observations
- `e(_N_stsize)` number of nonmissing observations within the standard strata
- `e(_p_stsize)` standardizing proportions
- `e(error)` error code corresponding to `e(b)`

Functions
- `e(sample)` marks estimation sample

Methods and formulas

Methods and formulas are presented under the following headings:

`The ratio estimator`
`Survey data`
`The survey ratio estimator`
`The standardized ratio estimator`
`The poststratified ratio estimator`
`The standardized poststratified ratio estimator`
`Subpopulation estimation`

The ratio estimator

Let $R = Y / X$ be the ratio to be estimated, where $Y$ and $X$ are totals; see [R] `total`. The estimate for $R$ is $\hat{R} = \hat{Y} / \hat{X}$ (the ratio of the sample totals). From the delta method (that is, a first-order Taylor expansion), the approximate variance of the sampling distribution of the linearized $\hat{R}$ is
\[ V(\hat{R}) \approx \frac{1}{\hat{X}^2} \left\{ V(\hat{Y}) - 2R\text{Cov}(\hat{Y}, \hat{X}) + R^2V(\hat{X}) \right\} \]

Direct substitution of \( \hat{X} \), \( \hat{R} \), and the estimated variances and covariance of \( \hat{X} \) and \( \hat{Y} \) leads to the following variance estimator:

\[ \hat{V}(\hat{R}) = \frac{1}{\hat{X}^2} \left\{ \hat{V}(\hat{Y}) - 2\hat{R}\hat{R}\text{Cov}(\hat{Y}, \hat{X}) + \hat{R}^2\hat{V}(\hat{X}) \right\} \] (1)

**Survey data**

See [SVY] Variances estimation, [SVY] Direct standardization, and [SVY] Poststratification for discussions that provide background information for the following formulas.

**The survey ratio estimator**

Let \( Y_j \) and \( X_j \) be survey items for the \( j \)th individual in the population, where \( j = 1, \ldots, M \) and \( M \) is the size of the population. The associated population ratio for the items of interest is \( R = Y/X \) where

\[ Y = \sum_{j=1}^{M} Y_j \quad \text{and} \quad X = \sum_{j=1}^{M} X_j \]

Let \( y_j \) and \( x_j \) be the corresponding survey items for the \( j \)th sampled individual from the population, where \( j = 1, \ldots, m \) and \( m \) is the number of observations in the sample.

The estimator \( \hat{R} \) for the population ratio \( R \) is \( \hat{R} = \hat{Y}/\hat{X} \), where

\[ \hat{Y} = \sum_{j=1}^{m} w_jy_j \quad \text{and} \quad \hat{X} = \sum_{j=1}^{m} w_jx_j \]

and \( w_j \) is a sampling weight. The score variable for the ratio estimator is

\[ z_j(\hat{R}) = \frac{y_j - \hat{R}x_j}{\hat{X}} = \frac{\hat{X}y_j - \hat{Y}x_j}{\hat{X}^2} \]

**The standardized ratio estimator**

Let \( D_g \) denote the set of sampled observations that belong to the \( g \)th standard stratum and define \( I_{D_g}(j) \) to indicate if the \( j \)th observation is a member of the \( g \)th standard stratum; where \( g = 1, \ldots, L_D \) and \( L_D \) is the number of standard strata. Also, let \( \pi_g \) denote the fraction of the population that belongs to the \( g \)th standard stratum, thus \( \pi_1 + \cdots + \pi_{L_D} = 1 \). Note that \( \pi_g \) is derived from the stdweight() option.

The estimator for the standardized ratio is

\[ \hat{R}^D = \sum_{g=1}^{L_D} \pi_g \frac{\hat{Y}_g}{\hat{X}_g} \]
where
\[ \hat{Y}_g = \sum_{j=1}^{m} I_{Dg}(j) w_j y_j \]
and \( \hat{X}_g \) is similarly defined. The score variable for the standardized ratio is
\[ z_j(\hat{R}^D) = \sum_{g=1}^{L_D} \pi_g I_{Dg}(j) \frac{\hat{X}_g y_j - \hat{Y}_g x_j}{\hat{X}_g^2} \]

The poststratified ratio estimator

Let \( P_k \) denote the set of sampled observations that belong to poststratum \( k \), and define \( I_{P_k}(j) \) to indicate if the \( j \)th observation is a member of poststratum \( k \), where \( k = 1, \ldots, L_P \) and \( L_P \) is the number of poststrata. Also, let \( M_k \) denote the population size for poststratum \( k \). \( P_k \) and \( M_k \) are identified by specifying the \texttt{poststrata()} and \texttt{postweight()} options on \texttt{svyset}; see \texttt{[SVY] svyset}.

The estimator for the poststratified ratio is
\[ \hat{R}^P = \frac{\hat{Y}^P}{\hat{X}^P} \]
where
\[ \hat{Y}^P = \sum_{k=1}^{L_P} \frac{M_k}{\hat{M}_k} \hat{Y}_k = \sum_{k=1}^{L_P} \frac{M_k}{\hat{M}_k} \sum_{j=1}^{m} I_{P_k}(j) w_j y_j \]
and \( \hat{X}^P \) is similarly defined. The score variable for the poststratified ratio is
\[ z_j(\hat{R}^P) = \frac{z_j(\hat{Y}^P) - \hat{R}^P z_j(\hat{X}^P)}{\hat{X}^P} = \frac{\hat{X}^P z_j(\hat{Y}^P) - \hat{Y}^P z_j(\hat{X}^P)}{(\hat{X}^P)^2} \]
where
\[ z_j(\hat{Y}^P) = \sum_{k=1}^{L_P} I_{P_k}(j) \frac{M_k}{\hat{M}_k} \left( y_j - \frac{\hat{Y}_k}{\hat{M}_k} \right) \]
and \( z_j(\hat{X}^P) \) is similarly defined.

The standardized poststratified ratio estimator

The estimator for the standardized poststratified ratio is
\[ \hat{R}^{DP} = \sum_{g=1}^{L_D} \pi_g \frac{\hat{Y}_g^P}{\hat{X}_g^P} \]
where
\[ \hat{Y}_g^P = \sum_{k=1}^{L_P} \frac{M_k}{\hat{M}_k} \hat{Y}_{g,k} = \sum_{k=1}^{L_P} \frac{M_k}{\hat{M}_k} \sum_{j=1}^{m} I_{Dg}(j) I_{P_k}(j) w_j y_j \]
and $\hat{X}_g^P$ is similarly defined. The score variable for the standardized poststratified ratio is

$$
Z_j(\hat{R}_{DP}^P) = \sum_{g=1}^{L_D} \pi_g \frac{\hat{X}_g^P z_j(\hat{Y}_g^P) - \hat{Y}_g^P z_j(\hat{X}_g^P)}{\hat{X}_g^P}
$$

where

$$
Z_j(\hat{Y}_g^P) = \sum_{k=1}^{L_P} I_{P_k}(j) \frac{M_k}{M_k} \left\{ I_{D_g}(j) y_j - \hat{Y}_{g,k} \right\}
$$

and $z_j(\hat{X}_g^P)$ is similarly defined.

**Subpopulation estimation**

Let $S$ denote the set of sampled observations that belong to the subpopulation of interest, and define $I_S(j)$ to indicate if the $j$th observation falls within the subpopulation.

The estimator for the subpopulation ratio is $\hat{R}^S = \hat{Y}^S / \hat{X}^S$, where

$$
\hat{Y}^S = \sum_{j=1}^{m} I_S(j) w_j y_j \quad \text{and} \quad \hat{X}^S = \sum_{j=1}^{m} I_S(j) w_j x_j
$$

Its score variable is

$$
Z_j(\hat{R}^S) = I_S(j) \frac{y_j - \hat{R}^S x_j}{\hat{X}^S} = I_S(j) \frac{\hat{X}^S y_j - \hat{Y}^S x_j}{(\hat{X}^S)^2}
$$

The estimator for the standardized subpopulation ratio is

$$
\hat{R}^{DS} = \sum_{g=1}^{L_D} \pi_g \frac{\hat{Y}_g^S}{\hat{X}_g^S}
$$

where

$$
\hat{Y}_g^S = \sum_{j=1}^{m} I_{D_g}(j) I_S(j) w_j y_j
$$

and $\hat{X}_g^S$ is similarly defined. Its score variable is

$$
Z_j(\hat{R}^{DS}) = \sum_{g=1}^{L_D} \pi_g I_{D_g}(j) I_S(j) \frac{\hat{X}_g^S y_j - \hat{Y}_g^S x_j}{(\hat{X}_g^S)^2}
$$
The estimator for the poststratified subpopulation ratio is

$$\hat{R}^{PS} = \frac{\hat{Y}^{PS}}{\hat{X}^{PS}}$$

where

$$\hat{Y}^{PS} = \sum_{k=1}^{L_P} \frac{M_k}{M} \hat{Y}^S_k = \sum_{k=1}^{L_P} \frac{M_k}{M} \sum_{j=1}^{m} I_{P_k}(j) I_S(j) w_j y_j$$

and $$\hat{X}^{PS}$$ is similarly defined. Its score variable is

$$z_j(\hat{R}^{PS}) = \frac{\hat{X}^{PS} z_j(\hat{Y}^{PS}) - \hat{Y}^{PS} z_j(\hat{X}^{PS})}{(\hat{X}^{PS})^2}$$

where

$$z_j(\hat{Y}^{PS}) = \sum_{k=1}^{L_P} I_{P_k}(j) \frac{M_k}{M} \left\{ I_S(j) y_j - \frac{\hat{Y}^S_k}{M_k} \right\}$$

and $$z_j(\hat{X}^{PS})$$ is similarly defined.

The estimator for the standardized poststratified subpopulation ratio is

$$\hat{R}^{DPS} = \sum_{g=1}^{L_D} \frac{\hat{Y}^{PS}}{\hat{X}^{PS}}$$

where

$$\hat{Y}^{PS}_g = \sum_{k=1}^{L_p} \frac{M_k}{M} \hat{Y}^S_{g,k} = \sum_{k=1}^{L_p} \frac{M_k}{M} \sum_{j=1}^{m} I_{D_g}(j) I_{P_k}(j) I_S(j) w_j y_j$$

and $$\hat{X}^{PS}_g$$ is similarly defined. Its score variable is

$$z_j(\hat{R}^{DPS}) = \sum_{g=1}^{L_D} \frac{\hat{X}^{PS}_g z_j(\hat{Y}^{PS}) - \hat{Y}^{PS}_g z_j(\hat{X}^{PS})}{(\hat{X}^{PS}_g)^2}$$

where

$$z_j(\hat{Y}^{PS}_g) = \sum_{k=1}^{L_P} I_{P_k}(j) \frac{M_k}{M} \left\{ I_{D_g}(j) I_S(j) y_j - \frac{\hat{Y}^S_{g,k}}{M_k} \right\}$$

and $$z_j(\hat{X}^{PS}_g)$$ is similarly defined.

Description

`reg3` estimates a system of structural equations, where some equations contain endogenous variables among the explanatory variables. Estimation is via three-stage least squares (3SLS); see Zellner and Theil (1962). Typically, the endogenous explanatory variables are dependent variables from other equations in the system. `reg3` supports iterated GLS estimation and linear constraints.

`reg3` can also estimate systems of equations by seemingly unrelated regression estimation (SURE), multivariate regression (MVREG), and equation-by-equation ordinary least squares (OLS) or two-stage least squares (2SLS).

Nomenclature

Under 3SLS or 2SLS estimation, a structural equation is defined as one of the equations specified in the system. A dependent variable will have its usual interpretation as the left-hand-side variable in an equation with an associated disturbance term. All dependent variables are explicitly taken to be endogenous to the system and are treated as correlated with the disturbances in the system's equations. Unless specified in an endog() option, all other variables in the system are treated as exogenous to the system and uncorrelated with the disturbances. The exogenous variables are taken to be instruments for the endogenous variables.

Quick start

System of equations regressing `y1` on `x1`, `x2`, and `y2` and `y2` on `x1`, `x3`, and `y1`
```
reg3 (y1 x1 x2 y2) (y2 x1 x3 y1)
```
As above, but name equations `eq1` and `eq2`
```
reg3 (eq1: y1 x1 x2 y2) (eq2: y2 x1 x3 y1)
```
As above, but specify that `x1` is endogenous and add instrumental variable `v1`
```
reg3 (eq1: y1 x1 x2 y2) (eq2: y2 x1 x3 y1), endog(x1) exog(v1)
```
As above, but with iterated estimation
```
reg3 (eq1: y1 x1 x2 y2) (eq2: y2 x1 x3 y1), endog(x1) exog(v1) ireg3
```

Menu

Statistics > Endogenous covariates > Three-stage least squares
Syntax

Basic syntax

```
reg3 (depvar1 varlist1) (depvar2 varlist2) ... (depvarN varlistN) [if] [in] [weight]

Three-stage estimation for systems of simultaneous equations

Reporting

- `level(#)`: set confidence level; default is `level(95)`
- `first`: report first-stage regression
- `nocnsreport`: do not display constraints
- `display_options`: control columns and column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling

Optimization

- `optimization_options`: control the optimization process; seldom used
- `noheader`: suppress display of header
- `notable`: suppress display of coefficient table
- `nofooter`: suppress display of footer
- `coeflegend`: display legend instead of statistics

`varlist_1, ..., varlist_N` and the `exog()` and the `inst()` varlist may contain factor variables; see [U] \texttt{11.4.3 Factor variables}. You must have the same levels of factor variables in all equations that have factor variables.

`depvbar` and `varlist` may contain time-series operators; see [U] \texttt{11.4.4 Time-series varlists}.

`bootstrap`, `by`, `fp`, `jackknife`, `rolling`, and `statsby` are allowed; see [U] \texttt{11.1.10 Prefix commands}.

Weights are not allowed with the `bootstrap` prefix; see [R] \texttt{bootstrap}.

`aweights` are not allowed with the `jackknife` prefix; see [R] \texttt{jackknife}.

`aweights` and `fweights` are allowed; see [U] \texttt{11.1.6 weight}.

`noheader`, `notable`, `nofooter`, and `coeflegend` do not appear in the dialog box.

See [U] \texttt{20 Estimation and postestimation commands} for more capabilities of estimation commands.

Explicit equation naming (`eqname:`) cannot be combined with multiple dependent variables in an equation specification.

Options

\begin{itemize}
\item \textbf{Model 1}
\end{itemize}

`ireg3` causes `reg3` to iterate over the estimated disturbance covariance matrix and parameter estimates until the parameter estimates converge. Although the iteration is usually successful, there is no guarantee that it will converge to a stable point. Under SURE, this iteration converges to the maximum likelihood estimates.

`constraints(constants)`: see [R] \texttt{Estimation options}.

\begin{itemize}
\item \textbf{Model 2}
\end{itemize}

`exog(varlist)` specifies additional exogenous variables that are included in none of the system equations. This can occur when the system contains identities that are not estimated. If implicitly exogenous variables from the equations are listed here, `reg3` will just ignore the additional information. Specified variables will be added to the exogenous variables in the system and used in the first stage as instruments for the endogenous variables. By specifying dependent variables from the structural equations, you can use `exog()` to override their endogeneity.

`endog(varlist)` identifies variables in the system that are not dependent variables but are endogenous to the system. These variables must appear in the variable list of at least one equation in the system. Again the need for this identification often occurs when the system contains identities. For example, a variable that is the sum of an exogenous variable and a dependent variable may appear as an explanatory variable in some equations.
inst(varlist) specifies a full list of all exogenous variables and may not be used with the endog() or exog() options. It must contain a full list of variables to be used as instruments for the endogenous regressors. Like exog(), the list may contain variables not specified in the system of equations. This option can be used to achieve the same results as the endog() and exog() options, and the choice is a matter of convenience. Any variable not specified in the varlist of the inst() option is assumed to be endogenous to the system. As with exog(), including the dependent variables from the structural equations will override their endogeneity.

allexog indicates that all right-hand-side variables are to be treated as exogenous—even if they appear as the dependent variable of another equation in the system. This option can be used to enforce a SURE or MVREG estimation even when some dependent variables appear as regressors.

noconstant; see [R] Estimation options.

<table>

small specifies that small-sample statistics be computed. It shifts the test statistics from $\chi^2$ and $z$ statistics to $F$ statistics and $t$ statistics. This option is intended primarily to support MVREG. Although the standard errors from each equation are computed using the degrees of freedom for the equation, the degrees of freedom for the $t$ statistics are all taken to be those for the first equation. This approach poses no problem under MVREG because the regressors are the same across equations.

dfk specifies the use of an alternative divisor in computing the covariance matrix for the equation residuals. As an asymptotically justified estimator, reg3 by default uses the number of sample observations $n$ as a divisor. When the dfk option is set, a small-sample adjustment is made, and the divisor is taken to be $\sqrt{(n-k_i)(n-k_j)}$, where $k_i$ and $k_j$ are the number of parameters in equations $i$ and $j$, respectively.

dfk2 specifies the use of an alternative divisor in computing the covariance matrix for the equation errors. When the dfk2 option is set, the divisor is taken to be the mean of the residual degrees of freedom from the individual equations.

Reporting level(#); see [R] Estimation options.

first requests that the first-stage regression results be displayed during estimation.

nocnsreport; see [R] Estimation options.

display_options: noci, nopvalues, noomitted, vsquish, noemptycells, baselevels, allbaselevels, noflabel, fvwrap(#), fvwrapon(style), cformat(%,fmt), pformat(%,fmt), sformat(%,fmt), and nolstretch; see [R] Estimation options.

Optimization options control the iterative process that minimizes the sum of squared errors when ireg3 is specified. These options are seldom used.

iterate(#) specifies the maximum number of iterations. When the number of iterations equals #, the optimizer stops and presents the current results, even if the convergence tolerance has not been reached. The default value of iterate() is the current value of set maxiter, which is iterate(16000) if maxiter has not been changed.

trace adds to the iteration log a display of the current parameter vector.

log and nolog specify whether to display the iteration log. The iteration log is displayed by default unless you used set iterlog off to suppress it; see set iterlog in [R] set iter.

tolerance(#) specifies the tolerance for the coefficient vector. When the relative change in the coefficient vector from one iteration to the next is less than or equal to #, the optimization process is stopped. tolerance(1e-6) is the default.

The following options are available with reg3 but are not shown in the dialog box:

noheader suppresses display of the header reporting the estimation method and the table of equation summary statistics.

notable suppresses display of the coefficient table.

nofooter suppresses display of the footer reporting the list of endogenous and exogenous variables in the model.

c coeflegend; see [R] Estimation options.
Remarks and examples

`reg3` estimates systems of structural equations where some equations contain endogenous variables among the explanatory variables. Generally, these endogenous variables are the dependent variables of other equations in the system, though not always. The disturbance is correlated with the endogenous variables—violating the assumptions of OLS. Further, because some of the explanatory variables are the dependent variables of other equations in the system, the error terms among the equations are expected to be correlated. `reg3` uses an instrumental-variables approach to produce consistent estimates and generalized least squares (GLS) to account for the correlation structure in the disturbances across the equations. Good general references on three-stage estimation include Davidson and MacKinnon (1993, 651–661) and Greene (2018, 363–365).

Three-stage least squares can be thought of as producing estimates from a three-step process.

**Step 1.** Develop instrumented values for all endogenous variables. These instrumented values can simply be considered as the predicted values resulting from a regression of each endogenous variable on all exogenous variables in the system. This stage is identical to the first step in 2SLS and is critical for the consistency of the parameter estimates.

**Step 2.** Obtain a consistent estimate for the covariance matrix of the equation disturbances. These estimates are based on the residuals from a 2SLS estimation of each structural equation.

**Step 3.** Perform a GLS-type estimation using the covariance matrix estimated in the second stage and with the instrumented values in place of the right-hand-side endogenous variables.

---

**Technical note**

The estimation and use of the covariance matrix of disturbances in three-stage estimation is almost identical to the SURE method—`sureg`. As with SURE, using this covariance matrix improves the efficiency of the three-stage estimator. Even without the covariance matrix, the estimates would be consistent. (They would be 2SLS estimates.) This improvement in efficiency comes with a caveat. All the parameter estimates now depend on the consistency of the covariance matrix estimates. If one equation in the system is misspecified, the disturbance covariance estimates will be inconsistent, and the resulting coefficients will be biased and inconsistent. Alternatively, if each equation is estimated separately by 2SLS ([R] `regress`), only the coefficients in the misspecified equation are affected.

---

**Technical note**

If an equation is just identified, the 3SLS point estimates for that equation are identical to the 2SLS estimates. However, as with `sureg`, even if all equations are just identified, fitting the model via `reg3` has at least one advantage over fitting each equation separately via `ivregress`; by using `reg3`, tests involving coefficients in different equations can be performed easily using `test` or `testnl`.

---

**Example 1**

A simple macroeconomic model relates consumption (`consump`) to private and government wages paid (`wagepriv` and `wagegovt`). Simultaneously, private wages depend on consumption, total government expenditures (`govt`), and the lagged stock of capital in the economy (`capital1`). Although this is not a plausible model, it does meet the criterion of being simple. This model could be written as

\[
\begin{align*}
\text{consump} &= \beta_0 + \beta_1 \text{wagepriv} + \beta_2 \text{wagegovt} + \epsilon_1 \\
\text{wagepriv} &= \beta_3 + \beta_4 \text{consump} + \beta_5 \text{govt} + \beta_6 \text{capital1} + \epsilon_2
\end{align*}
\]
If we assume that this is the full system, `consump` and `wagepriv` will be endogenous variables, with `wagegovt`, `govt`, and `capital1` exogenous. Data for the U.S. economy on these variables are taken from Klein (1950). This model can be fit with `reg3` by typing

```
use https://www.stata-press.com/data/r16/klein
.reg3 (consump wagepriv wagegovt) (wagepriv consump govt capital1)
```

Endogenous variables: `consump` `wagepriv`

Exogenous variables: `wagegovt` `govt` `capital1`

Without showing the 2SLS results, we note that the consumption function in this system falls under the conditions noted earlier. That is, the 2SLS and 3SLS coefficients for the equation are identical.

> Example 2

Some of the most common simultaneous systems encountered are supply-and-demand models. A simple system could be specified as

\[
q_{\text{Demand}} = \beta_0 + \beta_1 p_{\text{price}} + \beta_2 p_{\text{compete}} + \beta_3 \text{income} + \epsilon_1
\]

\[
q_{\text{Supply}} = \beta_4 + \beta_5 p_{\text{price}} + \beta_6 p_{\text{raw}} + \epsilon_2
\]

Equilibrium condition: quantity = qDemand = qSupply

where

- `quantity` is the quantity of a product produced and sold,
- `price` is the price of the product,
- `pcompete` is the price of a competing product,
- `income` is the average income level of consumers, and
- `praw` is the price of raw materials used to produce the product.

In this system, price is assumed to be determined simultaneously with demand. The important statistical implications are that price is not a predetermined variable and that it is correlated with
the disturbances of both equations. The system is somewhat unusual: quantity is associated with two disturbances. This fact really poses no problem because the disturbances are specified on the behavioral demand and supply equations—two separate entities. Often one of the two equations is rewritten to place price on the left-hand side, making this endogeneity explicit in the specification.

To provide a concrete illustration of the effects of simultaneous equations, we can simulate data for the above system by using known coefficients and disturbance properties. Specifically, we will simulate the data as

\[
q_{\text{Demand}} = 40 - 1.0 \text{price} + 0.25 \text{pcompete} + 0.5 \text{income} + \epsilon_1 \\
q_{\text{Supply}} = 0.5 \text{price} - 0.75 \text{praw} + \epsilon_2
\]

where

\[
\epsilon_1 \sim N(0, 3.8) \\
\epsilon_2 \sim N(0, 2.4)
\]

For comparison, we can estimate the supply and demand equations separately by OLS. The estimates for the demand equation are

```
use https://www.stata-press.com/data/r16/supDem
regress quantity price pcompete income
```

| _cons    | -6.97291 | 3.323105  | -2.10 | 0.041 | -13.66197 to -.283847 |

Examining the coefficients from these regressions, we note that they are not close to the known parameters used to generate the simulated data. In particular, the positive coefficient on price in the demand equation stands out. We constructed our simulated data to be consistent with economic theory—people demand less of a product if its price rises and more if their personal income rises.
Although the price coefficient is statistically insignificant, the positive value contrasts starkly with what is predicted from economic price theory and the −1.0 value that we used in the simulation. Likewise, we are disappointed with the insignificance and level of the coefficient on average income. The supply equation has correct signs on the two main parameters, but their levels are different from the known values. In fact, the coefficient on price (0.724675) is different from the simulated parameter (0.5) at the 5% level of significance.

All of these problems are to be expected. We explicitly constructed a simultaneous system of equations that violated one of the assumptions of least squares. Specifically, the disturbances were correlated with one of the regressors—price.

Two-stage least squares can be used to address the correlation between regressors and disturbances. Using instruments for the endogenous variable, price, 2SLS will produce consistent estimates of the parameters in the system. Let’s use ivregress (see [R] ivregress) to see how our simulated system behaves when fit using 2SLS.

```
. ivregress 2sls quantity (price = praw) pcompete income
Instrumental variables (2SLS) regression

|-------|--------|-----------|------|------|----------------------|
| price | .5773133 | .1749974 | 3.30 | 0.001 | .2343247 to .9203019 |
| praw  | -.7835496 | .1312414 | -5.97 | 0.000 | -1.040778 to -.5263213 |
| _cons | -2.550694 | 5.273067 | -0.48 | 0.629 | -12.88571 to 7.784327 |
```

We are now much happier with the estimation results. All the coefficients from both equations are close to the true parameter values for the system. In particular, the coefficients are all well within 95% confidence intervals for the parameters. The missing R-squared in the demand equation seems unusual; we will discuss that more later.

Finally, this system could be estimated using 3SLS. To demonstrate how large systems might be handled and to avoid multiline commands, we will use global macros (see [P] macro) to hold the specifications for our equations.
We must specify price as endogenous because it does not appear as a dependent variable in either equation. Without this option, reg3 would assume that there are no endogenous variables in the system and produce seemingly unrelated regression (sureg) estimates. The reg3 output from our series of commands is

The use of 3SLS over 2SLS is essentially an efficiency issue. The coefficients of the demand equation from 3SLS are close to the coefficients from two-stage least squares, and those of the supply equation are identical. The latter case was mentioned earlier for systems with some exactly identified equations. However, even for the demand equation, we do not expect the coefficients to change systematically. What we do expect from three-stage least squares are more precise estimates of the parameters given the validity of our specification and reg3’s use of the covariances among the disturbances.

Let’s summarize the results. With OLS, we got obviously biased estimates of the parameters. No amount of data would have improved the OLS estimates—they are inconsistent in the face of the violated OLS assumptions. With 2SLS, we obtained consistent estimates of the parameters, and these would have improved with more data. With 3SLS, we obtained consistent estimates of the parameters that are more efficient than those obtained by 2SLS.

Technical note

We noted earlier that the $R$-squared was missing from the two-stage estimates of the demand equation. Now we see that the $R$-squared is negative for the three-stage estimates of the same equation. How can we have a negative $R$-squared?

In most estimators, other than least squares, the $R$-squared is no more than a summary measure of the overall in-sample predictive power of the estimator. The computational formula for $R$-squared is $R$-squared $= 1 - RSS/TSS$, where RSS is the residual sum of squares (sum of squared residuals) and
TSS is the total sum of squared deviations about the mean of the dependent variable. In a standard linear model with a constant, the model from which the TSS is computed is nested within the full model from which RSS is computed—they both have a constant term based on the same data. Thus it must be that \( TSS \geq RSS \) and \( R^2 \)-squared is constrained between 0 and 1.

For 2SLS and 3SLS, some of the regressors enter the model as instruments when the parameters are estimated. However, because our goal is to fit the structural model, the actual values, not the instruments for the endogenous right-hand-side variables, are used to determine \( R^2 \)-squared. The model residuals are computed over a different set of regressors from those used to fit the model. The two- or three-stage estimates are no longer nested within a constant-only model of the dependent variable, and the residual sum of squares is no longer constrained to be smaller than the total sum of squares.

A negative \( R^2 \)-squared in 3SLS should be taken for exactly what it is—an indication that the structural model predicts the dependent variable worse than a constant-only model. Is this a problem? It depends on the application. Three-stage least squares applied to our contrived supply-and-demand example produced good estimates of the known true parameters. Still, the demand equation produced an \( R^2 \)-squared of \(-0.854\). How do we feel about our parameter estimates? This should be determined by the estimates themselves, their associated standard errors, and the overall model significance. On this basis, negative \( R^2 \)-squared and all, we feel pretty good about all the parameter estimates for both the supply and demand equations. Would we want to make predictions about equilibrium quantity by using the demand equation alone? Probably not. Would we want to make these quantity predictions by using the supply equation? Possibly, because based on in-sample predictions, they seem better than those from the demand equations. However, both the supply and demand estimates are based on limited information. If we are interested in predicting quantity, a reduced-form equation containing all our independent variables would usually be preferred.

### Technical note

As a matter of syntax, we could have specified the supply-and-demand model on one line without using global macros.

```stata
. reg3 (quantity price pcompete income) (quantity price praw), endog(price)
```

Endogenous variables: quantity price
Exogenous variables: pcompete income praw
However, here `reg3` has been forced to create a unique equation name for the supply equation—2quantity. Both the supply and demand equations could not be designated as quantity, so a number was prefixed to the name for the supply equation.

We could have specified

```
. reg3 (qDemand: quantity price pcompete income) (qSupply: quantity price praw), > endog(price)
```

and obtained the same results and equation labeling as when we used global macros to hold the equation specifications.

Without explicit equation names, `reg3` always assumes that the dependent variable should be used to name equations. When each equation has a different dependent variable, this rule causes no problems and produces easily interpreted result tables. If the same dependent variable appears in more than one equation, however, `reg3` will create a unique equation name based on the dependent variable name. Because equation names must be used for cross-equation tests, you have more control in this situation if explicit names are placed on the equations.

Example 3: Using the full syntax of `reg3`

Klein’s (1950) model of the U.S. economy is often used to demonstrate system estimators. It contains several common features that will serve to demonstrate the full syntax of `reg3`. The Klein model is defined by the following seven relationships:

\[
\begin{align*}
   c &= \beta_0 + \beta_1 p + \beta_2 L.p + \beta_3 w + \epsilon_1 \\
   i &= \beta_4 + \beta_5 p + \beta_6 L.p + \beta_7 L.k + \epsilon_2 \\
   wp &= \beta_8 + \beta_9 y + \beta_{10} L.y + \beta_{11} y r + \epsilon_3 \\
   y &= c + i + g \\
   p &= y - t - wp \\
   k &= L.k + i \\
   w &= wg + wp
\end{align*}
\]

Here we have used Stata’s lag operator `L.` to represent variables that appear with a one-period lag in our model; see [U] 13.10 Time-series operators.

The variables in the model are listed below. Two sets of variable names are shown. The concise first name uses traditional economics mnemonics, whereas the second name provides more guidance for everyone else. The concise names serve to keep the specification of the model small (and quite understandable to economists).

</tbody>
</table>

Equations (1)–(3) are behavioral and contain explicit disturbances ($\epsilon_1$, $\epsilon_2$, and $\epsilon_3$). The remaining equations are identities that specify additional variables in the system and their accounting relationships with the variables in the behavioral equations. Some variables are explicitly endogenous by appearing as dependent variables in (1)–(3). Others are implicitly endogenous as linear combinations that contain other endogenous variables (for example, $w$ and $p$). Still other variables are implicitly exogenous by appearing in the identities but not in the behavioral equations (for example, $wg$ and $g$).
Using the concise names, we can fit Klein’s model with the following command:

```
use https://www.stata-press.com/data/r16/klein2
reg3 (c p L.p w) (i p L.p L.k) (wp y L.y yr), endog(w p y) exog(t wg g)
```

**Endogenous variables:** c i wp w p y  
**Exogenous variables:** L.p L.k L.y yr t wg g

We used the `exog()` option to identify t, wg, and g as exogenous variables in the system. These variables must be identified because they are part of the system but appear directly in none of the behavioral equations. Without this option, `reg3` would not know they were part of the system and could be used as instrumental variables. The `endog()` option specifying w, p, and y is also required. Without this information, `reg3` would be unaware that these variables are linear combinations that include endogenous variables. We did not include k in the `endog()` option because only its lagged value appears in the behavioral equations.

---

### Technical note

Rather than listing additional endogenous and exogenous variables, we could specify the full list of exogenous variables in an `inst()` option,

```
. reg3 (c p L.p w) (i p L.p L.k) (wp y L.y yr), inst(g t wg yr L.p L.k L.y)
```
or equivalently,

```stata
. global conseqn "(c p L.p w)"
. global inveqn "(i p L.p L.k)"
. global wageqn "(wp y L.y yr)"
. global inlist "g t wg yr L.p L.k L.y"
. reg3 $conseqn $inveqn $wageqn, inst($inlist)
```

Macros and explicit equations can also be mixed in the specification

```stata
. reg3 $conseqn (i p L.p L.k) $wageqn, endog(w p y) exog(t wg g)
```
or

```stata
. reg3 (c p L.p w) $inveqn (wp y L.y yr), endog(w p y) exog(t wg g)
```

Placing the equation-binding parentheses in the global macros was also arbitrary. We could have used

```stata
. global consump "c p L.p w"
. global invest "i p L.p L.k"
. global wagepriv "wp y L.y yr"
. reg3 ($consump) ($invest) ($wagepriv), endog(w p y) exog(t wg g)
```

`reg3` is tolerant of all combinations, and these commands will produce identical output.

Switching to the full variable names, we can fit Klein’s model with the commands below. We will use global macros to store the lists of endogenous and exogenous variables. Again this is not necessary: these lists could have been typed directly on the command line. However, assigning the lists to local macros makes additional processing easier if alternative models are to be fit. We will also use the `ireg3` option to produce the iterated estimates.

```stata
. use https://www.stata-press.com/data/r16/kleinfull
. global conseqn "(consump profits L.profits wagetot)"
. global inveqn "(invest profits L.profits L.capital)"
. global wageqn "(wagepriv totinc L.totinc year)"
. global enlist "wagetot profits totinc"
. global exlist "taxnetx wagegovt govt"
. reg3 $conseqn $inveqn $wageqn, endog($enlist) exog($exlist) ireg3
```

```
Iteration 1:  tolerance =  .3712549
Iteration 2:  tolerance =  .1894712
Iteration 3:  tolerance =  .1076401
(output omitted)
Iteration 24:  tolerance =  7.049e-07
```

Example 4: Constraints with reg3

As a simple example of constraints, (1) above may be rewritten with both wages explicitly appearing (rather than as a variable containing the sum). Using the longer variable names, we have

\[
\text{consump} = \beta_0 + \beta_1 \text{profits} + \beta_2 \text{L.profits} + \beta_3 \text{wagepriv} + \beta_{12} \text{wagegovt} + \epsilon_1
\]

To retain the effect of the identity in (7), we need \(\beta_3 = \beta_{12}\) as a constraint on the system. We obtain this result by defining the constraint in the usual way and then specifying its use in reg3. Because reg3 is a system estimator, we will need to use the full equation syntax of constraint. The assumption that the following commands are entered after the model above has been estimated. We are simply changing the definition of the consumption equation (consump) and adding a constraint on two of its parameters. The rest of the model definition is carried forward.

```
  . global conseqn "((consump profits L.profits wagepriv wagegovt))"
  . constraint define 1 [consump]wagepriv = [consump]wagegovt
  . reg3 $conseqn $inveqn $wageqn, endog($enlist) exog($exlist) constr(1) ireg3
```

> note: additional endogenous variables not in the system have no effect
> and are ignored: wagetot

Endogenous variables: consump invest wagepriv wagetot profits totinc
Exogenous variables: L.profits wagegovt L.capital L.totinc year taxnetx
govt

As expected, none of the parameter or standard error estimates has changed from the previous estimates (before the seventh significant digit). We have simply decomposed the total wage variable into its two parts and constrained the coefficients on these parts. The warning about additional endogenous variables was just \texttt{reg3}'s way of letting us know that we had specified some information that was irrelevant to the estimation of the system. We had left the \texttt{wagetot} variable in our \texttt{endog} macro. It does not mean anything to the system to specify \texttt{wagetot} as endogenous because it is no longer in the system. That's fine with \texttt{reg3} and fine for our current purposes.

We can also impose constraints across the equations. For example, the admittedly meaningless constraint of requiring \texttt{profits} to have the same effect in both the consumption and investment equations could be imposed. Retaining the constraint on the wage coefficients, we would estimate this constrained system.
. constraint define 2 [consump]profits = [invest]profits
. reg3 $conseqn $inveqn $wageqn, endog($enlist) exog($exlist) constr(1 2) i

Identification in a system of simultaneous equations involves the notion that there is enough information to estimate the parameters of the model given the specified functional form. Under-identification usually manifests itself as one matrix in the 3SLS computations. The most commonly violated order condition for 2SLS or 3SLS involves the number of endogenous and exogenous variables. There must be at least as many noncollinear exogenous variables in the remaining system as there are endogenous right-hand-side variables in an equation. This condition must hold for each structural equation in the system.

Put as a set of rules the following:
1. Count the number of right-hand-side endogenous variables in an equation and call this $m_i$.
2. Count the number of exogenous variables in the same equation and call this $k_i$.
3. Count the total number of exogenous variables in all the structural equations plus any additional variables specified in an `exog()` or `inst()` option and call this $K$.
4. If $m_i > (K - k_i)$ for any structural equation $(i)$, then the system is underidentified and cannot be estimated by 3SLS.

We are also possibly in trouble if any of the exogenous variables are linearly dependent. We must have $m_i$ linearly independent variables among the exogenous variables represented by $(K - k_i)$.

The complete conditions for identification involve rank-order conditions on several matrices. For a full treatment, see Theil (1971) or Greene (2018, 363–365).

---

**Henri Theil** (1924–2000) was born in Amsterdam and awarded a PhD in 1951 by the University of Amsterdam. He researched and taught econometric theory, statistics, microeconomics, macroeconomic modeling, and economic forecasting, and policy at (now) Erasmus University Rotterdam, the University of Chicago, and the University of Florida. Theil’s many specific contributions include work on 2SLS and 3SLS, inequality and concentration, and consumer demand.

---

**Stored results**

`reg3` stores the following in `e()`:  

Scalars
- `e(N)` number of observations  
- `e(k)` number of parameters  
- `e(k_eq)` number of equations in `e(b)`  
- `e(mss_#)` model sum of squares for equation `#`  
- `e(df_m#)` model degrees of freedom for equation `#`  
- `e(rss_#)` residual sum of squares for equation `#`  
- `e(df_r)` residual degrees of freedom (small)  
- `e(r2_#)` $R^2$ for equation `#`  
- `e(F_#)` $F$ statistic for equation `#` (small)  
- `e(rmse_#)` root mean squared error for equation `#`  
- `e(dfk2_adj)` divisor used with VCE when `dfk2` specified  
- `e(ll)` log likelihood  
- `e(ch12_#)` $\chi^2$ for equation `#`  
- `e(p_#)` $p$-value for model test for equation `#`  
- `e(cons_#)` 1 when equation `#` has a constant, 0 otherwise  
- `e(rank)` rank of `e(V)`  
- `e(ic)` number of iterations
Macros
- `e(cmd)` reg3
- `e(cmdline)` command as typed
- `e(depvar)` names of dependent variables
- `e(exog)` names of exogenous variables
- `e(endog)` names of endogenous variables
- `e(eqnames)` names of equations
- `e(corr)` correlation structure
- `e(wtype)` weight type
- `e(wexp)` weight expression
- `e(method)` 3sls, 2sls, ols, sure, or mvreg
- `e(small)` small, if specified
- `e(dfk)` dfk, if specified
- `e(properties)` b V
- `e(predict)` program used to implement predict
- `e(marginsok)` predictions allowed by margins
- `e(marginsnotok)` predictions disallowed by margins
- `e(marginsdefault)` default predict() specification for margins
- `e(asbalanced)` factor variables fvset as asbalanced
- `e(asobserved)` factor variables fvset as asobserved

Matrices
- `e(b)` coefficient vector
- `e(Cns)` constraints matrix
- `e(Sigma)` $\Sigma$ matrix
- `e(V)` variance–covariance matrix of the estimators

Functions
- `e(sample)` marks estimation sample

Methods and formulas

The most concise way to represent a system of equations for 3SLS requires thinking of the individual equations and their associated data as being stacked. reg3 does not expect the data in this format, but it is a convenient shorthand. The system could then be formulated as

$$
\begin{bmatrix}
y_1 \\
y_2 \\
\vdots \\
y_M
\end{bmatrix} =
\begin{bmatrix}
Z_1 & 0 & \ldots & 0 \\
0 & Z_2 & \ldots & 0 \\
\vdots & \vdots & \ddots & \vdots \\
0 & 0 & \ldots & Z_M
\end{bmatrix}
\begin{bmatrix}
\beta_1 \\
\beta_2 \\
\vdots \\
\beta_M
\end{bmatrix} +
\begin{bmatrix}
\epsilon_1 \\
\epsilon_2 \\
\vdots \\
\epsilon_M
\end{bmatrix}
$$

In full matrix notation, this is just

$$
y = Z \beta + \epsilon
$$

The $Z$ elements in these matrices represent both the endogenous and the exogenous right-hand-side variables in the equations.

Also assume that there will be correlation between the disturbances of the equations so that

$$
E(\epsilon \epsilon') = \Sigma
$$

where the disturbances are further assumed to have an expected value of 0; $E(\epsilon) = 0$.

The first stage of 3SLS regression requires developing instrumented values for the endogenous variables in the system. These values can be derived as the predictions from a linear regression of each endogenous regressor on all exogenous variables in the system or, more succinctly, as the projection of each regressor through the projection matrix of all exogenous variables onto the regressors. Designating the set of all exogenous variables as $X$ results in
\[ \hat{z}_i = X(X'X)^{-1}X'z_i \] for each \( i \)

Taken collectively, these \( \hat{Z} \) contain the instrumented values for all the regressors. They take on the actual values for the exogenous variables and first-stage predictions for the endogenous variables. Given these instrumented variables, a generalized least squares (GLS) or Aitken (1935) estimator can be formed for the parameters of the system

\[ \hat{B} = \left( \hat{Z}'(\Sigma^{-1} \otimes I)\hat{Z} \right)^{-1} \hat{Z}'(\Sigma^{-1} \otimes I)y \]

All that remains is to obtain a consistent estimator for \( \Sigma \). This estimate can be formed from the residuals of 2SLS estimates of each equation in the system. Alternately, and identically, the residuals can be computed from the estimates formed by taking \( \Sigma \) to be an identity matrix. This maintains the full system of coefficients and allows constraints to be applied when the residuals are computed.

If we take \( E \) to be the matrix of residuals from these estimates, a consistent estimate of \( \Sigma \) is

\[ \hat{\Sigma} = \frac{E'E}{n} \]

where \( n \) is the number of observations in the sample. An alternative divisor for this estimate can be obtained with the \texttt{dfk} option as outlined under options.

With the estimate of \( \hat{\Sigma} \) placed into the GLS estimating equation,

\[ \hat{B} = \left( \hat{Z}'(\hat{\Sigma}^{-1} \otimes I)\hat{Z} \right)^{-1} \hat{Z}'(\hat{\Sigma}^{-1} \otimes I)y \]

is the 3SLS estimates of the system parameters.

The asymptotic variance–covariance matrix of the estimator is just the standard formulation for a GLS estimator

\[ V_{\hat{B}} = \left( \hat{Z}'(\hat{\Sigma}^{-1} \otimes I)\hat{Z} \right)^{-1} \]

Iterated 3SLS estimates can be obtained by computing the residuals from the three-stage parameter estimates, using these to formulate a new \( \hat{\Sigma} \), and recomputing the parameter estimates. This process is repeated until the estimates \( \hat{B} \) converge—if they converge. Convergence is not guaranteed. When estimating a system by SURE, these iterated estimates will be the maximum likelihood estimates for the system. The iterated solution can also be used to produce estimates that are invariant to choice of system and restriction parameterization for many linear systems under full 3SLS.

The exposition above follows the parallel developments in Greene (2018) and Davidson and MacKinnon (1993).
Alexander Craig Aitken (1895–1967) was born in Dunedin, New Zealand. He attended the University of Otago on a full scholarship but left the university to enlist in the New Zealand Expeditionary Force during World War I. He would later reflect on the time he spent in active service and publish two war memoirs.

After returning from the war, he completed his studies at the University of Otago and then worked on his PhD at the University of Edinburgh under E. T. Whittaker. Although he suffered weeks of illness during the course of his postgraduate studies, he managed to write an impressive thesis on data smoothing. He then became a professor of mathematics, and later the Chair of Pure Mathematics, a post he would hold until his retirement in 1965.

Among his many accolades, he was elected a Fellow of the Royal Society of Edinburgh and a Fellow of the Royal Society of Literature, following the publication of his second war memoir. He published many papers on numerical analysis and statistics as well as a couple of books on matrices. Aitken is credited with deriving the generalized least squares estimator, which has been referred to as Aitken’s generalized least squares. Aside from his many academic contributions, he had mental calculating abilities like no other. He is known to have multiplied two 9-digit numbers in less than a minute and could recite up to 707 digits of \(\pi\).

*`estat ic` is not appropriate after `reg3, 2sls`.\*
predict

Description for predict

`predict` creates a new variable containing predictions such as linear predictions, standard errors, residuals, and differences between the linear predictions of two equations.

Menu for predict

Statistics > Postestimation

Syntax for predict

```
predict [type] newvar [if] [in] [, equation(eqno[,eqno]) statistic]
```

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>xb</td>
<td>linear prediction; the default</td>
</tr>
<tr>
<td>stdp</td>
<td>standard error of the linear prediction</td>
</tr>
<tr>

<td>residuals</td>
</tr>
<tr>
<td>difference</td>
<td>difference between the linear predictions of two equations</td>
</tr>
<tr>
<td>stddp</td>
<td>standard error of the difference in linear predictions</td>
</tr>
</tbody>
</table>

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

Options for predict

- `equation(eqno[,eqno])` specifies to which equation you are referring.

  `equation()` is filled in with one `eqno` for the `xb`, `stdp`, and `residuals` options. `equation(#1)` would mean the calculation is to be made for the first equation, `equation(#2)` would mean the second, and so on. You could also refer to the equations by their names. `equation(income)` would refer to the equation named income and `equation(hours)` to the equation named hours.

  If you do not specify `equation()`, results are the same as if you specified `equation(#1)`.

- `difference` and `stddp` refer to between-equation concepts. To use these options, you must specify two equations, for example, `equation(#1,#2)` or `equation(income,hours)`. When two equations must be specified, `equation()` is required.

- `xb`, the default, calculates the linear prediction (fitted values)—the prediction of \( x_j b \) for the specified equation.

- `stdp` calculates the standard error of the prediction for the specified equation. It can be thought of as the standard error of the predicted expected value or mean for the observation’s covariate pattern. The standard error of the prediction is also referred to as the standard error of the fitted value.

- `residuals` calculates the residuals.
difference calculates the difference between the linear predictions of two equations in the system. With equation(#1,#2), difference computes the prediction of equation(#1) minus the prediction of equation(#2).

stddp is allowed only after you have previously fit a multiple-equation model. The standard error of the difference in linear predictions \((x_{1j}b - x_{2j}b)\) between equations 1 and 2 is calculated.

For more information on using predict after multiple-equation estimation commands, see [R] predict.

margins

Description for margins

margins estimates margins of response for linear predictions and differences between the linear predictions of two equations.

Menu for margins

Statistics > Postestimation

Syntax for margins

margins [ marginslist ] [ , options ]
margins [ marginslist ] , predict(statistic ...) [ predict(statistic ...) ... ] [ options ]

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>default</td>

</tr>
</tbody>
</table>

xb defaults to the first equation.

Statistics not allowed with margins are functions of stochastic quantities other than \(e(b)\).

For the full syntax, see [R] margins.

Remarks and examples

Example 1: Using predict

In example 2 of [R] reg3, we fit a simple supply-and-demand model. Here we obtain the fitted supply and demand curves assuming that the exogenous regressors equal their sample means. We first replace each of the three exogenous regressors with their sample means, then we call predict to obtain the predictions.
As we would expect based on economic theory, the demand curve slopes downward while the supply curve slopes upward. With the exogenous variables at their mean levels, the equilibrium price and quantity are slightly less than 33 and 13, respectively.

Example 2: Obtaining forecasts

In example 3 of [R] reg3, we fit Klein’s (1950) model of the U.S. economy. That model includes three stochastic equations we fit using reg3 as well as four identities. Here we briefly illustrate how the forecast command can be used to obtain forecasts for all the endogenous variables in the model. For a more detailed discussion of how to forecast with this model, see [TS] forecast.
In Stata, we type

```
use https://www.stata-press.com/data/r16/klein2, clear
reg3 (c p L.p w) (i p L.p L.k) (wp y L.y yr), endog(w p y) exog(t wg g)
(output omitted)
estimates store kleineqs
forecast create kleinmodel
Forecast model kleinmodel started.
forecast estimates kleineqs
Added estimation results from reg3.
Forecast model kleinmodel now contains 3 endogenous variables.
forecast identity y = c + i + g
Forecast model kleinmodel now contains 4 endogenous variables.
forecast identity p = y - t - wp
Forecast model kleinmodel now contains 5 endogenous variables.
forecast identity k = L.k + i
Forecast model kleinmodel now contains 6 endogenous variables.
forecast identity w = wg + wp
Forecast model kleinmodel now contains 7 endogenous variables.
forecast solve, begin(1937)
```

Computing dynamic forecasts for model kleinmodel.

Starting period: 1937
Ending period: 1941
Forecast prefix: f_

```
1937: ...........................................
1938: ............................................
1939: ............................................
1940: ............................................
1941: ............................................
```

Forecast 7 variables spanning 5 periods.

Here we have obtained dynamic forecasts for our 7 endogenous variables beginning in 1937. By default, the variables containing the forecasts begin with the prefix f_. Next we plot the forecast and actual values of consumption:

```
tsline c f_c
```

![Consumption Graph](image-url)
For more information about producing forecasts, see [TS] \texttt{forecast}.

\subsection*{Methods and formulas}

The computational formulas for the statistics produced by \texttt{predict} can be found in [R] \texttt{predict} and [R] \texttt{regress postestimation}.

\section*{Reference}

[R] \texttt{reg3} — Three-stage estimation for systems of simultaneous equations

[U] 20 \textit{Estimation and postestimation commands}
**Description**

`regress` performs ordinary least-squares linear regression. `regress` can also perform weighted estimation, compute robust and cluster–robust standard errors, and adjust results for complex survey designs.

**Quick start**

Simple linear regression of $y$ on $x_1$

```
regress y x1
```

Regression of $y$ on $x_1, x_2,$ and indicators for categorical variable $a$

```
regress y x1 x2 i.a
```

Add the interaction between continuous variable $x_2$ and $a$

```
regress y x1 c.x2##i.a
```

Fit model for observations where $v_1$ is greater than zero

```
regress y x1 x2 i.a if v1>0
```

With cluster–robust standard errors for clustering by levels of $cvar$

```
regress y x1 x2 i.a, vce(cluster cvar)
```

With bootstrap standard errors

```
regress y x1 x2 i.a, vce(bootstrap)
```

Report standardized coefficients

```
regress y x1 x2 i.a, beta
```

Adjust for complex survey design using `svyset` data

```
svy: regress y x1 x2 i.a
```

Use sampling weight $wvar$

```
regress y x1 x2 i.a [pweight=wvar]
```

**Menu**

Statistics > Linear models and related > Linear regression
Syntax

```
regress depvar [indepvars] [if] [in] [weight] [, options]
```

*indepvars* may contain factor variables; see [U] 11.4.3 Factor variables.
*depvar* and *indepvars* may contain time-series operators; see [U] 11.4.4 Time-series varlists.
*bayes, bootstrap, by, fmm, fp, jackknife, mfp, mi estimate, nestreg, rolling, statsby, stepwise,* and *svy* are allowed; see [U] 11.1.10 Prefix commands. For more details, see [BAYES] bayes: regress and [FMM] fmm: regress.
*vce(bootstrap)* and *vce(jackknife)* are not allowed with the *mi estimate* prefix; see [MI] mi estimate.
Weights are not allowed with the *bootstrap* prefix; see [R] bootstrap.
aweights are not allowed with the *jackknife* prefix; see [R] jackknife.
*hascons, tsscons, vce(), beta, noheader, notable, plus, depname(), mse1,* and *aweights* are not allowed with the *svy* prefix; see [SVY] svy.
aweights, fweights, iweights, and pweights are allowed; see [U] 11.1.6 weight.
noheader, notable, plus, mse1, and coeflegend do not appear in the dialog box.
See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

**Options**

- `noconstant`; see [R] Estimation options.
  *hascons* indicates that a user-defined constant or its equivalent is specified among the independent variables in *indepvars*. Some caution is recommended when specifying this option, as resulting
estimates may not be as accurate as they otherwise would be. Use of this option requires “sweeping” the constant last, so the moment matrix must be accumulated in absolute rather than deviation form. This option may be safely specified when the means of the dependent and independent variables are all reasonable and there is not much collinearity between the independent variables. The best procedure is to view hascons as a reporting option—estimate with and without hascons and verify that the coefficients and standard errors of the variables not affected by the identity of the constant are unchanged.

tsscons forces the total sum of squares to be computed as though the model has a constant, that is, as deviations from the mean of the dependent variable. This is a rarely used option that has an effect only when specified with noconstant. It affects the total sum of squares and all results derived from the total sum of squares.

\[
\text{vce(VCETYPE)} \text{ specifies the type of standard error reported, which includes types that are derived from asymptotic theory (ols), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.}
\]

vce(ols), the default, uses the standard variance estimator for ordinary least-squares regression. \text{regress} also allows the following:

vce(hc2) and vce(hc3) specify alternative bias corrections for the robust variance calculation. vce(hc2) and vce(hc3) may not be specified with the svy prefix. In the unclustered case, vce(robust) uses \( \hat{\sigma}^2_j = \frac{n}{n-k} u_j^2 \) as an estimate of the variance of the \( j \)th observation, where \( u_j \) is the calculated residual and \( n/(n-k) \) is included to improve the overall estimate’s small-sample properties.

vce(hc2) instead uses \( u_j^2/(1-h_{jj}) \) as the observation’s variance estimate, where \( h_{jj} \) is the diagonal element of the hat (projection) matrix. This estimate is unbiased if the model really is homoskedastic. vce(hc2) tends to produce slightly more conservative confidence intervals.

vce(hc3) uses \( u_j^2/(1-h_{jj})^2 \) as suggested by Davidson and MacKinnon (1993), who report that this method tends to produce better results when the model really is heteroskedastic. vce(hc3) produces confidence intervals that tend to be even more conservative.

See Davidson and MacKinnon (1993, 554–556) and Angrist and Pischke (2009, 294–308) for more discussion on these two bias corrections.

level(#) \text{; see [R] Estimation options.}

beta asks that standardized beta coefficients be reported instead of confidence intervals. The beta coefficients are the regression coefficients obtained by first standardizing all variables to have a mean of 0 and a standard deviation of 1. beta may not be specified with vce(cluster clustvar) or the svy prefix.

eform(string) is used only in programs and ado-files that use \text{regress} to fit models other than linear regression. eform() specifies that the coefficient table be displayed in exponentiated form as defined in [R] \text{Maximize} and that \text{string} be used to label the exponentiated coefficients in the table.

depname(varname) is used only in programs and ado-files that use \text{regress} to fit models other than linear regression. depname() may be specified only at estimation time. \text{varname} is recorded as the identity of the dependent variable, even though the estimates are calculated using \text{depvar}. This
method affects the labeling of the output—not the results calculated—but could affect subsequent
calculations made by predict, where the residual would be calculated as deviations from varname
rather than depvar. depname() is most typically used when depvar is a temporary variable (see [P] macro)
used as a proxy for varname.

depname() is not allowed with the svy prefix.

display_options: noci, nopvalues, noomitted, vsquish, noemptycells, baselevels,
allbaselevels, noflabel, fwrap(#), fwrapon(style), cformat(%,fmt), pformat(%,fmt),
sformat(%,fmt), and nolstretch; see [R] Estimation options.

The following options are available with regress but are not shown in the dialog box:

noheader suppresses the display of the ANOVA table and summary statistics at the top of the output;
only the coefficient table is displayed. This option is often used in programs and ado-files.

notable suppresses display of the coefficient table.

plus specifies that the output table be made extendable. This option is often used in programs and
ado-files.

mse1 is used only in programs and ado-files that use regress to fit models other than linear
regression and is not allowed with the svy prefix. mse1 sets the mean squared error to 1, forcing
the variance–covariance matrix of the estimators to be (X’X)^{-1} (see Methods and formulas
below) and affecting calculated standard errors. Degrees of freedom for t statistics is calculated
as n rather than n – k.

coefflegend; see [R] Estimation options.

**Remarks and examples**

Remarks are presented under the following headings:

- Ordinary least squares
- Treatment of the constant
- Robust standard errors
- Weighted regression
- Video example

regress performs linear regression, including ordinary least squares and weighted least squares.
See [U] 27 Overview of Stata estimation commands for a list of other regression commands that
may be of interest. For a general discussion of linear regression, see Kutner et al. (2005).

See Stock and Watson (2019) and Wooldridge (2020) for an excellent treatment of estimation,
inference, interpretation, and specification testing in linear regression models. See Wooldridge (2010,
chap. 4) for a more advanced discussion along the same lines.

See Hamilton (2013, chap. 7) and Cameron and Trivedi (2010, chap. 3) for an introduction to
examples from epidemiology, and Stata datasets and do-files used in the text are available. Cameron
discusses how to use graphics and postestimation commands to understand a fitted regression model.

Chatterjee and Hadi (2012) explain regression analysis by using examples containing typical
problems that you might encounter when performing exploratory data analysis. We also recommend
Weisberg (2014), who emphasizes the importance of the assumptions of linear regression and problems
resulting from these assumptions. Beckett (2013) discusses regression analysis with an emphasis on
time-series data. Angrist and Pischke (2009) approach regression as a tool for exploring relationships,
estimating treatment effects, and providing answers to public policy questions. For a mathematically rigorous treatment, see Peracchi (2001, chap. 6). Finally, see Plackett (1972) if you are interested in the history of regression. Least squares, which dates back to the 1790s, was discovered independently by Legendre and Gauss.

**Ordinary least squares**

> **Example 1: Basic linear regression**

Suppose that we have data on the mileage rating and weight of 74 automobiles. The variables in our data are \( \text{mpg} \), \( \text{weight} \), and \( \text{foreign} \). The last variable assumes the value 1 for foreign and 0 for domestic automobiles. We wish to fit the model

\[
\text{mpg} = \beta_0 + \beta_1 \text{weight} + \beta_2 \text{foreign} + \epsilon
\]

This model can be fit with `regress` by typing

```
. use https://www.stata-press.com/data/r16/auto
(1978 Automobile Data)
. regress mpg weight foreign
```

\end{align*}
\]

`regress` produces a variety of summary statistics along with the table of regression coefficients. At the upper left, `regress` reports an analysis-of-variance (ANOVA) table. The column headings `SS`, `df`, and `MS` stand for “sum of squares”, “degrees of freedom”, and “mean square”, respectively. In this example, the total sum of squares is 2,443.5: 1,619.3 accounted for by the model and 824.2 left unexplained. Because the regression included a constant, the total sum reflects the sum after removal of means, as does the sum of squares due to the model. The table also reveals that there are 73 total degrees of freedom (counted as 74 observations less 1 for the mean removal), of which 2 are consumed by the model, leaving 71 for the residual.

To the right of the ANOVA table are presented other summary statistics. The \( F \) statistic associated with the ANOVA table is 69.75. The statistic has 2 numerator and 71 denominator degrees of freedom. The \( F \) statistic tests the hypothesis that all coefficients excluding the constant are zero. The chance of observing an \( F \) statistic that large or larger is reported as 0.0000, which is Stata’s way of indicating a number smaller than 0.00005. The \( R \)-squared (\( R^2 \)) for the regression is 0.6627, and the \( R \)-squared adjusted for degrees of freedom (\( R^2_a \)) is 0.6532. The root mean squared error, labeled `Root MSE`, is 3.4071. It is the square root of the mean squared error reported for the residual in the ANOVA table.

Finally, Stata produces a table of the estimated coefficients. The first line of the table indicates that the left-hand-side variable is `mpg`. Thereafter follow the estimated coefficients. Our fitted model is

\[
\text{mpg\_hat} = 41.68 - 0.0066 \text{weight} - 1.65 \text{foreign}
\]
Reported to the right of the coefficients in the output are the standard errors. For instance, the standard error for the coefficient on `weight` is 0.0006371. The corresponding $t$ statistic is $-10.34$, which has a two-sided significance level of 0.000. This number indicates that the significance is less than 0.0005. The 95% confidence interval for the coefficient is $[-0.0079, -0.0053]$.

### Example 2: Transforming the dependent variable

If we had a graph comparing `mpg` with `weight`, we would notice that the relationship is distinctly nonlinear. This is to be expected because energy usage per distance should increase linearly with weight, but `mpg` is measuring distance per energy used. We could obtain a better model by generating a new variable measuring the number of gallons used per 100 miles (`gp100m`) and then using this new variable in our model:

$$\text{gp100m} = \beta_0 + \beta_1 \text{weight} + \beta_2 \text{foreign} + \epsilon$$

We can now fit this model:

``` stata
. generate gp100m = 100/mpg
. regress gp100m weight foreign
```

<table>
<thead>
<tr>

<th>df</th>
<th>MS</th>
<th>Number of obs = 74</th>
</tr>
</thead>
<tbody>
<tr>
<td>Model</td>
<td>91.1761694</td>
<td>2</td>
<td>45.5880847</td>
<td>F(2, 71) = 113.97</td>
</tr>
<tr>
<td>Residual</td>
<td>28.4000913</td>
<td>71</td>
<td>.400001287</td>
<td>Prob &gt; F = 0.0000</td>
</tr>
<tr>
<td>Total</td>
<td>119.576261</td>
<td>73</td>
<td>1.63803097</td>
<td>R-squared = 0.7625</td>
</tr>
</tbody>
</table>

| gp100m   | Coef.    | Std. Err. | t     | P>|t|   | [95% Conf. Interval] |
|----------|----------|-----------|-------|-------|---------------------|
| weight   | .0016254 | .0001183  | 13.74 | 0.000 | .0013896 .0018612   |
| foreign  | .6220535 | .1997381  | 3.11  | 0.003 | .2237871 1.02032    |
| _cons    | -.0734839| .4019932  | -.18  | 0.855 | -.8750354 .7280677  |

Fitting the physically reasonable model increases our $R$-squared to 0.7625.

### Example 3: Obtaining beta coefficients

`regress` shares the features of all estimation commands. Among other things, this means that after running a regression, we can use `test` to test hypotheses about the coefficients, `estat vce` to examine the covariance matrix of the estimators, and `predict` to obtain predicted values, residuals, and influence statistics. See [U] 20 Estimation and postestimation commands. Options that affect how estimates are displayed, such as `beta` or `level()`, can be used when replaying results.
Suppose that we meant to specify the `beta` option to obtain beta coefficients (regression coefficients normalized by the ratio of the standard deviation of the regressor to the standard deviation of the dependent variable). Even though we forgot, we can specify the option now:

```
.regress, beta
```

<table>
<thead>
<tr>
<th>Source</th>
<th>SS</th>
<th>df</th>
<th>MS</th>
<th>Number of obs = 74</th>
</tr>
</thead>
<tbody>
<tr>
<td>Model</td>
<td>91.1761694</td>
<td>2</td>
<td>45.5880847</td>
<td>F(2, 71) = 113.97</td>
</tr>
<tr>
<td>Residual</td>
<td>28.4000913</td>
<td>71</td>
<td>.400001287</td>
<td>Prob &gt; F = 0.0000</td>
</tr>
<tr>

<td>119.576261</td>
<td>73</td>
<td>1.63803097</td>
<td>R-squared = 0.7625</td>
</tr>
</tbody>
</table>

```
| gp100m | Coef. | Std. Err. | t     | P>|t| | Beta   |
|--------|-------|-----------|-------|------|--------|
| weight | .0016254 | .0001183 | 13.74 | 0.000 | .9870255 |
| foreign | .6220535 | .1997381 | 3.11  | 0.003 | .2236673 |
| _cons  | -.0734839 | .4019932 | -0.18 | 0.855 | .        |
```

### Treatment of the constant

By default, `regress` includes an intercept (constant) term in the model. The `noconstant` option suppresses it, and the `hascons` option tells `regress` that the model already has one.

#### Example 4: Suppressing the constant term

We wish to fit a regression of the `weight` of an automobile against its `length`, and we wish to impose the constraint that the weight is zero when the length is zero.

If we simply type `regress weight length`, we are fitting the model

\[
weight = \beta_0 + \beta_1 \text{length} + \epsilon
\]

Here a `length` of zero corresponds to a `weight` of `\beta_0`. We want to force `\beta_0` to be zero or, equivalently, estimate an equation that does not include an intercept:

\[
weight = \beta_1 \text{length} + \epsilon
\]

We do this by specifying the `noconstant` option:

```
.regress weight length, noconstant
```

<table>

|--------|-------|-----------|-------|------|---------------------|
| length | 16.29829 | .2774752 | 58.74 | 0.000 | 15.74528 16.8513 |
```

In our data, `length` is measured in inches and `weight` in pounds. We discover that each inch of `length` adds 16 pounds to the weight.
Sometimes there is no need for Stata to include a constant term in the model. Most commonly, this occurs when the model contains a set of mutually exclusive indicator variables. The `hascons` option tells Stata not to add a constant to the regression because the regression specification already has one, either directly or indirectly.

For instance, we now refit our model of `weight` as a function of `length` and include separate constants for foreign and domestic cars by specifying `bn.foreign`. `bn.foreign` is factor-variable notation for “no base for foreign” or “include all levels of variable foreign in the model”; see [U] 11.4.3 Factor variables.

```
regress weight length bn.foreign, hascons
```

**Technical note**

There is a subtle distinction between the `hascons` and `noconstant` options. We can most easily reveal it by refitting the last regression, specifying `noconstant` rather than `hascons`:

```
regress weight length bn.foreign, noconstant
```

<table>
<thead>
<tr>
<th>Source</th>
<th>SS</th>
<th>df</th>
<th>MS</th>
<th>Number of obs = 74</th>
</tr>
</thead>
<tbody>
<tr>
<td>Model</td>
<td>714315766</td>

<td>238105255</td>
<td>F(3, 71) = 3802.03</td>
</tr>
<tr>
<td>Residual</td>
<td>4446433.7</td>
<td>71</td>
<td>62625.8268</td>
<td>Prob &gt; F = 0.0000</td>
</tr>
<tr>
<td>Total</td>
<td>718762200</td>
<td>74</td>
<td>9713002.7</td>
<td>R-squared = 0.9938</td>
</tr>
</tbody>
</table>

```
regress weight length bn.foreign, hascons
```

| weight   | Coef.          | Std. Err. | t    | P>|t| | [95% Conf. Interval] |
|----------|----------------|------------|------|------|----------------------|
| length   | 31.44455       | 1.601234   | 19.64| 0.000| 28.25178 34.63732    |
| foreign  | Domestic       | -2850.25   | 315.9691| -9.02| 0.000 -3480.274 -2220.225 |
|          | Foreign        | -2983.927  | 275.1041| -10.85| 0.000 -3532.469 -2435.385 |

Comparing this output with that produced by the *previous regress command*, we see that they are almost, but not quite, identical. The parameter estimates and their associated statistics—the second half of the output—are identical. The overall summary statistics and the ANOVA table—the first half of the output—are different, however.

In the first case, the $R^2$ is shown as 0.8992; here it is shown as 0.9938. In the first case, the $F$ statistic is 316.54; now it is 3,802.03. The numerator degrees of freedom is different as well. In the first case, the numerator degrees of freedom is 2; now the degrees of freedom is 3. Which is correct?
Both are. Specifying the hascons option causes `regress` to adjust the ANOVA table and its associated statistics for the explanatory power of the constant. The regression in effect has a constant; it is just written in such a way that a separate constant is unnecessary. No such adjustment is made with the noconstant option.

### Technical note

When the hascons option is specified, `regress` checks to make sure that the model does in fact have a constant term. If `regress` cannot find a constant term, it automatically adds one. Fitting a model of weight on length and specifying the hascons option, we obtain

```
. regress weight length, hascons
(note: hascons false)
```

```
Source          SS     df      MS
-------------   ------  ------  ------
Model          39461306.8   1  39461306.8
Residual      4632871.55   72  64345.4382
Total         44094178.4   73  604029.841
```

```
weight      Coef.    Std. Err.     t    P>|t|        [95% Conf. Interval]
-------------  --------  -------------  -----  --------        -------------
length      33.01988   1.333364    24.76  0.000        30.36187     35.67789
_cons      -3186.047   252.3113   -12.63  0.000       -3689.02    -2683.073
```

Even though we specified hascons, `regress` included a constant, anyway. It also added a note to our output: “note: hascons false”.

### Technical note

Even if the model specification effectively includes a constant term, we need not specify the hascons option. `regress` is always on the lookout for collinear variables and omits them from the model. For instance,

```
. regress weight length bn.foreign
(note: hascons false)
```

```
Source          SS     df      MS
-------------   ------  ------  ------
Model          39647744.7   2  19823872.3
Residual      4446433.7    71  62625.8268
Total         44094178.4   73  604029.841
```

```
weight      Coef.    Std. Err.     t    P>|t|        [95% Conf. Interval]
-------------  --------  -------------  -----  --------        -------------
length      31.44455   1.601234    19.64  0.000        28.25178     34.63732
_foreign     133.6775   77.47615     1.73  0.089      -20.80555    288.1605
Domestic          0 (omitted)
_foreign     -2983.927  275.1041   -10.85  0.000       -3532.469    -2435.385
```
Robust standard errors

`regress` with the `vce(robust)` option substitutes a robust variance matrix calculation for the conventional calculation, or if `vce(cluster clustvar)` is specified, allows relaxing the assumption of independence within groups. How this method works is explained in [U] 20.22 Obtaining robust variance estimates. Below we show how well this approach works.

Example 5: Heteroskedasticity and robust standard errors

Specifying the `vce(robust)` option is equivalent to requesting White-corrected standard errors in the presence of heteroskedasticity. We use the automobile data and, in the process of looking at the energy efficiency of cars, analyze a variable with considerable heteroskedasticity.

We will examine the amount of energy—measured in gallons of gasoline—that the cars in the data need to move 1,000 pounds of their weight 100 miles. We are going to examine the relative efficiency of foreign and domestic cars.

```
. generate gpmw = ((1/mpg)/weight)*100*1000
. summarize gpmw
```

```
<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>gpmw</td>
<td>74</td>
<td>1.682184</td>
<td>.2426311</td>
<td>1.09553</td>
<td>2.30521</td>
</tr>
</tbody>
</table>
```

In these data, the engines consume between 1.10 and 2.31 gallons of gas to move 1,000 pounds of the car’s weight 100 miles. If we ran a regression with conventional standard errors of `gpmw` on `foreign`, we would obtain:

```
. regress gpmw foreign
```

```
<table>
<thead>
<tr>
<th>Source</th>
<th>SS</th>
<th>df</th>
<th>MS</th>
<th>Number of obs = 74</th>
</tr>
</thead>
<tbody>
<tr>
<td>Model</td>
<td>.936705572</td>
<td>1</td>
<td>.936705572</td>
<td>F(1, 72) = 20.07</td>
</tr>
<tr>
<td>Residual</td>
<td>3.36079459 72</td>
<td>.046677703</td>
<td>Prob &gt; F = 0.0000</td>
<td></td>
</tr>
<tr>
<td>Total</td>
<td>4.29750017 73</td>
<td>.058869865</td>
<td>R-squared = 0.2180</td>
<td></td>
</tr>
</tbody>
</table>

| gpmw | Coef. | Std. Err. | t     | P>|t|  | [95% Conf. Interval] |
|------|-------|-----------|-------|------|----------------------|
| foreign | .2461526 | .0549487 | 4.48  | 0.000 | .1366143, .3556909   |
| _cons  | 1.609004 | .0299608 | 53.70 | 0.000 | 1.56225, 1.655758   |
```

`regress` with the `vce(robust)` option, on the other hand, reports:

```
. regress gpmw foreign, vce(robust)
```

```
| gpmw | Robust Coef. | Std. Err. | t     | P>|t|  | [95% Conf. Interval] |
|------|--------------|-----------|-------|------|----------------------|
| foreign | .2461526 | .0679238 | 3.62  | 0.001 | .1107489, .3815563   |
| _cons  | 1.609004 | .0234535 | 68.60 | 0.000 | 1.56225, 1.655758   |
```

The point estimates are the same (foreign cars need one-quarter gallon more gas), but the standard errors differ by roughly 20%. Conventional regression reports the 95% confidence interval as [0.14, 0.36], whereas the robust standard errors make the interval [0.11, 0.38].
Which is right? Notice that \texttt{gpmw} is a variable with considerable heteroskedasticity:

\begin{verbatim}
. tabulate foreign, summarize(gpmw)
\end{verbatim}

\begin{verbatim}
Summary of gpmw

<table>
<thead>
<tr>
<th>Car type</th>
<th>Summary of gpmw</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Mean</td>
</tr>
<tr>
<td>Domestic</td>
<td>1.6090039</td>
</tr>
<tr>
<td>Foreign</td>
<td>1.8551565</td>
</tr>
<tr>
<td>Total</td>
<td>1.6821844</td>
</tr>
</tbody>
</table>
\end{verbatim}

Thus here we favor the robust standard errors. In [U] 20.22 \textit{Obtaining robust variance estimates}, we show another example using linear regression where it makes little difference whether we specify \texttt{vce(robust)}. The linear-regression assumptions were true, and we obtained nearly linear-regression results. The advantage of the robust estimate is that in neither case did we have to check assumptions.

---

\textbf{Technical note}

\texttt{regress} purposefully suppresses displaying the ANOVA table when \texttt{vce(robust)} is specified. This is done because the sums of squares are no longer appropriate for use in the usual hypothesis tests, even though computationally the sums of squares remain the same. In the nonrobust setting, the \textit{F} statistic reported by \texttt{regress} is defined in terms of the sums of squares, as in ANOVA. When \texttt{vce(robust)} is specified, the ANOVA test is not valid, and the \textit{F} statistic corresponds to a Wald test based on the robustly estimated variance matrix.

Some references give formulas for the \textit{F} statistic in terms of either $R^2$ or the root MSE. It is not appropriate to use those formulas for the \textit{F} statistic with robust standard errors because the $R^2$ and root MSE are calculated from the sums of squares. Moreover, the root MSE can no longer be used as an estimate for $\sigma$ because there is no longer a single $\sigma$ to estimate—the variance of the residual varies observation by observation. However, \texttt{regress} continues to report the $R^2$ and the root MSE in the robust setting because those statistics are still usable in other settings. In particular, $R^2$ remains valid as a goodness-of-fit statistic.

---

\textbf{Example 6: Alternative robust standard errors}

The \texttt{vce(hc2)} and \texttt{vce(hc3)} options modify the robust variance calculation. In the context of linear regression without clustering, the idea behind the robust calculation is somehow to measure $\sigma_j^2$, the variance of the residual associated with the \textit{j}th observation, and then to use that estimate to improve the estimated variance of $\hat{\beta}$. Because residuals have (theoretically and practically) mean 0, one estimate of $\sigma_j^2$ is the observation’s squared residual itself—$u_j^2$. A finite-sample correction could improve that by multiplying $u_j^2$ by $n/(n-k)$, and, as a matter of fact, \texttt{vce(robust)} uses $\{n/(n-k)\}u_j^2$ as its estimate of the residual’s variance.

\texttt{vce(hc2)} and \texttt{vce(hc3)} use alternative estimators of the observation-specific variances. For instance, if the residuals are homoskedastic, we can show that the expected value of $u_j^2$ is $\sigma^2(1-h_{jj})$, where $h_{jj}$ is the \textit{j}th diagonal element of the projection (hat) matrix. $h_{jj}$ has average value $k/n$, so $1-h_{jj}$ has average value $1-k/n = (n-k)/n$. Thus the default robust estimator $\hat{\sigma}_j = \{n/(n-k)\}u_j^2$ amounts to dividing $u_j^2$ by the average of the expectation.
vce(hc2) divides \( u_j^2 \) by \( 1 - h_{jj} \) itself, so it should yield better estimates if the residuals really are homoskedastic. vce(hc3) divides \( u_j^2 \) by \( (1 - h_{jj})^2 \) and has no such clean interpretation. Davidson and MacKinnon (1993) show that \( u_j^2/(1 - h_{jj})^2 \) approximates a more complicated estimator that they obtain by jackknifing (MacKinnon and White 1985). Angrist and Pischke (2009) also illustrate the relative merits of these adjustments.

Here are the results of refitting our efficiency model using vce(hc2) and vce(hc3):

```
. regress gpmw foreign, vce(hc2)
Linear regression
Number of obs = 74
F(1, 72) = 12.93

```

Example 7: Standard errors for clustered data

The vce(cluster clustvar) option relaxes the assumption of independence. Below we have 28,534 observations on 4,711 women aged 14–46 years. Data were collected on these women between 1968 and 1988. We are going to fit a classic earnings model, and we begin by ignoring that the majority of the women in the dataset have multiple observations.
. use https://www.stata-press.com/data/r16/regsmpl, clear
(NLS Women 14-26 in 1968)
. regress ln_wage age c.age#c.age tenure

| ln_wage       | Coef. | Std. Err. | t    | P>|t|  | [95% Conf. Interval] |
|---------------|-------|-----------|------|---------|---------------------|
| age           | .0752172 | .0034736 | 21.65 | 0.000 | .0684088 | .0820257 |
| c.age#c.age   | -.0010851 | .0000575 | -18.86 | 0.000 | -.0011979 | -.0009724 |
| tenure        | .0390877 | .0007743 | 50.48 | 0.000 | .0375699 | .0406054 |
| _cons         | .3339821 | .0504413 | 6.62  | 0.000 | .2351148 | .4328495 |

The number of observations in our model is 28,101 because Stata drops observations that have a missing value for one or more of the variables in the model. We can be reasonably certain that the standard errors reported above are meaningless. Without a doubt, a woman with higher-than-average wages in one year typically has higher-than-average wages in other years, and so the residuals are not independent. One way to deal with this is to use cluster–robust standard errors. We do this by specifying vce(cluster id), which treats only observations with different person ids as truly independent:

. regress ln_wage age c.age#c.age tenure, vce(cluster id)

| ln_wage       | Coef. | Std. Err. | t    | P>|t|  | [95% Conf. Interval] |
|---------------|-------|-----------|------|---------|---------------------|
| age           | .0752172 | .0045711 | 16.45 | 0.000 | .0662557 | .0841788 |
| c.age#c.age   | -.0010851 | .0000778 | -13.94 | 0.000 | -.0012377 | -.0009325 |
| tenure        | .0390877 | .0004413 | 27.10 | 0.000 | .0362596 | .0419157 |
| _cons         | .3339821 | .0641918 | 5.20  | 0.000 | .208136 | .4598282 |

For comparison, we focus on the tenure coefficient, which in economics jargon can be interpreted as the rate of return for keeping your job. The 95% confidence interval we previously estimated—an interval we do not believe—is $[0.038, 0.041]$. The robust interval is twice as wide, being $[0.036, 0.042]$. 
Another possible way to account for the lack of independence is to fit a random-effects model. Here is the random-effects result:

```
xtreg ln_wage age c.age#c.age tenure, re
Random-effects GLS regression Number of obs = 28,101
Group variable: idcode Number of groups = 4,699
R-sq: within = 0.1370 Obs per group:
between = 0.2154 min = 1
overall = 0.1608 avg = 6.0
Wald chi2(3) = 4717.05 max = 15
corr(u_i, X) = 0 (assumed) Prob > chi2 = 0.0000

| ln_wage     | Coef. | Std. Err. | z     | P>|z|  | [95% Conf. Interval] |
|-------------|-------|-----------|-------|------|---------------------|
| age         | 0.0568296 | 0.0026958 | 21.08 | 0.000 | 0.0515459 - 0.0621132 |
| c.age#c.age | -0.0007566 | 0.0000447 | -16.93 | 0.000 | -0.0008441 - 0.000669 |
| tenure      | 0.0260135 | 0.0007477 | 34.79 | 0.000 | 0.0245481 - 0.0274789 |
| _cons       | 0.6136792 | 0.0394611 | 15.55 | 0.000 | 0.5363368 - 0.6910216 |
| sigma_u     | 0.33542449 |
| sigma_e     | 0.29674679 |
| rho         | 0.56095413 | (fraction of variance due to u_i) |
```

Robust regression estimated the 95% interval [0.036, 0.042], and xtreg (see [XT] xtreg) estimates [0.025, 0.027]. Which is better? The random-effects regression estimator assumes a lot. We can check some of these assumptions by performing a Hausman test. Using estimates (see [R] estimates store), we store the random-effects estimation results, and then we run the required fixed-effects regression to perform the test.

```
. estimates store random
. xtreg ln_wage age c.age#c.age tenure, fe
Fixed-effects (within) regression Number of obs = 28,101
Group variable: idcode Number of groups = 4,699
R-sq: within = 0.1375 Obs per group:
between = 0.2066 min = 1
overall = 0.1568 avg = 6.0
F(3, 23399) = 1243.00 max = 15
corr(u_i, Xb) = 0.1380 Prob > F = 0.0000

| ln_wage     | Coef. | Std. Err. | t     | P>|t|  | [95% Conf. Interval] |
|-------------|-------|-----------|-------|------|---------------------|

F test that all u_i=0: F(4698, 23399) = 7.98 Prob > F = 0.0000
The Hausman test casts grave suspicions on the random-effects model we just fit, so we should be careful in interpreting those results.

Meanwhile, our robust regression results still stand, as long as we are careful about the interpretation. The correct interpretation is that, if the data collection were repeated (on women sampled the same way as in the original sample), and if we were to refit the model, 95% of the time we would expect the estimated coefficient on tenure to be in the range \([0.036, 0.042]\).

Even with robust regression, we must be careful about going beyond that statement. Here the Hausman test is probably picking up something that differs within and between person, which would cast doubt on our robust regression model in terms of interpreting \([0.036, 0.042]\) to contain the rate of return for keeping a job, economywide, for all women, without exception.

### Weighted regression

`regress` can perform weighted and unweighted regression. We indicate the weight by specifying the `weight` qualifier.

#### Example 8: Using means as regression variables

We have census data recording the death rate (`drate`) and median age (`medage`) for each state. The data also record the region of the country in which each state is located and the overall population of the state:

```
. use https://www.stata-press.com/data/r16/census9
   (1980 Census data by state)
. describe
Contains data from https://www.stata-press.com/data/r16/census9.dta
    obs:      50  1980 Census data by state
    vars:       6  2 Dec 2018 15:22
storage  display value
variable name   type   format    label                  variable label
  state         str13  %13s   State
  state2        str2   %2s    Two-letter state abbreviation
  drate         int    %9.0g  Death rate
  pop           long   %12.0gc Population
  medage        float  %9.2f  Median age
  region        byte   %8.0g  cenreg Census region
```

Sorted by:
We can use factor variables to include dummy variables for region. Because the variables in the regression reflect means rather than individual observations, the appropriate method of estimation is analytically weighted least squares (Davidson and MacKinnon 2004, 261–262), where the weight is total population:

\[
\texttt{. regress drate medage i.region [aweight=pop]} \\
\text{(sum of wgt is 225,907,472)}
\]

To weight the regression by population, we added the qualifier \([\text{aweight=pop}]\) to the end of the \texttt{regress} command. Stata informed us that the sum of the weight is \(2.2591 \times 10^8\); there were approximately 226 million people residing in the United States according to our 1980 data.

In the weighted regression, we see that the coefficient on \texttt{West} is statistically significant but that the coefficients on \texttt{N Cntrl} and \texttt{South} are not. We use \texttt{testparm} to test the joint significance of the region variable. Because we fit a weighted regression, \texttt{testparm} uses the appropriately weighted variance–covariance matrix.

\[
\texttt{. testparm i.region} \\
\text{( 1) 2.region = 0} \\
\text{( 2) 3.region = 0} \\
\text{( 3) 4.region = 0} \\
\text{F( 3, 45) = 9.84} \\
\text{Prob > F = 0.0000}
\]

The results indicate that the region variables are jointly significant. Note that we could have performed this same test by typing \texttt{contrast region}. You may prefer to use the \texttt{contrast} command because, in addition to the joint test, you can perform other tests such as comparisons of each region’s mean to the grand mean; see \texttt{[R] contrast} for more information.

\texttt{regress} also accepts frequency weights (\texttt{fweights}). Frequency weights are appropriate when the data do not reflect cell means, but instead represent replicated observations. Specifying \texttt{aweights} or \texttt{fweights} will not change the parameter estimates, but it will change the corresponding significance levels.

For instance, if we specified \texttt{[fweight=pop]} in the weighted regression example above—which would be statistically incorrect—Stata would treat the data as if the data represented 226 million independent observations on death rates and median age. The data most certainly do not represent that—they represent 50 observations on state averages.
Technical note

A frequent inquiry sent to StataCorp Technical Services is to describe the effect of specifying [aweight=exp] with regress in terms of transformation of the dependent and independent variables. The mechanical answer is that typing

```
  . regress y x1 x2 [aweight=n]
```

is equivalent to fitting the model

\[ y_j \sqrt{n_j} = \beta_0 \sqrt{n_j} + \beta_1 x_{1j} \sqrt{n_j} + \beta_2 x_{2j} \sqrt{n_j} + u_j \sqrt{n_j} \]

This regression will reproduce the coefficients and covariance matrix produced by the aweighted regression. The mean squared errors (estimates of the variance of the residuals) will, however, be different. The transformed regression reports \( s_t^2 \), an estimate of \( \text{Var}(u_j \sqrt{n_j}) \). The aweighted regression reports \( s_a^2 \), an estimate of \( \text{Var}(u_j \sqrt{N/\sum_k n_k}) \), where \( N \) is the number of observations. Thus

\[ s_a^2 = \frac{N}{\sum_k n_k} s_t^2 = \frac{s_t^2}{\bar{n}} \tag{1} \]

The logic for this adjustment is as follows: Consider the model

\[ y = \beta_0 + \beta_1 x_1 + \beta_2 x_2 + u \]

Assume that, were this model fit on individuals, \( \text{Var}(u) = \sigma_u^2 \), a constant. Assume that individual data are not available; what is available are averages \((\bar{y}_j, \bar{x}_{1j}, \bar{x}_{2j})\) for \( j = 1, \ldots, N \), and each average is calculated over \( n_j \) observations. Then it is still true that

\[ \bar{y}_j = \beta_0 + \beta_1 \bar{x}_{1j} + \beta_2 \bar{x}_{2j} + \bar{u}_j \]

where \( \bar{n}_j \) is the average of \( n_j \) mean 0, variance \( \sigma_u^2 \) deviates and has variance \( \sigma_u^2 = \sigma_{\bar{n}}^2 / n_j \). Thus multiplying through by \( \sqrt{n_j} \) produces

\[ \bar{y}_j \sqrt{n_j} = \beta_0 \sqrt{n_j} + \beta_1 \bar{x}_{1j} \sqrt{n_j} + \beta_2 \bar{x}_{2j} \sqrt{n_j} + \bar{u}_j \sqrt{n_j} \]

and \( \text{Var}(\bar{y}_j \sqrt{n_j}) = \sigma_u^2 \). The mean squared error, \( s_t^2 \), reported by fitting this transformed regression is an estimate of \( \sigma_u^2 \). The coefficients and covariance matrix could also be obtained by aweighted regress. The only difference would be in the reported mean squared error, which from (1) is \( \sigma_u^2 / \bar{n} \). On average, each observation in the data reflects the averages calculated over \( \bar{n} = \sum_k n_k / N \) individuals, and thus this reported mean squared error is the average variance of an observation in the dataset. We can retrieve the estimate of \( \sigma_u^2 \) by multiplying the reported mean squared error by \( \bar{n} \).

More generally, aweights are used to solve general heteroskedasticity problems. In these cases, we have the model

\[ y_j = \beta_0 + \beta_1 x_{1j} + \beta_2 x_{2j} + u_j \]

and the variance of \( u_j \) is thought to be proportional to \( a_j \). If the variance is proportional to \( a_j \), it is also proportional to \( \alpha a_j \), where \( \alpha \) is any positive constant. Not quite arbitrarily, but with no loss of generality, we could choose \( \alpha = \frac{1}{\sum_k (1/a_k) / N} \), the average value of the inverse of \( a_j \). We can then write \( \text{Var}(u_j) = k \alpha a_j \sigma^2 \), where \( k \) is the constant of proportionality that is no longer a function of the scale of the weights.
Dividing this regression through by the $\sqrt{a_j}$,

$$y_j/\sqrt{a_j} = \beta_0/\sqrt{a_j} + \beta_1x_{1j}/\sqrt{a_j} + \beta_2x_{2j}/\sqrt{a_j} + u_j/\sqrt{a_j}$$

produces a model with $\text{Var}(u_j/\sqrt{a_j}) = k\alpha\sigma^2$, which is the constant part of $\text{Var}(u_j)$. This variance is a function of $\alpha$, the average of the reciprocal weights; if the weights are scaled arbitrarily, then so is this variance.

We can also fit this model by typing

```plaintext
. regress y x1 x2 [aweight=1/a]
```

This input will produce the same estimates of the coefficients and covariance matrix; the reported mean squared error is, from (1), $\left\{\frac{N}{\sum_k(1/a_k)}\right\}k\alpha\sigma^2 = k\sigma^2$. This variance is independent of the scale of $a_j$.

Simple linear regression in Stata

Stored results

`regress` stores the following in $\text{e()}$:

Scalars

- $\text{e(N)}$: number of observations
- $\text{e(mss)}$: model sum of squares
- $\text{e(df_m)}$: model degrees of freedom
- $\text{e(rss)}$: residual sum of squares
- $\text{e(df_r)}$: residual degrees of freedom
- $\text{e(r2)}$: $R$-squared
- $\text{e(r2_a)}$: adjusted $R$-squared
- $\text{e(F)}$: $F$ statistic
- $\text{e(rmse)}$: root mean squared error
- $\text{e(ll)}$: log likelihood under additional assumption of i.i.d. normal errors
- $\text{e(ll0)}$: log likelihood, constant-only model
- $\text{e(N_clust)}$: number of clusters
- $\text{e(rank)}$: rank of $\text{e(V)}$

Macros

- $\text{e(cmd)}$: `regress`
- $\text{e(cmdline)}$: command as typed
- $\text{e(depvar)}$: name of dependent variable
- $\text{e(wtype)}$: weight type
- $\text{e(wexp)}$: weight expression
- $\text{e(model)}$: ols
- $\text{e(title)}$: title in estimation output when `vce()` is not ols
- $\text{e(clustvar)}$: name of cluster variable
- $\text{e(vce)}$: vcetype specified in `vce()`
- $\text{e(vcetype)}$: title used to label Std. Err.
- $\text{e(properties)}$: `b V`
- $\text{e(estat_cmd)}$: program used to implement `estat`
- $\text{e(predict)}$: program used to implement `predict`
- $\text{e(marginsok)}$: predictions allowed by `margins`
- $\text{e(asbalanced)}$: factor variables fvset as `asbalanced`
- $\text{e(asobserved)}$: factor variables fvset as `asobserved`
Methods and formulas

Methods and formulas are presented under the following headings:

- Coefficient estimation and ANOVA table
- Weighted regression
- A general notation for the robust variance calculation
- Robust calculation for regress

Coefficient estimation and ANOVA table

Variables printed in lowercase and not boldfaced (for example, $x$) are scalars. Variables printed in lowercase and boldfaced (for example, $\mathbf{x}$) are column vectors. Variables printed in uppercase and boldfaced (for example, $\mathbf{X}$) are matrices.

Let $\mathbf{X}$ denote the matrix of observations on the right-hand-side variables, $\mathbf{y}$ the vector of observations on the left-hand-side variable. Define $\mathbf{A}$ as $\mathbf{X}'\mathbf{X}$ and $\mathbf{a}$ as $\mathbf{X}'\mathbf{y}$. The coefficient vector $\mathbf{b}$ is defined as $\mathbf{A}^{-1}\mathbf{a}$. Although not shown in the notation, unless `hascons` is specified, $\mathbf{A}$ and $\mathbf{a}$ are accumulated in deviation form and the constant is calculated separately. This comment applies to all statistics listed below.

The total sum of squares, $\text{TSS}$, equals $\mathbf{y}'\mathbf{y}$ if there is no intercept and $\mathbf{y}'\mathbf{y} - \{(\mathbf{1}'\mathbf{y})^2/n\}$ otherwise. The degrees of freedom is $n - c$, where $n$ is the number of observations and $c = 1$ if there is a constant in the regression and 0 otherwise.

The residual sum of squares, $\text{RSS}$, is defined as $(\mathbf{y} - \mathbf{X}\mathbf{b})'(\mathbf{y} - \mathbf{X}\mathbf{b})$. The degrees of freedom is $n - k$, where $n$ is the number of observations and $k$ is the number of right-hand-side variables (including the constant).

The model sum of squares, $\text{MSS}$, equals $\text{TSS} - \text{RSS}$. The degrees of freedom is $k - c$.

The mean squared error, $s^2$, is defined as $\text{RSS}/(n - k)$. The root mean squared error is $s$, its square root.

The $F$ statistic with $k - c$ and $n - k$ degrees of freedom is defined as

$$F = \frac{\text{MSS}}{(k - c)s^2}$$

The $R$-squared, $R^2$, is defined as $R^2 = 1 - \text{RSS}/\text{TSS}$.

The adjusted $R$-squared, $R_a^2$, is $1 - (1 - R^2)(n - c)/(n - k)$.

The conventional estimate of variance is $s^2\mathbf{A}^{-1}$. The calculation of variance estimates when robust variance estimates are specified is described below.
Weighted regression

Let \( \mathbf{v} \) be a column vector of weights specified by the user. Let \( \mathbf{w} \) be a column vector of normalized weights, 
\[
\mathbf{w} = \{ \mathbf{v}/(1'\mathbf{v}) \} (1'1).
\]
For \( \text{fweights} \), \( \mathbf{w} = \mathbf{v} \). For historical reasons, \( \text{iweights} \) are treated like \( \text{fweights} \) when robust standard errors are not specified. Instead, when \( \text{vce(robust)}, \text{vce(cluster clustvar)}, \text{vce(hc2)}, \text{or vce(hc3)} \) is specified, \( \text{iweights} \) are treated like \( \text{aweight} \)s.

If the user specifies weights, the number of observations, \( n \), in the above formulas is defined as \( 1'\mathbf{w} \). For \( \text{iweights} \), this is truncated to an integer. The sum of the weights is \( 1'\mathbf{v} \).

\( X'X, X'y, \) and \( y'y \) are replaced in the above formulas by \( X'DX, X'Dy, \) and \( y'Dy \), respectively, where \( D \) is a diagonal matrix whose diagonal elements are the elements of \( \mathbf{w} \).

A general notation for the robust variance calculation

Put aside all context of linear regression and the notation that goes with it—we will return to it. First, we are going to establish a notation for describing robust variance calculations.

The calculation formula for the robust variance calculation is
\[
\hat{\mathbf{V}} = q_c \hat{\mathbf{V}} \left( \sum_{k=1}^{M} \mathbf{u}_k^{(G)} \mathbf{u}_k^{(G)'} \right) \hat{\mathbf{V}}
\]
where
\[
\mathbf{u}_k^{(G)} = \sum_{j \in G_k} w_j \mathbf{u}_j
\]
\( G_1, G_2, \ldots, G_M \) are the clusters specified by \( \text{vce(cluster clustvar)} \), and \( w_j \) are the user-specified weights, normalized if \( \text{aweight} \)s or \( \text{pweight} \)s are specified and equal to 1 if no weights are specified.

For \( \text{fweights} \) without clusters, the variance formula is
\[
\hat{\mathbf{V}} = q_c \hat{\mathbf{V}} \left( \sum_{j=1}^{N} w_j \mathbf{u}_j \mathbf{u}_j' \right) \hat{\mathbf{V}}
\]
which is the same as expanding the dataset and making the calculation on the unweighted data.

If \( \text{vce(cluster clustvar)} \) is not specified, \( M = N \), and each cluster contains 1 observation. The inputs into this calculation are
- \( \hat{\mathbf{V}} \), which is typically a conventionally calculated variance matrix;
- \( \mathbf{u}_j, j = 1, \ldots, N \), a row vector of scores; and
- \( q_c \), a constant finite-sample adjustment.

Thus we can now describe how estimators apply the robust calculation formula by defining \( \hat{\mathbf{V}}, \mathbf{u}_j, \) and \( q_c \).

Two definitions are popular enough for \( q_c \) to deserve a name. The regression-like formula for \( q_c \) (Fuller et al. 1986) is
\[
q_c = \frac{N - 1}{N - k} \frac{M}{M - 1}
\]
where \( M \) is the number of clusters and \( N \) is the number of observations. For weights, \( N \) refers to the sum of the weights if weights are frequency weights and the number of observations in the dataset (ignoring weights) in all other cases. Also note that, weighted or not, \( M = N \) when \( \text{vce(cluster clustvar)} \) is not specified, and then \( q_c = N/(N - k) \).
The asymptotic-like formula for \( q_c \) is

\[
q_c = \frac{M}{M - 1}
\]

where \( M = N \) if `vce(cluster clustvar)` is not specified.

See [U] 20.22 Obtaining robust variance estimates and [P] _robust for a discussion of the robust variance estimator and a development of these formulas.

**Robust calculation for regress**

For `regress`, \( \hat{V} = A^{-1} \). The other terms are

`vce(robust)`, but not `vce(hc2)` or `vce(hc3)`,

\[
u_j = (y_j - x_j' b)x_j
\]

and \( q_c \) is given by its regression-like definition.

`vce(hc2)`,

\[
u_j = \frac{1}{\sqrt{1 - h_{jj}}}(y_j - x_j' b)x_j
\]

where \( q_c = 1 \) and \( h_{jj} = x_j(X'X)^{-1}x_j' \).

`vce(hc3)`,

\[
u_j = \frac{1}{1 - h_{jj}}(y_j - x_j' b)x_j
\]

where \( q_c = 1 \) and \( h_{jj} = x_j(X'X)^{-1}x_j' \).

**Acknowledgments**

The robust estimate of variance was first implemented in Stata by Mead Over of the Center for Global Development, Dean Jolliffe of the World Bank, and Andrew Foster of the Department of Economics at Brown University (Over, Jolliffe, and Foster 1996).
The history of regression is long and complicated: the books by Stigler (1986) and Hald (1998) are devoted largely to the story. Legendre published first on least squares in 1805. Gauss published later in 1809, but he had the idea earlier. Gauss, and especially Laplace, tied least squares to a normal errors assumption. The idea of the normal distribution can itself be traced back to De Moivre in 1733. Laplace discussed a variety of other estimation methods and error assumptions over his long career, while linear models long predate either innovation. Most of this work was linked to problems in astronomy and geodesy.

A second wave of ideas started when Galton used graphical and descriptive methods on data bearing on heredity to develop what he called regression. His term reflects the common phenomenon that characteristics of offspring are positively correlated with those of parents but with regression slope such that offspring “regress toward the mean”. Galton’s work was rather intuitive: contributions from Pearson, Edgeworth, Yule, and others introduced more formal machinery, developed related ideas on correlation, and extended application into the biological and social sciences. So most of the elements of regression as we know it were in place by 1900.

Pierre-Simon Laplace (1749–1827) was born in Normandy and was early recognized as a remarkable mathematician. He weathered a changing political climate well enough to rise to Minister of the Interior under Napoleon in 1799 (although only for 6 weeks) and to be made a Marquis by Louis XVIII in 1817. He made many contributions to mathematics and physics, his two main interests being theoretical astronomy and probability theory (including statistics). Laplace transforms are named for him.

Adrien-Marie Legendre (1752–1833) was born in Paris (or possibly in Toulouse) and educated in mathematics and physics. He worked in number theory, geometry, differential equations, calculus, function theory, applied mathematics, and geodesy. The Legendre polynomials are named for him. His main contribution to statistics is as one of the discoverers of least squares. He died in poverty, having refused to bow to political pressures.

Johann Carl Friedrich Gauss (1777–1855) was born in Braunschweig (Brunswick), now in Germany. He studied there and at Göttingen. His doctoral dissertation at the University of Helmstedt was a discussion of the fundamental theorem of algebra. He made many fundamental contributions to geometry, number theory, algebra, real analysis, differential equations, numerical analysis, statistics, astronomy, optics, geodesy, mechanics, and magnetism. An outstanding genius, Gauss worked mostly in isolation in Göttingen.

Francis Galton (1822–1911) was born in Birmingham, England, into a well-to-do family with many connections: he and Charles Darwin were first cousins. After an unsuccessful foray into medicine, he became independently wealthy at the death of his father. Galton traveled widely in Europe, the Middle East, and Africa, and became celebrated as an explorer and geographer. His pioneering work on weather maps helped in the identification of anticyclones, which he named. From about 1865, most of his work was centered on quantitative problems in biology, anthropology, and psychology. In a sense, Galton (re)invented regression, and he certainly named it. Galton also promoted the normal distribution, correlation approaches, and the use of median and selected quantiles as descriptive statistics. He was knighted in 1909.

Postestimation commands

The following postestimation commands are of special interest after `regress`:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>dfbeta</td>
<td>DFBETA influence statistics</td>
</tr>
<tr>
<td>estat hettest</td>
<td>tests for heteroskedasticity</td>
</tr>
<tr>
<td>estat imtest</td>
<td>information matrix test</td>
</tr>
<tr>
<td>estat ovtest</td>
<td>Ramsey regression specification-error test for omitted variables</td>
</tr>
<tr>
<td>estat szroeter</td>
<td>Szroeter’s rank test for heteroskedasticity</td>
</tr>
<tr>
<td>estat vif</td>
<td>variance inflation factors for the independent variables</td>
</tr>
<tr>
<td>estat esize</td>
<td>$\eta^2$, $\varepsilon^2$, and $\omega^2$ effect sizes</td>
</tr>
<tr>
<td>estat moran</td>
<td>Moran’s test of residual correlation with nearby residuals</td>
</tr>
</tbody>
</table>

These commands are not appropriate after the `svy` prefix.
The following standard postestimation commands are also available:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>contrast</td>
<td>contrasts and ANOVA-style joint tests of estimates</td>
</tr>
<tr>
<td>estat ic</td>
<td>Akaike’s and Schwarz’s Bayesian information criteria (AIC and BIC)</td>

Predictions

Description for predict

predict creates a new variable containing predictions such as linear predictions, residuals, standardized residuals, Studentized residuals, Cook’s distance, leverage, probabilities, expected values, DFBETAs for varname, standard errors, COVRATIOs, DFITS, and Welsch distances.

Unstarred statistics are available both in and out of sample; type predict ... if e(sample) ... if wanted only for the estimation sample. Starred statistics are calculated only for the estimation sample, even when if e(sample) is not specified.

rstandard, rstudent, cooksd, leverage, dfbeta(), stdp, stdf, stdr, covratio, dfits, and welsch are not available if any vce() other than vce(ols) was specified with regress.

xb, residuals, score, and stdp are the only options allowed with svy estimation results.

where a and b may be numbers or variables; a missing (a ≥ .) means −∞, and b missing (b ≥ .) means +∞; see [U] 12.2.1 Missing values.
Options for predict

xb, the default, calculates the linear prediction.

residuals calculates the residuals.

score is equivalent to residuals in linear regression.

rstandard calculates the standardized residuals.

coksd calculates the Cook’s D influence statistic (Cook 1977).

leverage or hat calculates the diagonal elements of the projection ("hat") matrix.

pr(a,b) calculates Pr(a < x_j*b + u_j < b), the probability that y_j|x_j would be observed in the interval (a, b).

a and b may be specified as numbers or variable names; lb and ub are variable names;

pr(20,30) calculates Pr(20 < x_j*b + u_j < 30);

pr(lb,ub) calculates Pr(lb < x_j*b + u_j < ub); and

pr(20,ub) calculates Pr(20 < x_j*b + u_j < ub).

a missing (a ≥ .) means −∞; pr(.,30) calculates Pr(−∞ < x_j*b + u_j < 30);

pr(lb,.) calculates Pr(lb < x_j*b + u_j < .) in observations for which lb ≥ .

and calculates Pr(lb < x_j*b + u_j < 30) elsewhere.

b missing (b ≥ .) means +∞; pr(20,.) calculates Pr(20 < x_j*b + u_j > 20);

pr(20,ub) calculates Pr(+∞ > x_j*b + u_j > 20) in observations for which ub ≥ .

and calculates Pr(20 < x_j*b + u_j < ub) elsewhere.

e(a,b) calculates E(x_j*b + u_j | a < x_j*b + u_j < b), the expected value of y_j|x_j conditional on y_j|x_j being in the interval (a, b), meaning that y_j|x_j is truncated. a and b are specified as they are for pr().

ystar(a,b) calculates E(y_j^*), where y_j^* = a if x_j*b + u_j ≤ a, y_j^* = b if x_j*b + u_j ≥ b, and y_j^* = x_j*b + u_j otherwise, meaning that y_j^* is censored. a and b are specified as they are for pr().

dfbeta(varname) calculates the DFBETA for varname, the difference between the regression coefficient when the jth observation is included and excluded, said difference being scaled by the estimated standard error of the coefficient. varname must have been included among the regressors in the previously fitted model. The calculation is automatically restricted to the estimation subsample.

stdp calculates the standard error of the prediction, which can be thought of as the standard error of the predicted expected value or mean for the observation’s covariate pattern. The standard error of the prediction is also referred to as the standard error of the fitted value.

stdf calculates the standard error of the forecast, which is the standard error of the point prediction for 1 observation. It is commonly referred to as the standard error of the future or forecast value. By construction, the standard errors produced by stdf are always larger than those produced by stdp; see Methods and formulas.

stdr calculates the standard error of the residuals.

covratio calculates COVRATIO (Belsley, Kuh, and Welsch 1980), a measure of the influence of the jth observation based on considering the effect on the variance–covariance matrix of the estimates. The calculation is automatically restricted to the estimation subsample.
dfits calculates DFITS (Welsch and Kuh 1977) and attempts to summarize the information in the leverage versus residual-squared plot into one statistic. The calculation is automatically restricted to the estimation subsample.

welsch calculates Welsch distance (Welsch 1982) and is a variation on dfits. The calculation is automatically restricted to the estimation subsample.

Remarks and examples for predict

Remarks are presented under the following headings:

Terminology
Fitted values and residuals
Prediction standard errors
Prediction with weighted data
Leverage statistics
Standardized and Studentized residuals
DFITS, Cook’s Distance, and Welsch Distance
COVRATIO

Terminology

Many of these commands concern identifying influential data in linear regression. This is, unfortunately, a field that is dominated by jargon, codified and partially begun by Belsley, Kuh, and Welsch (1980). In the words of Chatterjee and Hadi (1986, 416), “Belsley, Kuh, and Welsch’s book, Regression Diagnostics, was a very valuable contribution to the statistical literature, but it unleashed on an unsuspecting statistical community a computer speak (à la Orwell), the likes of which we have never seen.” Things have only gotten worse since then. Chatterjee and Hadi’s (1986, 1988) own attempts to clean up the jargon did not improve matters (see Hoaglin and Kempthorne [1986], Velleman [1986], and Welsch [1986]). We apologize for the jargon, and for our contribution to the jargon in the form of inelegant command names, we apologize most of all.

Model sensitivity refers to how estimates are affected by subsets of our data. Imagine data on $y$ and $x$, and assume that the data are to be fit by the regression $y_i = \alpha + \beta x_i + \epsilon_i$. The regression estimates of $\alpha$ and $\beta$ are $a$ and $b$, respectively. Now imagine that the estimated $a$ and $b$ would be different if a small portion of the dataset, perhaps even one observation, were deleted. As a data analyst, you would like to think that you are summarizing tendencies that apply to all the data, but you have just been told that the model you fit is unduly influenced by one point or just a few points and that, as a matter of fact, there is another model that applies to the rest of the data—a model that you have ignored. The search for subsets of the data that, if deleted, would change the results markedly is a predominant theme of this entry.

There are three key issues in identifying model sensitivity to individual observations, which go by the names residuals, leverage, and influence. In our $y_i = a + bx_i + \epsilon_i$ regression, the residuals are, of course, $\epsilon_i$—they reveal how much our fitted value $\hat{y}_i = a + bx_i$ differs from the observed $y_i$. A point $(x_i, y_i)$ with a corresponding large residual is called an outlier. Say that you are interested in outliers because you somehow think that such points will exert undue influence on your estimates. Your feelings are generally right, but there are exceptions. A point might have a huge residual and yet not affect the estimated $b$ at all. Nevertheless, studying observations with large residuals almost always pays off.

$(x_i, y_i)$ can be an outlier in another way—just as $y_i$ can be far from $\hat{y}_i$, $x_i$ can be far from the center of mass of the other $x$’s. Such an “outlier” should interest you just as much as the more traditional outliers. Picture a scatterplot of $y$ against $x$ with thousands of points in some sort of mass
at the lower left of the graph and one point at the upper right of the graph. Now run a regression line through the points—the regression line will come close to the point at the upper right of the graph and may in fact, go through it. That is, this isolated point will not appear as an outlier as measured by residuals because its residual will be small. Yet this point might have a dramatic effect on our resulting estimates in the sense that, were you to delete the point, the estimates would change markedly. Such a point is said to have high leverage. Just as with traditional outliers, a high leverage point does not necessarily have an undue effect on regression estimates, but if it does not, it is more the exception than the rule.

Now all of this is a most unsatisfactory state of affairs. Points with large residuals may, but need not, have a large effect on our results, and points with small residuals may still have a large effect. Points with high leverage may, but need not, have a large effect on our results, and points with low leverage may still have a large effect. Can you not identify the influential points and simply have the computer list them for you? You can, but you will have to define what you mean by “influential”.

“Influential” is defined with respect to some statistic. For instance, you might ask which points in your data have a large effect on your estimated \( a \), which points have a large effect on your estimated \( b \), which points have a large effect on your estimated standard error of \( b \), and so on, but do not be surprised when the answers to these questions are different. In any case, obtaining such measures is not difficult—all you have to do is fit the regression excluding each observation one at a time and record the statistic of interest which, in the day of the modern computer, is not too onerous. Moreover, you can save considerable computer time by doing algebra ahead of time and working out formulas that will calculate the same answers as if you ran each of the regressions. (Ignore the question of pairs of observations that, together, exert undue influence, and triples, and so on, which remains largely unsolved and for which the brute force fit-every-possible-regression procedure is not a viable alternative.)

### Fitted values and residuals

Typing `predict newvar` with no options creates `newvar` containing the fitted values. Typing `predict newvar, resid` creates `newvar` containing the residuals.

#### Example 1

Continuing with example 1 from [R] `regress`, we wish to fit the following model:

\[
mpg = \beta_0 + \beta_1 weight + \beta_2 foreign + \epsilon
\]

. use https://www.stata-press.com/data/r16/auto
(1978 Automobile Data)
. regress mpg weight foreign

That done, we can now obtain the predicted values from the regression. We will store them in a new variable called \texttt{pmpg} by typing \texttt{predict pmpg}. Because \texttt{predict} produces no output, we will follow that by summarizing our predicted and observed values.

\begin{verbatim}
. predict pmpg (option \texttt{xb} assumed; fitted values)
. summarize pmpg mpg
\end{verbatim}

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>

</tr>
<tr>
<td>mpg</td>
<td>74</td>
<td>21.29</td>
<td>5.785503</td>
<td>12</td>
<td>41</td>
</tr>
</tbody>
</table>

Example 2: Out-of-sample predictions

We can just as easily obtain predicted values from the model by using a wholly different dataset from the one on which the model was fit. The only requirement is that the data have the necessary variables, which here are \texttt{weight} and \texttt{foreign}.

Using the data on two new cars (the Pontiac Sunbird and the Volvo 260) from the \texttt{newautos.dta} dataset, we can obtain out-of-sample predictions (or forecasts) by typing

\begin{verbatim}
. use https://www.stata-press.com/data/r16/newautos, clear
(\textit{New Automobile Models})
. predict pmpg (option \texttt{xb} assumed; fitted values)
. list, divider
\end{verbatim}

<table>
<thead>
<tr>
<th>make</th>
<th>weight</th>
<th>foreign</th>
<th>pmpg</th>
</tr>
</thead>
<tbody>
<tr>
<td>Pont. Sunbird</td>
<td>2690</td>
<td>Domestic</td>
<td>23.95829</td>
</tr>
<tr>
<td>Volvo 260</td>
<td>3170</td>
<td>Foreign</td>
<td>19.14607</td>
</tr>
</tbody>
</table>

The Pontiac Sunbird has a predicted mileage rating of 23.96 mpg, whereas the Volvo 260 has a predicted rating of 19.15 mpg. In comparison, the actual mileage ratings are 24 for the Pontiac and 17 for the Volvo.

Prediction standard errors

\texttt{predict} can calculate the standard error of the forecast (\texttt{stdf} option), the standard error of the prediction (\texttt{stdp} option), and the standard error of the residual (\texttt{stdr} option). It is easy to confuse \texttt{stdf} and \texttt{stdp} because both are often called the prediction error. Consider the prediction \( \hat{y}_j = x_j b \), where \( b \) is the estimated coefficient (column) vector and \( x_j \) is a (row) vector of independent variables for which you want the prediction. First, \( \hat{y}_j \) has a variance due to the variance of the estimated coefficient vector \( b \),

\[
\text{Var}(\hat{y}_j) = \text{Var}(x_j b) = s^2 h_j
\]

where \( h_j = x_j (X'X)^{-1}x_j' \) and \( s^2 \) is the mean squared error of the regression. Do not panic over the algebra—just remember that \( \text{Var}(\hat{y}_j) = s^2 h_j \), whatever \( s^2 \) and \( h_j \) are. \texttt{stdp} calculates this quantity. This is the error in the prediction due to the uncertainty about \( b \).

If you are about to hand this number out as your forecast, however, there is another error. According to your model, the true value of \( y_j \) is given by

\[
y_j = x_j b + \epsilon_j = \hat{y}_j + \epsilon_j
\]
and thus the \( \text{Var}(y_j) = \text{Var}(\hat{y}_j) + \text{Var}(\epsilon_j) = s^2 h_j + s^2 \), which is the square of \text{stdf}. \text{stdf}, then, is the sum of the error in the prediction plus the residual error.

\text{stdr} has to do with an analysis-of-variance decomposition of \( s^2 \), the estimated variance of \( y \). The standard error of the prediction is \( s^2 h_j \), and therefore \( s^2 h_j + s^2 (1 - h_j) = s^2 \) decomposes \( s^2 \) into the prediction and residual variances.

> Example 3: Standard error of the forecast

Returning to our model of mpg on weight and foreign, we previously predicted the mileage rating for the Pontiac Sunbird and Volvo 260 as 23.96 and 19.15 mpg, respectively. We now want to put a standard error around our forecast. Remember, the data for these two cars were in newautos.dta:

```
use https://www.stata-press.com/data/r16/newautos, clear
(New Automobile Models)
predict pmpg (option xb assumed; fitted values)
predict se_pmpg, stdf
list, divider
```

<table>
<thead>
<tr>
<th>make</th>
<th>weight</th>
<th>foreign</th>
<th>pmpg</th>
<th>se_pmpg</th>
</tr>
</thead>
<tbody>
<tr>
<td>Pont. Sunbird</td>
<td>2690</td>
<td>Domestic</td>
<td>23.95829</td>
<td>3.462791</td>
</tr>
<tr>
<td>Volvo 260</td>
<td>3170</td>
<td>Foreign</td>
<td>19.14607</td>
<td>3.525875</td>
</tr>
</tbody>
</table>

Thus an approximate 95% confidence interval for the mileage rating of the Volvo 260 is \( 19.15 \pm 2 \cdot 3.53 = [12.09, 26.21] \).

Prediction with weighted data

\text{predict} can be used after frequency-weighted (fweight) estimation, just as it is used after unweighted estimation. The technical note below concerns the use of \text{predict} after analytically weighted (aweight) estimation.

Technical note

After analytically weighted estimation, \text{predict} is willing to calculate only the prediction (no options), residual (residual option), standard error of the prediction (stnp option), and diagonal elements of the projection matrix (hat option). For analytically weighted estimation, the standard error of the forecast and residuals, the standardized and Studentized residuals, and Cook’s \( D \) are not statistically well-defined concepts.

Leverage statistics

In addition to providing fitted values and the associated standard errors, the \text{predict} command can also be used to generate various statistics used to detect the influence of individual observations. This section provides a brief introduction to leverage (hat) statistics, and some of the following subsections discuss other influence statistics produced by \text{predict}. 
Example 4: Diagonal elements of projection matrix

The diagonal elements of the projection matrix, obtained by the hat option, are a measure of distance in explanatory variable space. *leverage* is a synonym for *hat*.

```
. use https://www.stata-press.com/data/r16/auto, clear
   (1978 Automobile Data)
. regress mpg weight foreign
   (output omitted)
. predict xdist, hat
. summarize xdist, detail
```

<table>
<thead>
<tr>
<th>Leverage</th>
</tr>
</thead>
<tbody>
<tr>
<td>Percentiles</td>
</tr>
<tr>
<td>1%</td>
</tr>
<tr>
<td>5%</td>
</tr>
<tr>
<td>10%</td>
</tr>
<tr>
<td>25%</td>
</tr>
<tr>
<td>50%</td>
</tr>
<tr>
<td>75%</td>
</tr>
<tr>
<td>90%</td>
</tr>
<tr>
<td>95%</td>
</tr>
<tr>
<td>99%</td>
</tr>
</tbody>
</table>

Some 5% of our sample has an *xdist* measure in excess of 0.08. Let’s force them to reveal their identities:

```
. list foreign make mpg if xdist>.08, divider
```

<table>
<thead>
<tr>
<th>foreign</th>
<th>make</th>
<th>mpg</th>
</tr>
</thead>
<tbody>
<tr>
<td>Domestic</td>
<td>Ford Fiesta</td>
<td>28</td>
</tr>
<tr>
<td>Domestic</td>
<td>Linc. Continental</td>
<td>12</td>
</tr>
<tr>
<td>Domestic</td>
<td>Linc. Mark V</td>
<td>12</td>
</tr>
<tr>
<td>Domestic</td>
<td>Plym. Champ</td>
<td>34</td>
</tr>
<tr>
<td>Foreign</td>
<td>Peugeot 604</td>
<td>14</td>
</tr>
</tbody>
</table>

To understand why these cars are on this list, we must remember that the explanatory variables in our model are *weight* and *foreign* and that *xdist* measures distance in this metric. The Ford Fiesta and the Plymouth Champ are the two lightest domestic cars in our data. The Lincolns are the two heaviest domestic cars, and the Peugeot is the heaviest foreign car.

See `lvr2plot` in [R] *regress postestimation diagnostic plots* for information on a leverage-versus-squared-residual plot.

### Standardized and Studentized residuals

The terms standardized and Studentized residuals have meant different things to different authors. In Stata, `predict` defines the standardized residual as $\hat{e}_i = e_i / (s \sqrt{1 - h_i})$ and the Studentized residual as $r_i = e_i / (s_{(i)} \sqrt{1 - h_i})$, where $s_{(i)}$ is the root mean squared error of a regression with the $i$th observation removed. Stata’s definition of the Studentized residual is the same as the one given in Bollen and Jackman (1990, 264) and is what Chatterjee and Hadi (1988, 74) call the “externally Studentized” residual. Stata’s “standardized” residual is the same as what Chatterjee and Hadi (1988, 74) call the “internally Studentized” residual.
Standardized and Studentized residuals are attempts to adjust residuals for their standard errors. Although the $e_i$ theoretical residuals are homoskedastic by assumption (that is, they all have the same variance), the calculated $e_i$ are not. In fact,

$$\text{Var}(e_i) = \sigma^2(1 - h_i)$$

where $h_i$ are the leverage measures obtained from the diagonal elements of hat matrix. Thus observations with the greatest leverage have corresponding residuals with the smallest variance.

Standardized residuals use the root mean squared error of the regression for $\sigma$. Studentized residuals use the root mean squared error of a regression omitting the observation in question for $\sigma$. In general, Studentized residuals are preferable to standardized residuals for purposes of outlier identification. Studentized residuals can be interpreted as the $t$ statistic for testing the significance of a dummy variable equal to 1 in the observation in question and 0 elsewhere (Belsley, Kuh, and Welsch 1980). Such a dummy variable would effectively absorb the observation and so remove its influence in determining the other coefficients in the model. Caution must be exercised here, however, because of the simultaneous testing problem. You cannot simply list the residuals that would be individually significant at the 5% level—their joint significance would be far less (their joint significance level would be far greater).

### Example 5: Standardized and Studentized residuals

In the Terminology section of Remarks and examples for predict, we distinguished residuals from leverage and speculated on the impact of an observation with a small residual but large leverage. If we adjust the residuals for their standard errors, however, the adjusted residual would be (relatively) larger and perhaps large enough so that we could simply examine the adjusted residuals. Taking our price on weight and foreign##c.mpg model from example 1 of [R] regress postestimation diagnostic plots, we can obtain the in-sample standardized and Studentized residuals by typing

```
. use https://www.stata-press.com/data/r16/auto, clear  
(1978 Automobile Data)
. regress price weight foreign##c.mpg
(output omitted)
. predict esta if e(sample), rstandard
. predict estu if e(sample), rstudent
```

In the lvr2plot section of [R] regress postestimation diagnostic plots, we discovered that the VW Diesel has the highest leverage in our data, but a corresponding small residual. The standardized and Studentized residuals for the VW Diesel are

```
. list make price esta estu if make=="VW Diesel"

<table>
<thead>
<tr>
<th>make</th>
<th>price</th>
<th>esta</th>
<th>estu</th>
</tr>
</thead>
<tbody>
<tr>
<td>VW Diesel</td>
<td>5,397</td>
<td>.6142691</td>
<td>.6114758</td>
</tr>
</tbody>
</table>
```

The Studentized residual of 0.611 can be interpreted as the $t$ statistic for including a dummy variable for VW Diesel in our regression. Such a variable would not be significant.
DFITS, Cook’s Distance, and Welsch Distance

DFITS (Welsch and Kuh 1977), Cook’s Distance (Cook 1977), and Welsch Distance (Welsch 1982) are three attempts to summarize the information in the leverage versus residual-squared plot into one statistic. That is, the goal is to create an index that is affected by the size of the residuals—outliers—and the size of $h_i$—leverage. Viewed mechanically, one way to write DFITS (Bollen and Jackman 1990, 265) is

$$DFITS_i = r_i \sqrt{\frac{h_i}{1-h_i}}$$

where $r_i$ are the Studentized residuals. Thus large residuals increase the value of DFITS, as do large values of $h_i$. Viewed more traditionally, DFITS is a scaled difference between predicted values for the $i$th case when the regression is fit with and without the $i$th observation, hence the name.

The mechanical relationship between DFITS and Cook’s Distance, $D_i$ (Bollen and Jackman 1990, 266), is

$$D_i = \frac{1}{k} \frac{s^2}{s^2(i)} \frac{DFITS_i^2}{s^2}$$

where $k$ is the number of variables (including the constant) in the regression, $s$ is the root mean squared error of the regression, and $s^2(i)$ is the root mean squared error when the $i$th observation is omitted. Viewed more traditionally, $D_i$ is a scaled measure of the distance between the coefficient vectors when the $i$th observation is omitted.

The mechanical relationship between DFITS and Welsch’s Distance, $W_i$ (Chatterjee and Hadi 1988, 123), is

$$W_i = DFITS_i \sqrt{\frac{n-1}{1-h_i}}$$

The interpretation of $W_i$ is more difficult, as it is based on the empirical influence curve. Although DFITS and Cook’s distance are similar, the Welsch distance measure includes another normalization by leverage.

Belsley, Kuh, and Welsch (1980, 28) suggest that DFITS values greater than $2\sqrt{k/n}$ deserve more investigation, and so values of Cook’s distance greater than $4/n$ should also be examined (Bollen and Jackman 1990, 265–266). Through similar logic, the cutoff for Welsch distance is approximately $3\sqrt{k}$ (Chatterjee and Hadi 1988, 124).

Example 6: DFITS influence measure

Continuing with our model of price on weight and foreign##c.mpg, we can obtain the DFITS influence measure:

```stata
. predict e if e(sample), resid
. predict dfits, dfits
```

We did not specify `if e(sample)` in computing the DFITS statistic. DFITS is available only over the estimation sample, so specifying `if e(sample)` would have been redundant. It would have done no harm, but it would not have changed the results.

Our model has $k = 5$ independent variables ($k$ includes the constant) and $n = 74$ observations; following the $2\sqrt{k/n}$ cutoff advice, we type
We calculate Cook’s distance and list the observations greater than the suggested 4/n cutoff:

```
. predict cooksd if e(sample), cooksd
. list make price e cooksd if cooksd > 4/74, divider
```

<table>
<thead>
<tr>
<th>make</th>

<td>13,594</td>
<td>3109.193</td>
<td>.1308004</td>
</tr>
<tr>
<td>Linc. Versailles</td>
<td>13,466</td>
<td>6560.912</td>
<td>.1700736</td>
</tr>
<tr>
<td>Plym. Arrow</td>
<td>4,647</td>
<td>-3312.968</td>
<td>-.9384231</td>
</tr>
</tbody>
</table>

Here we used `if e(sample)` because Cook’s distance is not restricted to the estimation sample by default. It is worth comparing this list with the preceding one.

Finally, we use Welsch distance and the suggested $3\sqrt{k}$ cutoff:

```
. predict wd, welsch
. list make price e wd if abs(wd) > 3*sqrt(5), divider
```

<table>
<thead>
<tr>
<th>make</th>
<th>price</th>
<th>e</th>
<th>wd</th>
</tr>
</thead>
<tbody>
<tr>
<td>Cad. Eldorado</td>
<td>14,500</td>
<td>7271.96</td>
<td>8.394372</td>
</tr>
<tr>
<td>Cad. Seville</td>
<td>15,906</td>
<td>5036.348</td>
<td>12.81125</td>
</tr>
<tr>
<td>Ford Fiesta</td>
<td>4,389</td>
<td>3164.872</td>
<td>7.703005</td>
</tr>
<tr>
<td>Linc. Versailles</td>
<td>13,466</td>
<td>6560.912</td>
<td>8.981481</td>
</tr>
</tbody>
</table>

Here we did not need to specify `if e(sample)` because `welsch` automatically restricts the prediction to the estimation sample.

### COVRATIO

COVRATIO (Belsley, Kuh, and Welsch 1980) measures the influence of the $i$th observation by considering the effect on the variance–covariance matrix of the estimates. The measure is the ratio of the determinants of the covariances matrix, with and without the $i$th observation. The resulting formula is

$$ COVRATIO_i = \frac{1}{1 - h_i} \left( \frac{n - k - \hat{c}_i^2}{n - k - 1} \right)^k $$

where $\hat{c}_i$ is the standardized residual.
For noninfluential observations, the value of COVRATIO is approximately 1. Large values of the residuals or large values of leverage will cause deviations from 1, although if both are large, COVRATIO may tend back toward 1 and therefore not identify such observations (Chatterjee and Hadi 1988, 139).

Belsley, Kuh, and Welsch (1980) suggest that observations for which

\[
|\text{COVRATIO}_i - 1| \geq \frac{3k}{n}
\]

are worthy of further examination.

Example 7: COVRATIO influence measure

Using our model of price on weight and foreign##c.mpg, we can obtain the COVRATIO measure and list the observations outside the suggested cutoff by typing

```
. predict covr, covratio
. list make price e covr if abs(covr-1) >= 3*5/74, divider
```

<table>
<thead>
<tr>
<th>make</th>

Statistics not allowed with margins are functions of stochastic quantities other than e(b).

For the full syntax, see \[R\] margins.
DFBETA influence statistics

Description for dfbeta

dfbeta will calculate one, more than one, or all the DFBETAs after regress. Although predict will also calculate DFBETAs, predict can do this for only one variable at a time. dfbeta is a convenience tool for those who want to calculate DFBETAs for multiple variables. The names for the new variables created are chosen automatically and begin with the letters _dfbeta_.

Menu for dfbeta

Statistics > Linear models and related > Regression diagnostics > DFBETAs

Syntax for dfbeta

dfbeta [indepvar [indepvar [...]]] [, stub(name)]

Option for dfbeta

stub(name) specifies the leading characters dfbeta uses to name the new variables to be generated. The default is stub(_dfbeta_).

Remarks and examples for dfbeta

DFBETAs are perhaps the most direct influence measure of interest to model builders. DFBETAs focus on one coefficient and measure the difference between the regression coefficient when the \(i\)th observation is included and excluded, the difference being scaled by the estimated standard error of the coefficient. Belsley, Kuh, and Welsch (1980, 28) suggest observations with \(|\text{DFBETA}_i| > 2/\sqrt{n}\) as deserving special attention, but it is also common practice to use 1 (Bollen and Jackman 1990, 267), meaning that the observation shifted the estimate at least one standard error.

Example 8: DFBETAs influence measure; the dfbeta() option

Using our model of price on weight and foreign##c.mpg, let’s first ask which observations have the greatest impact on the determination of the coefficient on 1.foreign. We will use the suggested \(2/\sqrt{n}\) cutoff:

```
use https://www.stata-press.com/data/r16/auto, clear
(output omitted)
regress price weight foreign##c.mpg
(output omitted)
```
. sort foreign make
. predict dfor, dfbeta(1.foreign)
. list make price foreign dfor if abs(dfor) > 2/sqrt(74), divider

<table>
<thead>
<tr>
<th>make</th>
<th>price</th>
<th>foreign</th>
<th>dfor</th>
</tr>
</thead>
<tbody>
<tr>
<td>Cad. Eldorado</td>
<td>14,500</td>
<td>Domestic</td>
<td>-.5290519</td>
</tr>
<tr>
<td>Cad. Seville</td>
<td>15,906</td>
<td>Domestic</td>
<td>.8243419</td>
</tr>
<tr>
<td>Linc. Versailles</td>
<td>13,466</td>
<td>Domestic</td>
<td>-.5283729</td>
</tr>
<tr>
<td>Plym. Arrow</td>
<td>4,647</td>
<td>Domestic</td>
<td>-.6622424</td>
</tr>
<tr>
<td>Plym. Champ</td>
<td>4,425</td>
<td>Domestic</td>
<td>.2371104</td>
</tr>
<tr>
<td>Peugeot 604</td>
<td>12,990</td>
<td>Foreign</td>
<td>.2552032</td>
</tr>
<tr>
<td>Toyota Corona</td>
<td>5,719</td>
<td>Foreign</td>
<td>-.256431</td>
</tr>
</tbody>
</table>

The Cadillac Seville shifted the coefficient on 1.foreign 0.82 standard deviations!

Now let us ask which observations have the greatest effect on the mpg coefficient:

. predict dmpg, dfbeta(mpg)
. list make price mpg dmpg if abs(dmpg) > 2/sqrt(74), divider

<table>
<thead>
<tr>
<th>make</th>
<th>price</th>
<th>mpg</th>
<th>dmpg</th>
</tr>
</thead>
<tbody>
<tr>
<td>Cad. Eldorado</td>
<td>14,500</td>
<td>14</td>
<td>-0.5970351</td>
</tr>
<tr>
<td>Cad. Seville</td>
<td>15,906</td>
<td>21</td>
<td>1.134269</td>
</tr>
<tr>
<td>Linc. Versailles</td>
<td>13,466</td>
<td>14</td>
<td>-.6069287</td>
</tr>
<tr>
<td>Plym. Arrow</td>
<td>4,647</td>
<td>28</td>
<td>-.8925859</td>
</tr>
<tr>
<td>Plym. Champ</td>
<td>4,425</td>
<td>34</td>
<td>.3186909</td>
</tr>
</tbody>
</table>

Once again we see the Cadillac Seville heading the list, indicating that our regression results may be dominated by this one car.

> Example 9: DFBETAs influence measure; the dfbeta command

We can use predict, dfbeta() or the dfbeta command to generate the DFBETAs. dfbeta makes up names for the new variables automatically and, without arguments, generates the DFBETAs for all the variables in the regression:

. dfbeta

    _dfbeta_1: dfbeta(weight)
    _dfbeta_2: dfbeta(1.foreign)
    _dfbeta_3: dfbeta(mpg)
    _dfbeta_4: dfbeta(1.foreign#c.mpg)

dfbeta created four new variables in our dataset: _dfbeta_1, containing the DFBETAs for weight; _dfbeta_2, containing the DFBETAs for mpg; and so on. Had we wanted only the DFBETAs for mpg and weight, we might have typed

. dfbeta mpg weight

    _dfbeta_5: dfbeta(weight)
    _dfbeta_6: dfbeta(mpg)

In the example above, we typed dfbeta mpg weight instead of dfbeta; if we had typed dfbeta followed by dfbeta mpg weight, here is what would have happened:
dfbeta would have made up different names for the new variables. dfbeta never replaces existing variables—it instead makes up a different name, so we need to pay attention to dfbeta’s output.

Tests for violation of assumptions

Description for estat hettest

estat hettest performs three versions of the Breusch–Pagan (1979) and Cook–Weisberg (1983) test for heteroskedasticity. All three versions of this test present evidence against the null hypothesis that $t = 0$ in $\text{Var}(e) = \sigma^2 \exp(zt)$. In the normal version, performed by default, the null hypothesis also includes the assumption that the regression disturbances are independent-normal draws with variance $\sigma^2$. The normality assumption is dropped from the null hypothesis in the iid and fstat versions, which respectively produce the score and $F$ tests discussed in Methods and formulas. If varlist is not specified, the fitted values are used for $z$. If varlist or the rhs option is specified, the variables specified are used for $z$.

Menu for estat

Statistics > Postestimation

Syntax for estat hettest

estat hettest [varlist] [ , rhs [normal|iid|fstat] mtest[<spec>]]

Options for estat hettest

rhs specifies that tests for heteroskedasticity be performed for the right-hand-side (explanatory) variables of the fitted regression model. The rhs option may be combined with a varlist.

normal, the default, causes estat hettest to compute the original Breusch–Pagan/Cook–Weisberg test, which assumes that the regression disturbances are normally distributed.

iid causes estat hettest to compute the $N \times R^2$ version of the score test that drops the normality assumption.

fstat causes estat hettest to compute the $F$-statistic version that drops the normality assumption.
mtest\([\text{spec}]\) specifies that multiple testing be performed. The argument specifies how \(p\)-values are adjusted. The following specifications, \text{spec}, are supported:

\begin{verbatim}
bonferroni    Bonferroni’s multiple testing adjustment
holm         Holm’s multiple testing adjustment
sidak        Šidák’s multiple testing adjustment
noadjust     no adjustment is made for multiple testing
\end{verbatim}

\mtest may be specified without an argument. This is equivalent to specifying \texttt{mtest(noadjust)}; that is, tests for the individual variables should be performed with unadjusted \(p\)-values. By default, estat hettest does not perform multiple testing. \texttt{mtest} may not be specified with \texttt{iid} or \texttt{fstat}.

**Description for estat imtest**

estat \texttt{imtest} performs an information matrix test for the regression model and an orthogonal decomposition into tests for heteroskedasticity, skewness, and kurtosis due to Cameron and Trivedi (1990); White’s test for homoskedasticity against unrestricted forms of heteroskedasticity (1980) is available as an option. White’s test is usually similar to the first term of the Cameron–Trivedi decomposition.

**Menu for estat**

Statistics \(\rightarrow\) Postestimation

**Syntax for estat imtest**

\begin{verbatim}
estat \texttt{imtest [ , preserve white]}
\end{verbatim}

**Options for estat imtest**

\texttt{preserve} specifies that the data in memory be preserved, all variables and cases that are not needed in the calculations be dropped, and at the conclusion the original data be restored. This option is costly for large datasets. However, because estat \texttt{imtest} has to perform an auxiliary regression on \(k(k + 1)/2\) temporary variables, where \(k\) is the number of regressors, it may not be able to perform the test otherwise.

\texttt{white} specifies that White’s original heteroskedasticity test also be performed.

**Description for estat ovtest**

estat \texttt{ovtest} performs two versions of the Ramsey (1969) regression specification-error test (RESET) for omitted variables. This test amounts to fitting \(y = xb + zt + u\) and then testing \(t = 0\). If the \texttt{rhs} option is not specified, powers of the fitted values are used for \(z\). If \texttt{rhs} is specified, powers of the individual elements of \(x\) are used.
Menu for estat

Statistics > Postestimation

Syntax for estat ovtest

    estat ovtest [, rhs]

Option for estat ovtest

rhs specifies that powers of the right-hand-side (explanatory) variables be used in the test rather than powers of the fitted values.

Description for estat szroeter

    estat szroeter performs Szroeter’s rank test for heteroskedasticity for each of the variables in \textit{varlist} or for the explanatory variables of the regression if \textit{rhs} is specified.

Menu for estat

Statistics > Postestimation

Syntax for estat szroeter

    estat szroeter \textit{[varlist]} [, rhs mtest(\textit{spec})]

Either \textit{varlist} or \textit{rhs} must be specified.

Options for estat szroeter

rhs specifies that tests for heteroskedasticity be performed for the right-hand-side (explanatory) variables of the fitted regression model. The \textit{rhs} option may be combined with a \textit{varlist}.

\textit{mtest(\textit{spec})} specifies that multiple testing be performed. The argument specifies how \textit{p}-values are adjusted. The following specifications, \textit{spec}, are supported:

\begin{itemize}
    \item \texttt{bonferroni} \quad Bonferroni’s multiple testing adjustment
    \item \texttt{holm} \quad Holm’s multiple testing adjustment
    \item \texttt{sidak} \quad Šidák’s multiple testing adjustment
    \item \texttt{noadjust} \quad no adjustment is made for multiple testing
\end{itemize}

\texttt{estat szroeter} always performs multiple testing. By default, it does not adjust the \textit{p}-values.
Remarks and examples for estat hettest, estat imtest, estat ovtest, and estat szroeter

We introduce some regression diagnostic commands that are designed to test for certain violations that rvfplot (see [R] regress postestimation diagnostic plots) less formally attempts to detect. estat ovtest provides Ramsey’s test for omitted variables—a pattern in the residuals. estat hettest provides a test for heteroskedasticity—the increasing or decreasing variation in the residuals with fitted values, with respect to the explanatory variables, or with respect to yet other variables. The score test implemented in estat hettest (Breusch and Pagan 1979; Cook and Weisberg 1983) performs a score test of the null hypothesis that \( b = 0 \) against the alternative hypothesis of multiplicative heteroskedasticity. estat hettest provides a rank test for heteroskedasticity, which is an alternative to the score test computed by estat hettest. Finally, estat imtest computes an information matrix test, including an orthogonal decomposition into tests for heteroskedasticity, skewness, and kurtosis (Cameron and Trivedi 1990). The heteroskedasticity test computed by estat imtest is similar to the general test for heteroskedasticity that was proposed by White (1980). Cameron and Trivedi (2010, chap. 3) discuss most of these tests and provides more examples.

Example 10: estat ovtest, estat hettest, estat szroeter, and estat imtest

We use our model of price on weight and foreign##c.mpg.

```
. use https://www.stata-press.com/data/r16/auto, clear
  (1978 Automobile Data)
. regress price weight foreign##c.mpg
  (output omitted)
. estat ovtest
  Ramsey RESET test using powers of the fitted values of price
  Ho: model has no omitted variables
  \[ F(3, 66) = 7.77 \]
  \[ \text{Prob} > F = 0.0002 \]
. estat hettest
  Breusch-Pagan / Cook-Weisberg test for heteroskedasticity
  Ho: Constant variance
  Variables: fitted values of price
  \[ \text{chi2}(1) = 6.50 \]
  \[ \text{Prob} > \text{chi2} = 0.0108 \]
```

Testing for heteroskedasticity in the right-hand-side variables is requested by specifying the rhs option. By specifying the mtest(bonferroni) option, we request that tests be conducted for each of the variables, with a Bonferroni adjustment for the \( p \)-values to accommodate our testing multiple hypotheses.

| Total             | 32.87 | 15 | 0.0049 |

We find evidence for omitted variables, heteroskedasticity, and nonnormal skewness.

So, why bother with the various graphical commands when the tests seem so much easier to interpret? In part, it is a matter of taste: both are designed to uncover the same problem, and both are, in fact, going about it in similar ways. One is based on a formal calculation, whereas the other is based on personal judgment in evaluating a graph. On the other hand, the tests are seeking evidence of specific problems, whereas judgment is more general. The careful analyst will use both.

We performed the omitted-variable test first. Omitted variables are a more serious problem than heteroskedasticity or the violations of higher moment conditions tested by estat imtest. If this
were not a manual, having found evidence of omitted variables, we would never have run the `estat hettest`, `estat szroeter`, and `estat imtest` commands, at least not until we solved the omitted-variable problem.

Technical note

`estat ovtest` and `estat hettest` both perform two flavors of their respective tests. By default, `estat ovtest` looks for evidence of omitted variables by fitting the original model augmented by \( \hat{y}^2 \), \( \hat{y}^3 \), and \( \hat{y}^4 \), which are the fitted values from the original model. Under the assumption of no misspecification, the coefficients on the powers of the fitted values will be zero. With the `rhs` option, `estat ovtest` instead augments the original model with powers (second through fourth) of the explanatory variables (except for dummy variables).

`estat hettest`, by default, looks for heteroskedasticity by modeling the variance as a function of the fitted values. If, however, we specify a variable or variables, the variance will be modeled as a function of the specified variables. In our example, if we had, a priori, some reason to suspect heteroskedasticity and that the heteroskedasticity is a function of a car’s weight, then using a test that focuses on weight would be more powerful than the more general tests such as White’s test or the first term in the Cameron–Trivedi decomposition test.

`estat hettest`, by default, computes the original Breusch–Pagan/Cook–Weisberg test, which includes the assumption of normally distributed errors. Koenker (1981) derived an \( N \ast R^2 \) version of this test that drops the normality assumption. Wooldridge (2020, 270) gives an \( F \)-statistic version that does not require the normality assumption.

Stored results for `estat hettest`, `estat imtest`, and `estat ovtest`

`estat hettest` stores the following results for the (multivariate) score test in `r()`:  
Scalars  
- `r(chi2)` \( \chi^2 \) test statistic  
- `r(df)` \#df for the asymptotic \( \chi^2 \) distribution under \( H_0 \)  
- `r(p)` \( p \)-value  

`estat hettest`, `fstat` stores results for the (multivariate) score test in `r()`:  
Scalars  
- `r(F)` test statistic  
- `r(df_m)` \#df of the test for the \( F \) distribution under \( H_0 \)  
- `r(df_r)` \#df of the residuals for the \( F \) distribution under \( H_0 \)  
- `r(p)` \( p \)-value  

`estat hettest` (if `mtest` is specified) and `estat szroeter` store the following in `r()`:  
Matrices  
- `r(mtest)` a matrix of test results, with rows corresponding to the univariate tests  
  - `mtest[,1]` \( \chi^2 \) test statistic  
  - `mtest[,2]` \#df  
  - `mtest[,3]` unadjusted \( p \)-value  
  - `mtest[,4]` adjusted \( p \)-value (if an `mtest()` adjustment method is specified)  

Macros  
- `r(mtmethod)` adjustment method for \( p \)-value
estat imtest stores the following in r():

Scalars
- r(chi2_t) IM-test statistic ( = r(chi2_h) + r(chi2_s) + r(chi2_k) )
- r(df_t) df for limiting $\chi^2$ distribution under $H_0$ ( = r(df_h) + r(df_s) + r(df_k) )
- r(chi2_h) heteroskedasticity test statistic
- r(df_h) df for limiting $\chi^2$ distribution under $H_0$
- r(chi2_s) skewness test statistic
- r(df_s) df for limiting $\chi^2$ distribution under $H_0$
- r(chi2_k) kurtosis test statistic
- r(df_k) df for limiting $\chi^2$ distribution under $H_0$
- r(chi2_w) White’s heteroskedasticity test (if white specified)
- r(df_w) df for limiting $\chi^2$ distribution under $H_0$

estat ovtest stores the following in r():

Scalars
- r(p) two-sided $p$-value
- r(F) $F$ statistic
- r(df) degrees of freedom
- r(df_r) residual degrees of freedom

Variance inflation factors

Description for estat vif

estat vif calculates the centered or uncentered variance inflation factors (VIFs) for the independent variables specified in a linear regression model.

Menu for estat

Statistics > Postestimation

Syntax for estat vif

```
estat vif [, uncentered]
```

Option for estat vif

uncentered requests that the computation of the uncentered variance inflation factors. This option is often used to detect the collinearity of the regressors with the constant. estat vif, uncentered may be used after regression models fit without the constant term.

Remarks and examples for estat vif

Problems arise in regression when the predictors are highly correlated. In this situation, there may be a significant change in the regression coefficients if you add or delete an independent variable. The estimated standard errors of the fitted coefficients are inflated, or the estimated coefficients may not be statistically significant even though a statistical relation exists between the dependent and independent variables.
Data analysts rely on these facts to check informally for the presence of multicollinearity. *estat vif*, another command for use after *regress*, calculates the variance inflation factors and tolerances for each of the independent variables.

The output shows the variance inflation factors together with their reciprocals. Some analysts compare the reciprocals with a predetermined tolerance. In the comparison, if the reciprocal of the VIF is smaller than the tolerance, the associated predictor variable is removed from the regression model. However, most analysts rely on informal rules of thumb applied to the VIF; see Chatterjee and Hadi (2012). According to these rules, there is evidence of multicollinearity if

1. The largest VIF is greater than 10 (some choose a more conservative threshold value of 30).
2. The mean of all the VIFs is considerably larger than 1.

Example 11: *estat vif*

We examine a regression model fit using the ubiquitous automobile dataset:

```
. use https://www.stata-press.com/data/r16/auto
(1978 Automobile Data)
. regress price mpg rep78 trunk headroom length turn displ gear_ratio
```

```

Mean VIF | 4.02
```

The results are mixed. Although we have no VIFs greater than 10, the mean VIF is greater than 1, though not considerably so. We could continue the investigation of collinearity, but given that other authors advise that collinearity is a problem only when VIFs exist that are greater than 30 (contradicting our rule above), we will not do so here.
Example 12: estat vif, with strong evidence of multicollinearity

This example comes from a dataset described in Kutner, Nachtsheim, and Neter (2004, 257) that examines body fat as modeled by caliper measurements on the triceps, midarm, and thigh.

```
use https://www.stata-press.com/data/r16/bodyfat
(Body Fat)
.regress bodyfat tricep thigh midarm
```

<table>

<tr>
<td>midarm</td>
<td>104.61</td>
<td>0.009560</td>
</tr>
</tbody>
</table>

| Mean VIF | 459.26 |

Here we see strong evidence of multicollinearity in our model. More investigation reveals that the measurements on the thigh and the triceps are highly correlated:

```
correlate triceps thigh midarm
```

<table>
<thead>
<tr>
<th>triceps</th>
<th>thigh</th>
<th>midarm</th>
</tr>
</thead>
<tbody>
<tr>
<td>1.0000</td>
<td>0.9238</td>
<td>0.4578</td>
</tr>
</tbody>
</table>

If we remove the predictor triceps from the model (because it had the highest VIF), we get

```
.regress bodyfat thigh midarm
```

<table>

If we remove the predictor triceps from the model (because it had the highest VIF), we get
Note how the coefficients change and how the estimated standard errors for each of the regression coefficients become much smaller. The calculated value of $R^2$ for the overall regression for the subset model does not appreciably decline when we remove the correlated predictor. Removing an independent variable from the model is one way to deal with multicollinearity. Other methods include ridge regression, weighted least squares, and restricting the use of the fitted model to data that follow the same pattern of multicollinearity. In economic studies, it is sometimes possible to estimate the regression coefficients from different subsets of the data by using cross-section and time series.

All examples above demonstrated the use of centered VIFs. As pointed out by Belsley (1991), the centered VIFs may fail to discover collinearity involving the constant term. One solution is to use the uncentered VIFs instead. According to the definition of the uncentered VIFs, the constant is viewed as a legitimate explanatory variable in a regression model, which allows one to obtain the VIF value for the constant term.

Example 13: estat vif, with strong evidence of collinearity with the constant term

Consider the extreme example in which one of the regressors is highly correlated with the constant. We simulate the data and examine both centered and uncentered VIF diagnostics after fitted regression model as follows.
. estat vif, uncentered

<table>
<thead>
<tr>
<th>Variable</th>
<th>VIF</th>
<th>1/VIF</th>

</tr>
<tr>
<td>x</td>
<td>1.13</td>
<td>0.888705</td>
</tr>
</tbody>
</table>

Mean VIF | 202.06

According to the values of the centered VIFs (1.03, 1.03, 1.00), no harmful collinearity is detected in the model. However, by the construction of these simulated data, we know that one is highly collinear with the constant term. As such, the large values of uncentered VIFs for one (402.94) and intercept (401.26) reveal high collinearity of the variable one with the constant term.

Measures of effect size

Description for estat esize

estat esize calculates effect sizes for linear models after regress or anova. By default, estat esize reports $\eta^2$ (eta-squared) estimates (Kerlinger and Lee 2000), which are equivalent to $R^2$ estimates. If the option epsilon is specified, estat esize reports $\epsilon^2$ estimates (Grissom and Kim 2012). If the option omega is specified, estat esize reports $\omega^2$ estimates (Grissom and Kim 2012). Both $\epsilon^2$ and $\omega^2$ are adjusted $R^2$ estimates. Confidence intervals for $\eta^2$ estimates are estimated by using the noncentral $F$ distribution (Smithson 2001). See Kline (2013) or Thompson (2006) for further information.

Menu for estat

Statistics > Postestimation

Syntax for estat esize

    estat esize [, epsilon omega level(#) ]

Options for estat esize

epsilon specifies that the $\epsilon^2$ estimates of effect size be reported. The default is $\eta^2$ estimates.

omega specifies that the $\omega^2$ estimates of effect size be reported. The default is $\eta^2$ estimates.

level(#) specifies the confidence level, as a percentage, for confidence intervals. The default is level(95) or as set by set level; see [U] 20.8 Specifying the width of confidence intervals.
Remarks and examples for estat esize

Whereas \( p \)-values are used to assess the statistical significance of a result, measures of effect size are used to assess the practical significance of a result. Effect sizes can be broadly categorized as “measures of group differences” (the \( d \) family) and “measures of association” (the \( r \) family); see Ellis (2010, table 1.1). The \( d \) family includes estimators such as Cohen’s \( D \), Hedges’s \( G \), and Glass’s \( \Delta \) (also see \( \text{[R] esize} \)). The \( r \) family includes estimators such as the point-biserial correlation coefficient, \( \eta^2 \), \( \epsilon^2 \), and \( \omega^2 \). For an introduction to the concepts and calculation of effect sizes, see Kline (2013) or Thompson (2006). For a more detailed discussion, see Kirk (1996), Ellis (2010), Cumming (2012), Grissom and Kim (2012), and Kelley and Preacher (2012).

Example 14: Calculating effect sizes for a linear regression model

Suppose we fit a linear regression model for low-birthweight infants.

```stata
. use https://www.stata-press.com/data/r16/lbw
(Hosmer & Lemeshow data)
. regress bwt smoke i.race
```

```
<table>

| other   | -454.1813 | 116.436 | -3.90 | 0.000 | -683.8944 -224.4683 |
| _cons   | 3334.858 | 91.74301 | 36.35 | 0.000 | 3153.86 3515.855   |
```

We can use the \texttt{estat esize} command to calculate \( \eta^2 \) for the entire model and a partial \( \eta^2 \) for each term in the model.

```stata
. estat esize
```

```
<table>
<thead>
<tr>
<th>Source</th>
<th>Eta-Squared</th>
<th>df</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>Model</td>
<td>.1235736</td>
<td>3</td>
<td>.0399862 .2041365</td>
</tr>
<tr>
<td>smoke</td>
<td>.0769345</td>
<td>1</td>
<td>.0193577 .1579213</td>
</tr>
<tr>
<td>race</td>
<td>.0908394</td>
<td>2</td>
<td>.0233037 .1700334</td>
</tr>
</tbody>
</table>
```

Note: Eta-Squared values for individual model terms are partial.

The overall model effect size is 0.124. This means that roughly 12.4% of the variation in \texttt{bwt} is explained by the model. The partial effect size for \texttt{smoke} is 0.077. This means that roughly 7.7% of the variation in \texttt{bwt} is explained by \texttt{smoke}, after you remove the variation explained by all other terms.
The omega option causes \texttt{estat esize} to report $\omega^2$ and partial $\omega^2$.

\begin{verbatim}
. estat esize, omega
Effect sizes for linear models
\end{verbatim}

\begin{table}[h]
\begin{tabular}{lll}
\hline
Source & Omega-Squared & df \\
\hline
Model & .1088457 & 3 \\
smoke & .0715877 & 1 \\
race & .0806144 & 2 \\
\hline
\end{tabular}
\end{table}

Note: Omega-Squared values for individual model terms are partial.

\textbf{Example 15: Calculating effect size for an ANOVA model}

We can use \texttt{estat esize} after ANOVA models as well.

\begin{verbatim}
. anova bwt smoke race
\end{verbatim}

\begin{verbatim}
Number of obs = 189  R-squared =  0.1236
Root MSE =  687.999  Adj R-squared =  0.1094
\end{verbatim}

\begin{verbatim}

\hline
Model   & .1235736    & 3   & .0399862 .2041365 \\
smoke   & .0769345    & 1   & .0193577 .1579213 \\
race    & .0908394    & 2   & .0233037 .1700334 \\
\hline
\end{tabular}
\end{table}

Note: Eta-Squared values for individual model terms are partial.

\textbf{Technical note}

$\eta^2$ was developed in the context of analysis of variance. Thus, the published research on the calculation of confidence intervals focuses on cases where the numerator degrees of freedom are relatively small (for example, df < 20).

Some combinations of the $F$ statistic, numerator degrees of freedom, and denominator degrees of freedom yield confidence limits that do not contain the corresponding estimated value for an $\eta^2$. This problem is most commonly observed for larger numerator degrees of freedom.

Nothing in the literature suggests alternative methods for constructing confidence intervals in such cases; therefore, we recommend cautious interpretation of confidence intervals for $\eta^2$ when the numerator degrees of freedom are greater than 20.
Stored results for estat esize

estat esize stores the following results in r():

Scalars
r(level)  confidence level

Matrices
r(esize)  a matrix of effect sizes, confidence intervals, degrees of freedom, and $F$ statistics with rows corresponding to each term in the model

- esize[,2]  lower confidence bound for $\eta^2$
- esize[,3]  upper confidence bound for $\eta^2$
- esize[,4]  $\varepsilon^2$
- esize[,5]  $\omega^2$
- esize[,6]  numerator degrees of freedom
- esize[,7]  denominator degrees of freedom
- esize[,8]  $F$ statistic

Methods and formulas

See Hamilton (2013, chap. 7), Kohler and Kreuter (2012, sec. 9.3), or Baum (2006, chap. 5) for an overview of using Stata to perform regression diagnostics. See Peracchi (2001, chap. 8) for a mathematically rigorous discussion of diagnostics.

Methods and formulas are presented under the following headings:

predict
Special-interest postestimation commands

predict

Assume that you have already fit the regression model

$$y = Xb + e$$

where $X$ is $n \times k$.

Denote the previously estimated coefficient vector by $b$ and its estimated variance matrix by $V$. predict works by recalling various aspects of the model, such as $b$, and combining that information with the data currently in memory. Let $x_j$ be the $j$th observation currently in memory, and let $s^2$ be the mean squared error of the regression.

If the user specified weights in regress, then $X'X$ in the following formulas is replaced by $X'DX$, where $D$ is defined in Weighted regression under Methods and formulas in [R] regress.

Let $V = s^2(X'X)^{-1}$. Let $k$ be the number of independent variables including the intercept, if any, and let $y_j$ be the observed value of the dependent variable.

The predicted value (xb option) is defined as $\hat{y}_j = x_jb$.

Let $\ell_j$ represent a lower bound for an observation $j$ and $u_j$ represent an upper bound. The probability that $y_j|x_j$ would be observed in the interval $(\ell_j, u_j)$—the pr($\ell$, $u$) option—is

$$P(\ell_j, u_j) = \Pr(\ell_j < x_jb + e_j < u_j) = \Phi \left( \frac{u_j - \hat{y}_j}{s} \right) - \Phi \left( \frac{\ell_j - \hat{y}_j}{s} \right)$$

where for the pr($\ell$, $u$), e($\ell$, $u$), and ystar($\ell$, $u$) options, $\ell_j$ and $u_j$ can be anywhere in the range $(-\infty, +\infty)$.
The option `e(ℓ, u)` computes the expected value of \( y_j | x_j \) conditional on \( y_j | x_j \) being in the interval \((\ell_j, u_j)\), that is, when \( y_j | x_j \) is truncated. It can be expressed as

\[
E(\ell_j, u_j) = E(x_j b + e_j | \ell_j < x_j b + e_j < u_j) = \hat{y}_j - s \frac{\phi \left( \frac{u_j - \hat{y}_j}{s} \right) - \phi \left( \frac{\ell_j - \hat{y}_j}{s} \right)}{\Phi \left( \frac{u_j - \hat{y}_j}{s} \right) - \Phi \left( \frac{\ell_j - \hat{y}_j}{s} \right)}
\]

where \( \phi \) is the normal density and \( \Phi \) is the cumulative normal.

You can also compute \( y^*_j(\ell, u) \)—the expected value of \( y_j | x_j \), where \( y_j \) is assumed censored at \( \ell_j \) and \( u_j \):

\[
y^*_j = \begin{cases} 
\ell_j & \text{if } x_j b + e_j \leq \ell_j \\
x_j b + e_j & \text{if } \ell_j < x_j b + e_j < u_j \\
u_j & \text{if } x_j b + e_j \geq u_j 
\end{cases}
\]

This computation can be expressed in several ways, but the most intuitive formulation involves a combination of the two statistics just defined:

\[
y^*_j = P(-\infty, \ell_j)\ell_j + P(\ell_j, u_j)E(\ell_j, u_j) + P(u_j, +\infty)u_j
\]

A diagonal element of the projection matrix (hat) or (leverage) is given by

\[
h_j = x_j (X'X)^{-1}x'_j
\]

The standard error of the prediction (the `stdp` option) is defined as \( s_{pj} = \sqrt{x_j Vx'_j} \) and can also be written as \( s_{pj} = s\sqrt{h_j} \).

The standard error of the forecast (`stdf`) is defined as \( s_{fj} = s\sqrt{1 + h_j} \).

The standard error of the residual (`stdr`) is defined as \( s_{rj} = s\sqrt{1 - h_j} \).

The residuals (residuals) are defined as \( \hat{e}_j = y_j - \hat{y}_j \).

The standardized residuals (rstandard) are defined as \( \hat{e}_{sj} = \hat{e}_j / s_{rj} \).

The Studentized residuals (rstudent) are defined as

\[
r_j = \frac{\hat{e}_j}{s(j)\sqrt{1 - h_j}}
\]

where \( s(j) \) represents the root mean squared error with the \( j \)th observation removed, which is given by

\[
s^2_{(j)} = \frac{s^2(T - k)}{T - k - 1} - \frac{\hat{e}^2_j}{(T - k - 1)(1 - h_j)}
\]

Cook’s \( D \) (cooksd) is given by

\[
D_j = \frac{\hat{e}^2_{sj}(s_{pj}/s_{rj})^2}{k} = \frac{h_j \hat{e}^2_j}{k s^2(1 - h_j)^2}
\]
DFITS (dfits) is given by
\[ \text{DFITS}_j = r_j \sqrt{\frac{h_j}{1 - h_j}} \]

Welsch distance (welsch) is given by
\[ W_j = \frac{r_j \sqrt{h_j(n - 1)}}{1 - h_j} \]

COVRATIO (covratio) is given by
\[ \text{COVRATIO}_j = \frac{1}{1 - h_j} \left( \frac{n - k - \hat{e}_j^2}{n - k - 1} \right)^k \]

The DFBETAs (dfbeta) for a particular regressor \( x_i \) are given by
\[ \text{DFBETA}_j = \frac{r_j u_j}{\sqrt{U^2(1 - h_j)}} \]

where \( u_j \) are the residuals obtained from a regression of \( x_i \) on the remaining \( x \)'s and \( U^2 = \sum_j u_j^2 \).

**Special-interest postestimation commands**

The omitted-variable test (Ramsey 1969) reported by `estat ovtest` fits the regression \( y_i = x_i b + z_i t + u_i \) and then performs a standard \( F \) test of \( t = 0 \). The default test uses \( z_i = (\hat{y}_i^2, \hat{y}_i^3, \hat{y}_i^4) \). If `rhs` is specified, \( z_i = (x_{1i}^2, x_{1i}^3, x_{1i}^4, x_{2i}^2, \ldots, x_{mi}^4) \). In either case, the variables are normalized to have minimum 0 and maximum 1 before powers are calculated.

The test for heteroskedasticity (Breusch and Pagan 1979; Cook and Weisberg 1983) models \( \text{Var}(e_i) = \sigma^2 \exp(zt) \), where \( z \) is a variable list specified by the user, the list of right-hand-side variables, or the fitted values \( x \hat{\beta} \). The test is of \( t = 0 \). Mechanically, `estat hettest` fits the augmented regression \( \hat{e}_i^2 / \hat{\sigma}^2 = a + z_i t + v_i \).

The original Breusch–Pagan/Cook–Weisberg version of the test assumes that the \( e_i \) are normally distributed under the null hypothesis which implies that the score test statistic \( S \) is equal to the model sum of squares from the augmented regression divided by 2. Under the null hypothesis, \( S \) has the \( \chi^2 \) distribution with \( m \) degrees of freedom, where \( m \) is the number of columns of \( z \).

Koenker (1981) derived a score test of the null hypothesis that \( t = 0 \) under the assumption that the \( e_i \) are independent and identically distributed (i.i.d.). Koenker showed that \( S = N * R^2 \) has a large-sample \( \chi^2 \) distribution with \( m \) degrees of freedom, where \( N \) is the number of observations and \( R^2 \) is the \( R \)-squared in the augmented regression and \( m \) is the number of columns of \( z \). `estat hettest, iid` produces this version of the test.

Wooldridge (2020, 270) showed that an \( F \) test of \( t = 0 \) in the augmented regression can also be used under the assumption that the \( e_i \) are i.i.d. `estat hettest, fstat` produces this version of the test.

Szroeter’s class of tests for homoskedasticity against the alternative that the residual variance increases in some variable \( x \) is defined in terms of
\[ H = \frac{\sum_{i=1}^n h(x_i) e_i^2}{\sum_{i=1}^n e_i^2} \]
where \( h(x) \) is some weight function that increases in \( x \) (Szroeter 1978). \( H \) is a weighted average of the \( h(x) \), with the squared residuals serving as weights. Under homoskedasticity, \( H \) should be approximately equal to the unweighted average of \( h(x) \). Large values of \( H \) suggest that \( e^2 \) tends to be large where \( h(x) \) is large; that is, the variance indeed increases in \( x \), whereas small values of \( H \) suggest that the variance actually decreases in \( x \). *estat szroeter* uses \( h(x_i) = \text{rank}(x_i \text{ in } x_1 \ldots x_n) \); see Judge et al. [1985, 452] for details. *estat szroeter* displays a normalized version of \( H \),

\[
Q = \sqrt{\frac{6n}{n^2 - 1} H}
\]

which is approximately \( N(0, 1) \) distributed under the null (homoskedasticity).

*estat hettest* and *estat szroeter* provide adjustments of \( p \)-values for multiple testing. The supported methods are described in [R] test.

*estat imtest* performs the information matrix test for the regression model, as well as an orthogonal decomposition into tests for heteroskedasticity \( \delta_1 \), nonnormal skewness \( \delta_2 \), and nonnormal kurtosis \( \delta_3 \) (Cameron and Trivedi 1990; Long and Trivedi 1993). The decomposition is obtained via three auxiliary regressions. Let \( e \) be the regression residuals, \( \hat{\sigma}^2 \) be the maximum likelihood estimate of \( \sigma^2 \) in the regression, \( n \) be the number of observations, \( X \) be the set of \( k \) variables specified with *estat imtest*, and \( R^2_{\text{un}} \) be the uncentered \( R^2 \) from a regression. \( \delta_1 \) is obtained as \( nR^2_{\text{un}} \) from a regression of \( e^2 - \hat{\sigma}^2 \) on the cross products of the variables in \( X \). \( \delta_2 \) is computed as \( nR^2_{\text{un}} \) from a regression of \( e^3 - 3\hat{\sigma}^2e \) on \( X \). Finally, \( \delta_3 \) is obtained as \( nR^2_{\text{un}} \) from a regression of \( e^4 - 6\hat{\sigma}^2e^2 - 3\hat{\sigma}^4 \) on \( X \). \( \delta_1 \), \( \delta_2 \), and \( \delta_3 \) are asymptotically \( \chi^2 \) distributed with \( 1/2k(k+1) \), \( K \), and 1 degree of freedom. The information test statistic \( \delta = \delta_1 + \delta_2 + \delta_3 \) is asymptotically \( \chi^2 \) distributed with \( 1/2k(k+3) \) degrees of freedom. White’s test for heteroskedasticity is computed as \( nR^2 \) from a regression of \( \hat{u}^2 \) on \( X \) and the cross products of the variables in \( X \). This test statistic is usually close to \( \delta_1 \).

*estat vif* calculates the centered variance inflation factor (VIF\(_c\)) (Chatterjee and Hadi 2012, 248–251) for \( x_j \), given by

\[
\text{VIF}_c(x_j) = \frac{1}{1 - \tilde{R}^2_j}
\]

where \( \tilde{R}^2_j \) is the square of the centered multiple correlation coefficient that results when \( x_j \) is regressed with intercept against all the other explanatory variables.

The uncentered variance inflation factor (VIF\(_uc\)) (Belsley 1991, 28–29) for \( x_j \) is given by

\[
\text{VIF}_uc(x_j) = \frac{1}{1 - \tilde{R}^2_j}
\]

where \( \tilde{R}^2_j \) is the square of the uncentered multiple correlation coefficient that results when \( x_j \) is regressed without intercept against all the other explanatory variables including the constant term.

The methods and formulas for *estat esize* are described in *Methods and formulas* of [R] esize.

**Acknowledgments**

*estat ovtest* and *estat hettest* are based on programs originally written by Richard Goldstein. *estat imtest*, *estat szroeter*, and the current version of *estat hettest* were written by Jeroen Weesie of the Department of Sociology at Utrecht University, The Netherlands. *estat imtest* is based in part on code written by J. Scott Long of the Department of Sociology at Indiana University, coauthor of the Stata Press book *Regression Models for Categorical and Limited Dependent Variables*, and author of the Stata Press book *The Workflow of Data Analysis Using Stata*.

[U] 20 Estimation and postestimation commands
The following postestimation commands are of special interest after `regress`:

<table>
<thead>
<tr>
<th>Command</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>rvpplot</td>
<td>residual-versus-fitted plot</td>
</tr>
<tr>
<td>avplot</td>
<td>added-variable plot</td>
</tr>
<tr>
<td>avplots</td>
<td>all added-variables plots in one image</td>
</tr>
<tr>
<td>cprplot</td>
<td>component-plus-residual plot</td>
</tr>
<tr>
<td>acprplot</td>
<td>augmented component-plus-residual plot</td>
</tr>
<tr>
<td>rvpplot</td>
<td>residual-versus-predictor plot</td>
</tr>
<tr>
<td>lvr2plot</td>
<td>leverage-versus-squared-residual plot</td>
</tr>
</tbody>
</table>

These commands are not appropriate after the `svy` prefix.

For a discussion of the terminology used in this entry, see the Terminology section of Remarks and examples for `predict` in [R] regress postestimation.

### rvpplot

**Description for rvpplot**

`rvpplot` graphs a residual-versus-fitted plot, a graph of the residuals against the fitted values.

**Menu for rvpplot**

Statistics > Linear models and related > Regression diagnostics > Residual-versus-fitted plot

**Syntax for rvpplot**

```
rvpplot [, rvpplot_options ]
```

<table>
<thead>
<tr>
<th>rvpplot_options</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Plot</strong></td>
<td></td>
</tr>
<tr>
<td>marker_options</td>
<td>change look of markers (color, size, etc.)</td>
</tr>
<tr>
<td>marker_label_options</td>
<td>add marker labels; change look or position</td>
</tr>
<tr>
<td><strong>Add plots</strong></td>
<td></td>
</tr>
<tr>
<td>addplot(plot)</td>
<td>add plots to the generated graph</td>
</tr>
</tbody>
</table>

**Y axis, X axis, Titles, Legend, Overall**

`twoway_options` any options other than `by()` documented in [G-3] `twoway_options`
Options for rvfplot

marker_options affects the rendition of markers drawn at the plotted points, including their shape, size, color, and outline; see [G-3] marker_options.

marker_label_options specify if and how the markers are to be labeled; see [G-3] marker_label_options.

addplot(plot) provides a way to add plots to the generated graph. See [G-3] addplot_option.

twoway_options are any of the options documented in [G-3] twoway_options, excluding by(). These include options for titling the graph (see [G-3] title_options) and for saving the graph to disk (see [G-3] saving_option).

Remarks and examples for rvfplot

rvfplot graphs the residuals against the fitted values.

Example 1

Using auto.dta described in [U] 1.2.2 Example datasets, we will use regress to fit a model of price on weight, mpg, foreign, and the interaction of foreign with mpg. We specify foreign##c.mpg to obtain the interaction of foreign with mpg; see [U] 11.4.3 Factor variables.

```
. use https://www.stata-press.com/data/r16/auto
   (1978 Automobile Data)
. regress price weight foreign##c.mpg
```

```
Source | SS      df    MS
-------|---------|--|--
Model   | 350319665 4 87579916.3 Prob > F = 0.0000

Foreign |
Once we have fit a model, we may use any of the regression diagnostics commands. *rvfplot* (read residual-versus-fitted plot) graphs the residuals against the fitted values:

```
    . rvfplot, yline(0)
```

All the diagnostic plot commands allow the `graph twoway` and `graph twoway scatter` options; we specified a `yline(0)` to draw a line across the graph at $y = 0$; see [G-2]`graph twoway scatter`

In a well-fitted model, there should be no pattern to the residuals plotted against the fitted values—something not true of our model. Ignoring the two outliers at the top center of the graph, we see curvature in the pattern of the residuals, suggesting a violation of the assumption that price is linear in our independent variables. We might also have seen increasing or decreasing variation in the residuals—heteroskedasticity. Any pattern whatsoever indicates a violation of the least-squares assumptions.
avplot

Description for avplot

avplot graphs an added-variable plot (a.k.a. partial-regression leverage plot, partial regression plot, or adjusted partial residual plot) after `regress`. `indepvar` may be an independent variable (a.k.a. predictor, carrier, or covariate) that is currently in the model or not.

Menu for avplot

Statistics > Linear models and related > Regression diagnostics > Added-variable plot

Syntax for avplot

```
avplot `indepvar' [, `avplot_options']
```

`avplot_options'  

<table>
<thead>
<tr>
<th>Description</th>

</tr>
</thead>
<tbody>
<tr>
<td>`twoway_options'</td>
</tr>
<tr>
<td>any options other than by() documented in [G-3] `twoway_options'</td>
</tr>
</tbody>
</table>

Options for avplot

`marker_options' affects the rendition of markers drawn at the plotted points, including their shape, size, color, and outline; see [G-3] `marker_options'.

`marker_label_options' specify if and how the markers are to be labeled; see [G-3] `marker_label_options'.

`rlopts(` `cline_options')' affects the rendition of the reference line. See [G-3] `cline_options'.

`addplot(` `plot')' provides a way to add plots to the generated graph. See [G-3] `addplot_option'.

`twoway_options' are any of the options documented in [G-3] `twoway_options', excluding by(). These include options for titling the graph (see [G-3] `title_options') and for saving the graph to disk (see [G-3] `saving_option').
Remarks and examples for avplot

avplot graphs an added-variable plot, also known as the partial-regression leverage plot.

One of the wonderful features of one-regressor regressions (regressions of \( y \) on one \( x \)) is that we can graph the data and the regression line. There is no easier way to understand the regression than to examine such a graph. Unfortunately, we cannot do this when we have more than one regressor. With two regressors, it is still theoretically possible—the graph must be drawn in three dimensions, but with three or more regressors no graph is possible.

The added-variable plot is an attempt to project multidimensional data back to the two-dimensional world for each of the original regressors. This is, of course, impossible without making some concessions. Call the coordinates on an added-variable plot \( y \) and \( x \). The added-variable plot has the following properties:

- There is a one-to-one correspondence between \((x_i, y_i)\) and the \(i\)th observation used in the original regression.
- A regression of \( y \) on \( x \) has the same coefficient and standard error (up to a degree-of-freedom adjustment) as the estimated coefficient and standard error for the regressor in the original regression.
- The “outlierness” of each observation in determining the slope is in some sense preserved.

It is equally important to note the properties that are not listed. The \( y \) and \( x \) coordinates of the added-variable plot cannot be used to identify functional form, or, at least, not well (see Mallows [1986]). In the construction of the added-variable plot, the relationship between \( y \) and \( x \) is forced to be linear.

Example 2

Let’s use the same model as we used in example 1.

```
. use https://www.stata-press.com/data/r16/auto
 (1978 Automobile Data)
 . regress price weight foreign##c.mpg
(output omitted)
```

We can now examine the added-variable plot for mpg.

```
. avplot mpg
```

![Added-variable plot example](image-url)
This graph suggests a problem in determining the coefficient on \textit{mpg}. Were this a one-regressor regression, the two points at the top-left corner and the one at the top right would cause us concern, and so it does in our more complicated multiple-regressor case. To identify the problem points, we retyped our command, modifying it to read \texttt{avplot mpg, mlabel(make)}, and discovered that the two cars at the top left are the Cadillac Eldorado and the Lincoln Versailles; the point at the top right is the Cadillac Seville. These three cars account for 100\% of the luxury cars in our data, suggesting that our model is misspecified. By the way, the point at the lower right of the graph, also cause for concern, is the Plymouth Arrow, our data entry error.

### Technical note

Stata’s \texttt{avplot} command can be used with regressors already in the model, as we just did, or with potential regressors not yet in the model. In either case, \texttt{avplot} will produce the correct graph. The name “added-variable plot” is unfortunate in the case when the variable is already among the list of regressors but is, we think, still preferable to the name “partial-regression leverage plot” assigned by Belsley, Kuh, and Welsch (1980, 30) and more in the spirit of the original use of such plots by Mosteller and Tukey (1977, 271–279). Welsch (1986, 403), however, disagrees: “I am sorry to see that Chatterjee and Hadi [1986] endorse the term ‘added-variable plot’ when $X_j$ is part of the original model” and goes on to suggest the name “adjusted partial residual plot”.

### avplots

#### Description for avplots

\texttt{avplots} graphs all the added-variable plots in one image.

#### Menu for avplots

Statistics $>$ Linear models and related $>$ Regression diagnostics $>$ Added-variable plot

#### Syntax for avplots

\begin{verbatim}
avplots [ , avplots_options ]
\end{verbatim}

<table>

_Y axis, X axis, Titles, Legend, Overall_

_**twoway_options**_ any options other than _by()_ documented in _[G-3] twoway_options_

Options for cprplot

Plot

_marker_options_ affects the rendition of markers drawn at the plotted points, including their shape, size, color, and outline; see _[G-3] marker_options_.

_marker_label_options_ specify if and how the markers are to be labeled; see _[G-3] marker_label_options_.

Reference line

_rlopts(cline_options)_ affects the rendition of the reference line. See _[G-3] cline_options_.

Options

lowess adds a lowess smooth of the plotted points to assist in detecting nonlinearities.
lsopts(lowess_options) affects the rendition of the lowess smooth. For an explanation of these options, especially the bwidth() option, see [R] lowess. Specifying lsopts() implies the lowess option.

mspline adds a median spline of the plotted points to assist in detecting nonlinearities.
msopts(mspline_options) affects the rendition of the spline. For an explanation of these options, especially the bands() option, see [G-2] graph twoway mspline. Specifying msopts() implies the mspline option.

Add plots

addplot(plot) provides a way to add other plots to the generated graph. See [G-3] addplot_option.

Y axis, X axis, Titles, Legend, Overall

twoway_options are any of the options documented in [G-3] twoway_options, excluding by(). These include options for titling the graph (see [G-3] title_options) and for saving the graph to disk (see [G-3] saving_option).

Remarks and examples for cprplot

Added-variable plots are successful at identifying outliers, but they cannot be used to identify functional form. The component-plus-residual plot (Ezekiel 1924; Larsen and McCleary 1972) is another attempt at projecting multidimensional data into a two-dimensional form, but with different properties. Although the added-variable plot can identify outliers, the component-plus-residual plot cannot. It can, however, be used to examine the functional form assumptions of the model. Both plots have the property that a regression line through the coordinates has a slope equal to the estimated coefficient in the regression model.

Example 4

We illustrate component-plus-residual plots using a variation of auto.dta.

```
. use https://www.stata-press.com/data/r16/auto1
(Automobile Models)
. regress price mpg weight
```

```

```
In fact, we know that the effects of \texttt{mpg} in this model are nonlinear—if we added \texttt{mpg} squared to the model, its coefficient would have a \( t \) statistic of 2.38, the \( t \) statistic on \texttt{mpg} would become \(-2.48\), and \texttt{weight}'s effect would become about one-third of its current value and become statistically insignificant. Pretend that we do not know this.

The component-plus-residual plot for \texttt{mpg} is

```stata
.cprplot mpg, mspline msopts(bands(13))
```

We are supposed to examine the above graph for nonlinearities or, equivalently, ask if the regression line, which has slope equal to the estimated effect of \texttt{mpg} in the original model, fits the data adequately. To assist our eyes, we added a median spline. Perhaps some people may detect nonlinearity from this graph, but we assert that if we had not previously revealed the nonlinearity of \texttt{mpg} and if we had not added the median spline, the graph would not overly bother us.
acprplot

Description for acprplot

acprplot graphs an augmented component-plus-residual plot (a.k.a. augmented partial residual plot) as described by Mallows (1986). This seems to work better than the component-plus-residual plot for identifying nonlinearities in the data.

Menu for acprplot

Statistics > Linear models and related > Regression diagnostics > Augmented component-plus-residual plot

Syntax for acprplot

acprplot indepvar [ , acprplot_options ]

lsopts(lowess_options) affects the rendition of the lowess smooth. For an explanation of these options, especially the bwidth() option, see [R] lowess. Specifying lsopts() implies the lowess option.

mspline adds a median spline of the plotted points to assist in detecting nonlinearities.

msopts(mspline_options) affects the rendition of the spline. For an explanation of these options, especially the bands() option, see [G-2] graph twoway mspline. Specifying msopts() implies the mspline option.

addplot(plot) provides a way to add other plots to the generated graph. See [G-3] addplot_option.

Y axis, X axis, Titles, Legend, Overall

twoway_options are any of the options documented in [G-3] twoway_options, excluding by(). These include options for titling the graph (see [G-3] title_options) and for saving the graph to disk (see [G-3] saving_option).

Remarks and examples for acprplot

In the cprplot section above, we discussed the component-plus-residual plot. Mallows (1986) proposed an augmented component-plus-residual plot that is often more sensitive to detecting nonlinearity.

Example 5

Let’s compare the augmented component-plus-residual plot with the component-plus-residual plot of example 4.

. use https://www.stata-press.com/data/r16/auto
   (1978 Automobile Data)
. regress price weight foreign##c.mpg
   (output omitted)
. acprplot mpg, mspline msopts(bands(13))

![Augmented component plus residual](image)

It does do somewhat better.
rvpplot

Description for rvpplot

rvpplot graphs a residual-versus-predictor plot (a.k.a. independent variable plot or carrier plot), a graph of the residuals against the specified predictor.

Menu for rvpplot

Statistics > Linear models and related > Regression diagnostics > Residual-versus-predictor plot

Syntax for rvpplot

```
rvpplot indepvar [, rvpplot_options]
```

<table>
<thead>
<tr>
<th>rvpplot_options</th>

</tr>
</tbody>
</table>

Options for rvpplot

---

Plot

`marker_options` affects the rendition of markers drawn at the plotted points, including their shape, size, color, and outline; see [G-3] marker_options.

`marker_label_options` specify if and how the markers are to be labeled; see [G-3] marker_label_options.

---

Add plots

`addplot(plot)` provides a way to add other plots to the generated graph; see [G-3] addplot_option.

---

Y axis, X axis, Titles, Legend, Overall

`twoway_options` are any of the options documented in [G-3] twoway_options, excluding by(). These include options for titling the graph (see [G-3] title_options) and for saving the graph to disk (see [G-3] saving_option).
Remarks and examples for rvpplot

The residual-versus-predictor plot is a simple way to look for violations of the regression assumptions. If the assumptions are correct, there should be no pattern on the graph.

Example 6

Let's use our model of price on mpg and weight.

```
. use https://www.stata-press.com/data/r16/auto
   (1978 Automobile Data)
. regress price weight foreign##c.mpg
   (output omitted)
. rvpplot mpg, yline(0)
```

Remember, any pattern counts as a problem, and in this graph, we see that the variation in the residuals decreases as mpg increases.
**lvr2plot**

**Description for lvr2plot**

lvr2plot graphs a leverage-versus-squared-residual plot (a.k.a. L-R plot).

</tr>
</tbody>
</table>
Remarks and examples for \texttt{lvr2plot}

One of the most useful diagnostic graphs is provided by \texttt{lvr2plot} (leverage-versus-residual-squared plot), a graph of leverage against the (normalized) residuals squared.

\textbf{Example 7}

We illustrate \texttt{lvr2plot} using our model in example 1.

\begin{verbatim}
  . use https://www.stata-press.com/data/r16/auto
     (1978 Automobile Data)
  . regress price weight foreign##c.mpg
     (output omitted)
  . lvr2plot
\end{verbatim}

The lines on the chart show the average values of leverage and the (normalized) residuals squared. Points above the horizontal line have higher-than-average leverage; points to the right of the vertical line have larger-than-average residuals.

One point immediately catches our eye, and four more make us pause. The point at the top of the graph has high leverage and a smaller-than-average residual. The other points that bother us all have higher-than-average leverage, two with smaller-than-average residuals and two with larger-than-average residuals.

A less pretty but more useful version of the above graph specifies that \texttt{make} be used as the symbol (see [G-3] \texttt{marker_label_options}):
The VW Diesel, Plymouth Champ, Plymouth Arrow, and Peugeot 604 are the points that cause us the most concern. When we further examine our data, we discover that the VW Diesel is the only diesel in our data and that the data for the Plymouth Arrow were entered incorrectly into the computer. No such simple explanations were found for the Plymouth Champ and Peugeot 604.

Methods and formulas

See Hamilton (2013, 209–214) and Kohler and Kreuter (2012, sec. 9.3) for a discussion of these diagnostic graphs.

The lvr2plot command plots leverage against the squares of the normalized residuals. The normalized residuals are defined as $\hat{e}_{n_j} = \hat{e}_j / (\sum_i \hat{e}_i^2)^{1/2}$.

<td><code>estat sbknown</code></td>
<td>perform tests for a structural break with a known break date</td>
</tr>
<tr>
<td><code>estat sbsingle</code></td>
<td>perform tests for a structural break with an unknown break date</td>
</tr>
</tbody>
</table>

These commands provide regression diagnostic tools specific to time series. You must `tsset` your data before using these commands; see `[TS] tsset`.

`estat archlm`

Description for `estat archlm`

`estat archlm` performs Engle’s Lagrange multiplier (LM) test for the presence of autoregressive conditional heteroskedasticity.

Menu for `estat`

Statistics  >  Postestimation

Syntax for `estat archlm`

```
estat archlm [ , archlm_options ]
```

<table>
<thead>
<tr>
<th><code>archlm_options</code></th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>lags(numlist)</code></td>
<td>test <code>numlist</code> lag orders</td>
</tr>
<tr>
<td><code>force</code></td>
<td>allow test after <code>regress, vce(robust)</code></td>
</tr>
</tbody>
</table>
Options for estat archlm

lags(numlist) specifies a list of numbers, indicating the lag orders to be tested. The test will be performed separately for each order. The default is order one.

force allows the test to be run after regress, vce(robust). The command will not work if the vce(cluster clustvar) option is specified with regress; see [R] regress.

estat bgodfrey

Description for estat bgodfrey

estat bgodfrey performs the Breusch–Godfrey test for higher-order serial correlation in the disturbance. This test does not require that all the regressors be strictly exogenous.

Menu for estat

Statistics > Postestimation

Syntax for estat bgodfrey

    estat bgodfrey [ , bgodfrey_options ]

<table>
<thead>
<tr>
<th>bgodfrey_options</th>
<th>Description</th>

</tr>
<tr>
<td>nomiss0</td>
<td>do not use Davidson and MacKinnon’s approach</td>
</tr>
<tr>
<td>small</td>
<td>obtain p-values using the F or t distribution</td>
</tr>
</tbody>
</table>

Options for estat bgodfrey

lags(numlist) specifies a list of numbers, indicating the lag orders to be tested. The test will be performed separately for each order. The default is order one.

nomiss0 specifies that Davidson and MacKinnon’s approach (1993, 358), which replaces the missing values in the initial observations on the lagged residuals in the auxiliary regression with zeros, not be used.

small specifies that the p-values of the test statistics be obtained using the F or t distribution instead of the default chi-squared or normal distribution.
estat durbinalt

Description for estat durbinalt

estat durbinalt performs Durbin’s alternative test for serial correlation in the disturbance. This test does not require that all the regressors be strictly exogenous.

Menu for estat

Statistics > Postestimation

Syntax for estat durbinalt

estat durbinalt [, durbinalt_options ]

durbinalt_options Description

lags(numlist) test numlist lag orders
nomiss0 do not use Davidson and MacKinnon’s approach
robust compute standard errors using the robust/sandwich estimator
small obtain p-values using the F or t distribution
force allow test after regress, vce(robust) or after newey

Options for estat durbinalt

lags(numlist) specifies a list of numbers, indicating the lag orders to be tested. The test will be performed separately for each order. The default is order one.

nomiss0 specifies that Davidson and MacKinnon’s approach (1993, 358), which replaces the missing values in the initial observations on the lagged residuals in the auxiliary regression with zeros, not be used.

robust specifies that the Huber/White/sandwich robust estimator for the variance–covariance matrix be used in Durbin’s alternative test.

small specifies that the p-values of the test statistics be obtained using the F or t distribution instead of the default chi-squared or normal distribution. This option may not be specified with robust, which always uses an F or a t distribution.

force allows the test to be run after regress, vce(robust) and after newey (see [R] regress and [TS] newey). The command will not work if the vce(cluster clustvar) option is specified with regress.
estat dwatson

Description for estat dwatson

estat dwatson computes the Durbin–Watson $d$ statistic (Durbin and Watson 1950) to test for first-order serial correlation in the disturbance when all the regressors are strictly exogenous.

Menu for estat

Statistics > Postestimation

Syntax for estat dwatson

estat dwatson

Remarks and examples

The Durbin–Watson test is used to determine whether the error term in a linear regression model follows an AR(1) process. For the linear model

$$y_t = x_t \beta + u_t$$

the AR(1) process can be written as

$$u_t = \rho u_{t-1} + \epsilon_t$$

In general, an AR(1) process requires only that $\epsilon_t$ be independent and identically distributed (i.i.d.). The Durbin–Watson test, however, requires $\epsilon_t$ to be distributed $N(0, \sigma^2)$ for the statistic to have an exact distribution. Also, the Durbin–Watson test can be applied only when the regressors are strictly exogenous. A regressor $x$ is strictly exogenous if $\text{Corr}(x_s, u_t) = 0$ for all $s$ and $t$, which precludes the use of the Durbin–Watson statistic with models where lagged values of the dependent variable are included as regressors.

The null hypothesis of the test is that there is no first-order autocorrelation. The Durbin–Watson $d$ statistic can take on values between 0 and 4 and under the null $d$ is equal to 2. Values of $d$ less than 2 suggest positive autocorrelation ($\rho > 0$), whereas values of $d$ greater than 2 suggest negative autocorrelation ($\rho < 0$). Calculating the exact distribution of the $d$ statistic is difficult, but empirical upper and lower bounds have been established based on the sample size and the number of regressors. Extended tables for the $d$ statistic have been published by Savin and White (1977). For example, suppose you have a model with 30 observations and three regressors (including the constant term). For a test of the null hypothesis of no autocorrelation versus the alternative of positive autocorrelation, the lower bound of the $d$ statistic is 1.284, and the upper bound is 1.567 at the 5% significance level. You would reject the null if $d < 1.284$, and you would fail to reject if $d > 1.567$. A value falling within the range (1.284, 1.567) leads to no conclusion about whether or not to reject the null hypothesis.

When lagged dependent variables are included among the regressors, the past values of the error term are correlated with those lagged variables at time $t$, implying that they are not strictly exogenous regressors. The inclusion of covariates that are not strictly exogenous causes the $d$ statistic to be biased toward the acceptance of the null hypothesis. Durbin (1970) suggested an alternative test for models with lagged dependent variables and extended that test to the more general AR($p$) serial correlation process

$$u_t = \rho_1 u_{t-1} + \cdots + \rho_p u_{t-p} + \epsilon_t$$

where $\epsilon_t$ is i.i.d. with variance $\sigma^2$ but is not assumed or required to be normal for the test.
The null hypothesis of Durbin’s alternative test is

\[ H_0 : \rho_1 = 0, \ldots, \rho_p = 0 \]

and the alternative is that at least one of the \( \rho \)'s is nonzero. Although the null hypothesis was originally derived for an AR(\( p \)) process, this test turns out to have power against MA(\( p \)) processes as well. Hence, the actual null of this test is that there is no serial correlation up to order \( p \) because the MA(\( p \)) and the AR(\( p \)) models are locally equivalent alternatives under the null. See Godfrey (1988, 113–115) for a discussion of this result.

Durbin’s alternative test is in fact a LM test, but it is most easily computed with a Wald test on the coefficients of the lagged residuals in an auxiliary OLS regression of the residuals on their lags and all the covariates in the original regression. Consider the linear regression model

\[ y_t = \beta_1 x_{1t} + \cdots + \beta_k x_{kt} + u_t \]  

(1)

in which the covariates \( x_1 \) through \( x_k \) are not assumed to be strictly exogenous and \( u_t \) is assumed to be i.i.d. and to have finite variance. The process is also assumed to be stationary. (See Wooldridge [2020, sec. 11.1] for a discussion of stationarity.) Estimating the parameters in (1) by OLS obtains the residuals \( \hat{u}_t \). Next another OLS regression is performed of \( \hat{u}_t \) on \( \hat{u}_{t-1}, \ldots, \hat{u}_{t-p} \) and the other regressors,

\[ \hat{u}_t = \gamma_1 \hat{u}_{t-1} + \cdots + \gamma_p \hat{u}_{t-p} + \beta_1 x_{1t} + \cdots + \beta_k x_{kt} + \epsilon_t \]  

(2)

where \( \epsilon_t \) stands for the random-error term in this auxiliary OLS regression. Durbin’s alternative test is then obtained by performing a Wald test that \( \gamma_1, \ldots, \gamma_p \) are jointly zero. The test can be made robust to an unknown form of heteroskedasticity by using a robust VCE estimator when estimating the regression in (2). When there are only strictly exogenous regressors and \( p = 1 \), this test is asymptotically equivalent to the Durbin–Watson test.

The Breusch–Godfrey test is also an LM test of the null hypothesis of no autocorrelation versus the alternative that \( u_t \) follows an AR(\( p \)) or MA(\( p \)) process. Like Durbin’s alternative test, it is based on the auxiliary regression (2), and it is computed as \( NR^2 \), where \( N \) is the number of observations and \( R^2 \) is the simple \( R^2 \) from the regression. This test and Durbin’s alternative test are asymptotically equivalent. The test statistic \( NR^2 \) has an asymptotic \( \chi^2 \) distribution with \( p \) degrees of freedom. It is valid with or without the strict exogeneity assumption but is not robust to conditional heteroskedasticity, even if a robust VCE is used when fitting (2).

In fitting (2), the values of the lagged residuals will be missing in the initial periods. As noted by Davidson and MacKinnon (1993), the residuals will not be orthogonal to the other covariates in the model in this restricted sample, which implies that the \( R^2 \) from the auxiliary regression will not be zero when the lagged residuals are left out. Hence, Breusch and Godfrey’s \( NR^2 \) version of the test may overreject in small samples. To correct this problem, Davidson and MacKinnon (1993) recommend setting the missing values of the lagged residuals to zero and running the auxiliary regression in (2) over the full sample used in (1). This small-sample correction has become conventional for both the Breusch–Godfrey and Durbin’s alternative test, and it is the default for both commands. Specifying the \texttt{nomiss0} option overrides this default behavior and treats the initial missing values generated by regressing on the lagged residuals as missing. Hence, \texttt{nomiss0} causes these initial observations to be dropped from the sample of the auxiliary regression.

Durbin’s alternative test and the Breusch–Godfrey test were originally derived for the case covered by \texttt{regress} without the \texttt{vce(robust)} option. However, after \texttt{regress}, \texttt{vce(robust)} and \texttt{newey}, Durbin’s alternative test is still valid and can be invoked if the \texttt{robust} and \texttt{force} options are specified.
Example 1: tests for serial correlation

Using data from Klein (1950), we first fit an OLS regression of consumption on the government wage bill:

```
. use https://www.stata-press.com/data/r16/klein
. tsset yr
    time variable: yr, 1920 to 1941
delta: 1 unit
. regress consump wagegovt
```

```
Source | SS      df       MS
------|---------|---------|---------
Model  | 532.567711  1 532.567711
Residual | 601.207167  20 30.0603584
Total  | 1133.77488  21 53.9892799

F(1, 20) = 17.72 Prob > F = 0.0004
R-squared = 0.4697 Adj R-squared = 0.4432
Root MSE = 5.4827

consump Coef. Std. Err. t P>|t| [95% Conf. Interval]
wagegovt  2.50744 .5957173 4.21 0.000 1.264796 3.750085
_cons  40.84699 3.192183 12.80 0.000 34.18821 47.50577
```

If we assume that wagegovt is a strictly exogenous variable, we can use the Durbin–Watson test to check for first-order serial correlation in the errors.

```
. estat dwatson
Durbin-Watson d-statistic( 2, 22) = .3217998
```

The Durbin–Watson $d$ statistic, 0.32, is far from the center of its distribution ($d = 2.0$). Given 22 observations and two regressors (including the constant term) in the model, the lower 5% bound is about 0.997, much greater than the computed $d$ statistic. Assuming that wagegovt is strictly exogenous, we can reject the null of no first-order serial correlation. Rejecting the null hypothesis does not necessarily mean an AR process; other forms of misspecification may also lead to a significant test statistic. If we are willing to assume that the errors follow an AR(1) process and that wagegovt is strictly exogenous, we could refit the model using arima or prais and model the error process explicitly; see [TS] arima and [TS] prais.

If we are not willing to assume that wagegovt is strictly exogenous, we could instead use Durbin’s alternative test or the Breusch–Godfrey to test for first-order serial correlation. Because we have only 22 observations, we will use the small option.

```
. estat durbinalt, small
Durbin’s alternative test for autocorrelation

lags(p) | F    | df | Prob > F
--------|------|----|---------
   1    | 35.035 | ( 1, 19 ) | 0.0000

H0: no serial correlation
```
Both tests strongly reject the null of no first-order serial correlation, so we decide to refit the model with two lags of consump included as regressors and then rerun estat durbinalt and estat bgodfrey. Because the revised model includes lagged values of the dependent variable, the Durbin–Watson test is not applicable.

Although wagegovt and the constant term are no longer statistically different from zero at the 5% level, the output from estat durbinalt and estat bgodfrey indicates that including the two lags of consump has removed any serial correlation from the errors.
Engle (1982) suggests an LM test for checking for autoregressive conditional heteroskedasticity (ARCH) in the errors. The $p$th-order ARCH model can be written as

$$
\sigma_t^2 = E(u_t^2|u_{t-1}, \ldots, u_{t-p}) = \gamma_0 + \gamma_1 u_{t-1}^2 + \cdots + \gamma_p u_{t-p}^2
$$

To test the null hypothesis of no autoregressive conditional heteroskedasticity (that is, $\gamma_1 = \cdots = \gamma_p = 0$), we first fit the OLS model (1), obtain the residuals $\hat{u}_t$, and run another OLS regression on the lagged residuals:

$$
\hat{u}_t^2 = \gamma_0 + \gamma_1 \hat{u}_{t-1}^2 + \cdots + \gamma_p \hat{u}_{t-p}^2 + \epsilon
$$

(3)

The test statistic is $NR^2$, where $N$ is the number of observations in the sample and $R^2$ is the $R^2$ from the regression in (3). Under the null hypothesis, the test statistic follows a $\chi_p^2$ distribution.

> Example 2: estat archlm

We refit the original model that does not include the two lags of $\text{consump}$ and then use `estat archlm` to see if there is any evidence that the errors are autoregressive conditional heteroskedastic.

```
. regress consump wagegovt
Source | SS df MS
------ | ------ ------ ------
Model | 532.567711 1 532.567711 F(1, 20) = 17.72 Prob > F = 0.0004
Residual | 601.207167 20 30.0603584 R-squared = 0.4697 Adj R-squared = 0.4432
Total | 1133.77488 21 53.9892799 Root MSE = 5.4827

consump | Coef. Std. Err. t P>|t|  [95% Conf. Interval]

H0: no ARCH effects vs. H1: ARCH(p) disturbance

`estat archlm` shows the results for tests of ARCH(1), ARCH(2), and ARCH(3) effects, respectively. At the 5% significance level, all three tests reject the null hypothesis that the errors are not autoregressive conditional heteroskedastic. See [TS] arch for information on fitting ARCH models.
**Stored results**

`estat archlm` stores the following in `r()`:

Scalars
- `r(N)` number of observations
- `r(k)` number of regressors
- `r(N_gaps)` number of gaps

Macros
- `r(lags)` lag order

Matrices
- `r(arch)` test statistic for each lag order
- `r(df)` degrees of freedom
- `r(p)` two-sided $p$-values

`estat bgodfrey` stores the following in `r()`:

Scalars
- `r(N)` number of observations
- `r(k)` number of regressors
- `r(N_gaps)` number of gaps

Macros
- `r(lags)` lag order

Matrices
- `r(chi2)` $\chi^2$ statistic for each lag order
- `r(F)` $F$ statistic for each lag order (small only)
- `r(df_r)` residual degrees of freedom (small only)
- `r(df)` degrees of freedom
- `r(p)` two-sided $p$-values

`estat durbinalt` stores the following in `r()`:

Scalars
- `r(N)` number of observations
- `r(k)` number of regressors
- `r(N_gaps)` number of gaps

Macros
- `r(lags)` lag order

Matrices
- `r(chi2)` $\chi^2$ statistic for each lag order
- `r(F)` $F$ statistic for each lag order (small only)
- `r(df_r)` residual degrees of freedom (small only)
- `r(df)` degrees of freedom
- `r(p)` two-sided $p$-values

`estat dwatson` stores the following in `r()`:

Scalars
- `r(N)` number of observations
- `r(k)` number of regressors
- `r(N_gaps)` number of gaps
- `r(dw)` Durbin–Watson statistic
Consider the regression
\[ y_t = \beta_1 x_{1t} + \cdots + \beta_k x_{kt} + u_t \] (4)
in which some of the covariates are not strictly exogenous. In particular, some of the \( x_{it} \) may be lags of the dependent variable. We are interested in whether the \( u_t \) are serially correlated.

The Durbin–Watson \( d \) statistic reported by \texttt{estat dwatson} is
\[ d = \frac{\sum_{t=1}^{n-1} (\hat{u}_{t+1} - \hat{u}_t)^2}{\sum_{t=1}^{n} \hat{u}_t^2} \]
where \( \hat{u}_t \) represents the residual of the \( t \)th observation.

To compute Durbin’s alternative test and the Breusch–Godfrey test against the null hypothesis that there is no \( p \)th order serial correlation, we fit the regression in (4), compute the residuals, and then fit the following auxiliary regression of the residuals \( \hat{u}_t \) on \( p \) lags of \( \hat{u}_t \) and on all the covariates in the original regression in (4):
\[ \hat{u}_t = \gamma_1 \hat{u}_{t-1} + \cdots + \gamma_p \hat{u}_{t-p} + \beta_1 x_{1t} + \cdots + \beta_k x_{kt} + \epsilon \] (5)

Durbin’s alternative test is computed by performing a Wald test to determine whether the coefficients of \( \hat{u}_{t-1}, \ldots, \hat{u}_{t-p} \) are jointly different from zero. By default, the statistic is assumed to be distributed \( \chi^2(p) \). When \texttt{small} is specified, the statistic is assumed to follow an \( F(p, N - p - k) \) distribution. The reported \( p \)-value is a two-sided \( p \)-value. When \texttt{robust} is specified, the Wald test is performed using the Huber/White/sandwich estimator of the variance–covariance matrix, and the test is robust to an unspecified form of heteroskedasticity.

The Breusch–Godfrey test is computed as \( NR^2 \), where \( N \) is the number of observations in the auxiliary regression (5) and \( R^2 \) is the \( R^2 \) from the same regression (5). Like Durbin’s alternative test, the Breusch–Godfrey test is asymptotically distributed \( \chi^2(p) \), but specifying \texttt{small} causes the \( p \)-value to be computed using an \( F(p, N - p - k) \).

By default, the initial missing values of the lagged residuals are replaced with zeros, and the auxiliary regression is run over the full sample used in the original regression of (4). Specifying the \texttt{nomiss0} option causes these missing values to be treated as missing values, and the observations are dropped from the sample.

Engle’s LM test for ARCH(\( p \)) effects fits an OLS regression of \( \hat{u}_t^2 \) on \( \hat{u}_{t-1}^2, \ldots, \hat{u}_{t-p}^2 \):
\[ \hat{u}_t^2 = \gamma_0 + \gamma_1 \hat{u}_{t-1}^2 + \cdots + \gamma_p \hat{u}_{t-p}^2 + \epsilon \]
The test statistic is \( nR^2 \) and is asymptotically distributed \( \chi^2(p) \).

Acknowledgment

The original versions of \texttt{estat archlm}, \texttt{estat bgodfrey}, and \texttt{estat durbinalt} were written by Christopher F. Baum of the Department of Economics at Boston College and author of the Stata Press books \textit{An Introduction to Modern Econometrics Using Stata} and \textit{An Introduction to Stata Programming}.

James Durbin (1923–2012) was a British statistician who was born in Wigan, near Manchester. He studied mathematics at Cambridge and after military service and various research posts joined the London School of Economics in 1950. Later in life, he was also affiliated with University College London. His many contributions to statistics centered on serial correlation, time series (including major contributions to structural or unobserved components models), sample survey methodology, goodness-of-fit tests, and sample distribution functions, with emphasis on applications in the social sciences. He served terms as president of the Royal Statistical Society and the International Statistical Institute.

Geoffrey Stuart Watson (1921–1998) was born in Victoria, Australia, and earned degrees at Melbourne University and North Carolina State University. After a visit to the University of Cambridge, he returned to Australia, working at Melbourne and then the Australian National University. Following periods at Toronto and Johns Hopkins, he settled at Princeton. Throughout his wide-ranging career, he made many notable accomplishments and important contributions, including the Durbin–Watson test for serial correlation, the Nadaraya–Watson estimator in nonparametric regression, and methods for analyzing directional data.

Leslie G. Godfrey (1946– ) was born in London and earned degrees at the Universities of Exeter and London. He is now a professor of econometrics at the University of York. His interests center on implementation and interpretation of tests of econometric models, including nonnested models.

Trevor Stanley Breusch (1953– ) was born in Queensland and earned degrees at the University of Queensland and Australian National University (ANU). After a post at the University of Southampton, he returned to work at ANU. His background is in econometric methods and his recent interests include political values and social attitudes, earnings and income, and measurement of underground economic activity.

Title

#review — Review previous commands

Description

The #review command displays the last few lines typed at the terminal.

Syntax

#review [ #1 [ #2 ]]

Remarks and examples

#review (pronounced pound-review) is a Stata preprocessor command. #commands do not generate a return code or generate ordinary Stata errors. The only error message associated with #commands is “unrecognized #command”.

The #review command displays the last few lines typed at the terminal. If no arguments follow #review, the last five lines typed at the terminal are displayed. The first argument specifies the number of lines to be reviewed, so #review 10 displays the last 10 lines typed. The second argument specifies the number of lines to be displayed, so #review 10 5 displays five lines, starting at the 10th previous line.

Stata reserves a buffer for #review lines and stores as many previous lines in the buffer as will fit, rolling out the oldest line to make room for the newest. Requests to #review lines no longer stored will be ignored. Only lines typed at the terminal are placed in the #review buffer. See [U] 10.5 Editing previous lines in Stata.

Example 1

Typing #review by itself will show the last five lines you typed at the terminal:

```
. #review
5 use mydata
4 * comments go into the #review buffer, too
3 describe
2 tabulate marriage educ [freq=number]
1 tabulate marriage educ [freq=number], chi2
```

Typing #review 15 2 shows the 15th and 14th previous lines:

```
. #review 15 2
15 replace x=. if x<200
14 summarize x
```

2258
ROC analysis quantifies the accuracy of diagnostic tests or other evaluation modalities used to discriminate between two states or conditions, which are here referred to as normal and abnormal or control and case. The discriminatory accuracy of a diagnostic test is measured by its ability to correctly classify known normal and abnormal subjects. For this reason, we often refer to the diagnostic test as a classifier. The analysis uses the ROC curve, a graph of the sensitivity versus 1 – specificity of the diagnostic test. The sensitivity is the fraction of positive cases that are correctly classified by the diagnostic test, whereas the specificity is the fraction of negative cases that are correctly classified. Thus the sensitivity is the true-positive rate, and the specificity is the true-negative rate.

There are six ROC commands:

<table>
<thead>
<tr>

<td>roctab</td>
<td>[R] roctab</td>
<td>Nonparametric ROC analysis</td>
</tr>
</tbody>
</table>

Postestimation commands are available after rocfit and rocreg; see [R] rocfit postestimation and [R] rocreg postestimation.

Both nonparametric and parametric (semiparametric) methods have been suggested for generating the ROC curve. The roctab command performs nonparametric ROC analysis for a single classifier. roccomp extends the nonparametric ROC analysis function of roctab to situations where we have multiple diagnostic tests of interest to be compared and tested. The rocgold command also provides ROC analysis for multiple classifiers. rocgold compares each classifier’s ROC curve to a “gold standard” ROC curve and makes adjustments for multiple comparisons in the analysis. Both rocgold and roccomp also allow parametric estimation of the ROC curve through a binormal fit. In a binormal fit, both the control and the case populations are normal.

The rocfit command also estimates the ROC curve of a classifier through a binormal fit. Unlike roctab, roccomp, and rocgold, rocfit is an estimation command. In postestimation, graphs of the ROC curve and confidence bands can be produced. Additional tests on the parameters can also be conducted.

ROC analysis can be interpreted as a two-stage process. First, the control distribution of the classifier is estimated, assuming a normal model or using a distribution-free estimation technique. The classifier is standardized using the control distribution to 1 – percentile value, the false-positive rate. Second, the ROC curve is estimated as the case distribution of the standardized classifier values.

Covariates may affect both stages of ROC analysis. The first stage may be affected, yielding a covariate-adjusted ROC curve. The second stage may also be affected, producing multiple covariate-specific ROC curves.
The `rocreg` command performs ROC analysis under both types of covariate effects. Both parametric (semiparametric) and nonparametric methods may be used by `rocreg`. Like `rocfit`, `rocreg` is an estimation command and provides many postestimation capabilities.

The global performance of a diagnostic test is commonly summarized by the area under the ROC curve (AUC). This area can be interpreted as the probability that the result of a diagnostic test of a randomly selected abnormal subject will be greater than the result of the same diagnostic test from a randomly selected normal subject. The greater the AUC, the better the global performance of the diagnostic test. Each of the ROC commands provides computation of the AUC.

Citing a lack of clinical relevance for the AUC, other ROC summary measures have been suggested. These include the partial area under the ROC curve for a given false-positive rate \( t \) \([\text{pAUC}(t)]\). This is the area under the ROC curve from the false-positive rate of 0 to \( t \). The ROC value at a particular false-positive rate and the false-positive rate for a particular ROC value are also useful summary measures for the ROC curve. These three measures are directly estimated by `rocreg` during the model fit or postestimation stages. Point estimates of ROC value are computed by the other ROC commands, but no standard errors are reported.

References

Description

roccomp and rocgold are used to perform receiver operating characteristic (ROC) analyses with rating and discrete classification data.

The two variables refvar and classvar must be numeric. The reference variable indicates the true state of the observation, such as diseased and nondiseased or normal and abnormal, and must be coded as 0 and 1. The rating or outcome of the diagnostic test or test modality is recorded in classvar, which must be at least ordinal, with higher values indicating higher risk.

roccomp tests the equality of two or more ROC areas obtained from applying two or more test modalities to the same sample or to independent samples. roccomp expects the data to be in wide form when comparing areas estimated from the same sample and in long form for areas estimated from independent samples.

rocgold independently tests the equality of the ROC area of each of several test modalities, specified by classvar, against a “gold standard” ROC curve, goldvar. For each comparison, rocgold reports the raw and the Bonferroni-adjusted p-value. Optionally, Šidák’s adjustment for multiple comparisons can be obtained.

See [R] rocfit and [R] rocreg for commands that fit maximum-likelihood ROC models.

Quick start

Equality of AUCs for rating v1 of true state true between samples defined by catvar
   roccomp true v1, by(catvar)

Equality of AUCs for ratings v1 and v2 for the same sample
   roccomp true v1 v2

As above, but plot ROC curves without reporting summary statistics and test of equality
   roccomp true v1 v2, graph

As above, but plot v1 with a dashed line and v2 with a solid line
   roccomp true v1 v2, graph plot1opts(lpattern(dash)) ///
   plot2opts(lpattern(solid))

Use contrast matrix mymat to compare ROC areas for v1, v2, v3, and v4
   matrix mymat = (1,0,-1,0 \ 0,1,0,-1)
   roccomp true v1 v2 v3 v4, test(mymat)

Test equality of ROC area for v1 against a “gold standard” gold
   rocgold true gold v1

## Options

### Main

- **by(varname)** (roccomp only) is required when comparing independent ROC areas. The `by()` variable identifies the groups to be compared.

- **sidak** (rocgold only) requests that the $p$-value be adjusted for the effect of multiple comparisons by using Šidák’s method. Bonferroni’s adjustment is reported by default.

- **test(matname)** specifies the contrast matrix to be used when comparing ROC areas. By default, the null hypothesis that all areas are equal is tested.

- **graph** produces graphical output of the ROC curve.

- **norefline** suppresses plotting the 45-degree reference line from the graphical output of the ROC curve.

- **separate** is meaningful only with roccomp and specifies that each ROC curve be placed on its own graph rather than one curve on top of the other.

- **summary** reports the area under the ROC curve, its standard error, and its confidence interval. This option is needed only when also specifying `graph`.  

---

roccomp — Tests of equality of ROC areas  2263
binormal specifies that the areas under the ROC curves to be compared should be estimated using the binormal distribution assumption. By default, areas to be compared are computed using the trapezoidal rule.

Line# opts(cline options) affect the rendition of the line representing the #th ROC curve drawn using the binormal distribution assumption; see [G-3] cline options. These lines are drawn only if the binormal option is specified.

Level(#) specifies the confidence level, as a percentage, for the confidence intervals. The default is level(95) or as set by set level; see [R] level.

Plot# opts(plot options) affect the rendition of the #th ROC curve—the curve’s plotted points connected by lines. The plot options can affect the size and color of markers, whether and how the markers are labeled, and whether and how the points are connected; see [G-3] marker options, [G-3] marker label options, and [G-3] cline options.

For rocgold, plot# opts() are applied to the ROC for the gold standard.

Rlopts(cline options) affects the rendition of the reference line; see [G-3] cline options.

Y axis, X axis, Titles, Legend, Overall

twoway options are any of the options documented in [G-3] twoway options. These include options for titling the graph (see [G-3] title options), options for saving the graph to disk (see [G-3] saving option), and the by() option (see [G-3] by option).

Remarks and examples

Remarks are presented under the following headings:

Introduction
Comparing areas under the ROC curve
Correlated data
Independent data
Comparing areas with a gold standard

Introduction

roccomp provides comparison of the ROC curves of multiple classifiers. rocgold compares the ROC curves of multiple classifiers with a single “gold standard” classifier. Adjustment of inference for multiple comparisons is also provided by rocgold.

Comparing areas under the ROC curve

The area under multiple ROC curves can be compared by using roccomp. The command syntax is slightly different if the ROC curves are correlated (that is, different diagnostic tests are applied to the same sample) or independent (that is, diagnostic tests are applied to different samples).

Correlated data

Example 1

Hanley and McNeil (1983) presented data from an evaluation of two computer algorithms designed to reconstruct CT images from phantoms. We will call these two algorithms’ modalities 1 and 2. A sample of 112 phantoms was selected; 58 phantoms were considered normal, and the remaining 54 were abnormal. Each of the two modalities was applied to each phantom, and the resulting images were rated by a reviewer using a six-point scale: 1 = definitely normal, 2 = probably normal, 3 = possibly normal, 4 = possibly abnormal, 5 = probably abnormal, and 6 = definitely abnormal. Because each modality was applied to the same sample of phantoms, the two sets of outcomes are correlated.

We list the first 7 observations:

```
use https://www.stata-press.com/data/r16/ct
list in 1/7, sep(0)
```

```
  mod1  mod2  status
---  ---  ----
  1.  2   1    0
  2.  5   5    1
  3.  2   1    0
  4.  2   3    0
  5.  5   6    1
  6.  2   2    0
  7.  3   2    0
```

The data are in wide form, which is required when dealing with correlated data. Each observation corresponds to one phantom. The variable mod1 identifies the rating assigned for the first modality, and mod2 identifies the rating assigned for the second modality. The true status of the phantoms is given by status=0 if they are normal and status=1 if they are abnormal. The observations with at least one missing rating were dropped from the analysis.

We plot the two ROC curves and compare their areas.

```
. roccomp status mod1 mod2, graph summary
```

<table>

Ho: area(mod1) = area(mod2)

\[
\chi^2(1) = 2.31\quad \text{Prob}>\chi^2 = 0.1282
\]
By default, `roccomp`, with the `graph` option specified, plots the ROC curves on the same graph. Optionally the curves can be plotted side by side, each on its own graph, by also specifying `separate`.

For each curve, `roccomp` reports summary statistics and provides a test for the equality of the area under the curves, using an algorithm suggested by DeLong, DeLong, and Clarke-Pearson (1988).

Although the area under the ROC curve for modality 2 is larger than that of modality 1, the chi-squared test yielded a $p$-value of 0.1282, suggesting that there is no significant difference between these two areas.

The `roccomp` command can also be used to compare more than two ROC areas. To illustrate this, we modified the previous dataset by including a fictitious third modality.

```
. use https://www.stata-press.com/data/r16/ct2
. roccomp status mod1 mod2 mod3, graph summary
```

</tbody>
</table>

Ho: area(mod1) = area(mod2) = area(mod3)
chi2(2) = 6.54 Prob>chi2 = 0.0381
By default, roccomp tests whether the areas under the ROC curves are all equal. Other comparisons can be tested by creating a contrast matrix and specifying `test(matname)`, where `matname` is the name of the contrast matrix.

For example, assume that we are interested in testing whether the area under the ROC for `mod1` is equal to that of `mod3`. To do this, we can first create an appropriate contrast matrix and then specify its name with the `test()` option.

Of course, this is a trivial example because we could have just specified

```
    . roccomp status mod1 mod3
```

without including `mod2` to obtain the same test results. However, for illustration, we will continue with this example.

The contrast matrix must have its number of columns equal to the number of `classvars` (that is, the total number of ROC curves) and a number of rows less than or equal to the number of `classvars`, and the elements of each row must add to zero.

```
    . matrix C=(1,0,-1)
    . roccomp status mod1 mod2 mod3, test(C)
```

<td>1</td>
</tr>
</tbody>
</table>

Independent data

Example 2

In example 1, we noted that because each test modality was applied to the same sample of phantoms, the classification outcomes were correlated. Now assume that we have collected the same data presented by Hanley and McNeil (1983), except that we applied the first test modality to one sample of phantoms and the second test modality to a different sample of phantoms. The resulting measurements are now considered independent.

Here are a few of the observations.

. use https://www.stata-press.com/data/r16/ct3
. list in 1/7, sep(0)

<table>
<thead>
<tr>
<th>pop</th>
<th>status</th>
<th>rating</th>
<th>mod</th>
</tr>
</thead>
<tbody>
<tr>

<td>0</td>
<td>2</td>
</tr>
<tr>
<td>7</td>
<td>3</td>
<td>1</td>
<td>2</td>
</tr>
</tbody>
</table>

The data are in long form, which is required when dealing with independent data. The data consist of 24 observations: 6 observations corresponding to abnormal phantoms and 6 to normal phantoms evaluated using the first modality, and similarly 6 observations corresponding to abnormal phantoms and 6 to normal phantoms evaluated using the second modality. The number of phantoms corresponding to each observation is given by the pop variable. Once again we have frequency-weighted data. The variable mod identifies the modality, and rating is the assigned classification.
We can better view our data by using the `table` command.

```
. table status rating [fw=pop], by(mod) row col
```

<table>
<thead>
<tr>
<th>mod and status</th>
<th>rating</th>
<th>1</th>
<th>2</th>
<th>3</th>
<th>4</th>
<th>5</th>

<td></td>
<td>34</td>
<td>21</td>
<td>10</td>
<td>22</td>
<td>15</td>
<td>10</td>
<td>112</td>
</tr>
</tbody>
</table>

The `status` variable indicates the true status of the phantoms: `status = 0` if they are normal and `status = 1` if they are abnormal.

We now compare the areas under the two ROC curves.

```
. roccomp status rating [fw=pop], by(mod) graph summary
```

<table>

</table>

Ho: area(1) = area(2)
chi2(1) = 1.35   Prob>chi2 = 0.2447
Comparing areas with a gold standard

The area under multiple ROC curves can be compared with a gold standard using rocgold. The command syntax is similar to that of roccomp. The tests are corrected for the effect of multiple comparisons.

Example 3

We will use the same data (presented by Hanley and McNeil [1983]) as in the roccomp examples. Let’s assume that the first modality is considered to be the standard against which both the second and third modalities are compared.

We want to plot and compare both the areas of the ROC curves of mod2 and mod3 with mod1. Because we consider mod1 to be the gold standard, it is listed first after the reference variable in the rocgold command line.

```
use https://www.stata-press.com/data/r16/ct2
rocgold status mod1 mod2 mod3, graph summary
```

<table>
<thead>
<tr>
<th></th>
<th>ROC Area</th>
<th>Std. Err.</th>
<th>chi2</th>
<th>df</th>
<th>Pr&gt;chi2</th>
<th>Pr&gt;chi2</th>
</tr>
</thead>
<tbody>
<tr>
<td>mod1 (standard)</td>
<td>0.8828</td>
<td>0.0317</td>
<td></td>
<td>1</td>
<td>0.1282</td>
<td>0.2563</td>
</tr>
<tr>
<td>mod2</td>
<td>0.9302</td>
<td>0.0256</td>
<td>2.3146</td>
<td>1</td>
<td>0.0220</td>
<td>0.0439</td>
</tr>
<tr>
<td>mod3</td>
<td>0.9240</td>
<td>0.0241</td>
<td>5.2480</td>
<td>1</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Equivalently, we could have done this in two steps by using the roccomp command.

```
roccomp status mod1 mod2, graph summary
roccomp status mod1 mod3, graph summary
```
**Stored results**

roccomp stores the following in r():

Scalars
- \( r(N_g) \): number of groups
- \( r(p) \): \( p \)-value for \( \chi^2 \) test

Matrices
- \( r(V) \): variance–covariance matrix
- \( r(chi2) \): \( \chi^2 \)
- \( r(df) \): \( \chi^2 \) degrees-of-freedom vector

rocgold stores the following in r():

Scalars
- \( r(N_g) \): number of groups

Matrices
- \( r(V) \): variance–covariance matrix
- \( r(chi2) \): \( \chi^2 \)
- \( r(df) \): \( \chi^2 \) degrees-of-freedom vector
- \( r(p) \): vector of \( p \)-values for \( \chi^2 \) tests
- \( r(p_{-adj}) \): vector of adjusted \( p \)-values

**Methods and formulas**

Assume that we applied a diagnostic test to each of \( N_n \) normal and \( N_a \) abnormal subjects. Further assume that the higher the outcome value of the diagnostic test, the higher the risk of the subject being abnormal. Let \( \hat{\theta} \) be the estimated area under the curve, and let \( X_i, i = 1, 2, \ldots, N_a \) and \( Y_j, j = 1, 2, \ldots, N_n \) be the values of the diagnostic test for the abnormal and normal subjects, respectively.

Areas under ROC curves are compared using an algorithm suggested by DeLong, DeLong, and Clarke-Pearson (1988). Let \( \hat{\theta} = (\hat{\theta}^1, \hat{\theta}^2, \ldots, \hat{\theta}^k) \) be a vector representing the areas under \( k \) ROC curves. See **Methods and formulas** in [R] roctab for the definition of these area estimates.

For the \( r \)th area, define

\[
V_{10}^r(X_i) = \frac{1}{N_n} \sum_{j=1}^{N_n} \psi(X_i^r, Y_j^r)
\]

and for each normal subject, \( j \), define

\[
V_{01}^r(Y_j) = \frac{1}{N_a} \sum_{i=1}^{N_a} \psi(X_i^r, Y_j^r)
\]

where

\[
\psi(X^r, Y^r) = \begin{cases} 1 & Y^r < X^r \\ \frac{1}{2} & Y^r = X^r \\ 0 & Y^r > X^r \end{cases}
\]

Define the \( k \times k \) matrix \( S_{10} \) such that the \((r,s)\)th element is

\[
S_{10}^{r,s} = \frac{1}{N_a - 1} \sum_{i=1}^{N_a} \{V_{10}^r(X_i) - \hat{\theta}^r\} \{V_{10}^s(X_i) - \hat{\theta}^s\}
\]

and \( S_{01} \) such that the \((r,s)\)th element is

\[
S_{01}^{r,s} = \frac{1}{N_n - 1} \sum_{j=1}^{N_n} \{V_{01}^r(Y_i) - \hat{\theta}^r\} \{V_{01}^s(Y_i) - \hat{\theta}^s\}
\]
Then the covariance matrix is

\[ S = \frac{1}{N_a} S_{10} + \frac{1}{N_n} S_{01} \]

Let \( L \) be a contrast matrix defining the comparison, so that

\[ (\hat{\theta} - \theta)' L' (L S L')^{-1} L (\hat{\theta} - \theta) \]

has a chi-squared distribution with degrees of freedom equal to the rank of \( L S L' \).

[R] rocreg — Receiver operating characteristic (ROC) regression

[R] roctab — Nonparametric ROC analysis
Description

rocfit fits maximum-likelihood ROC models assuming a binormal distribution of the latent variable.

The two variables refvar and classvar must be numeric. The reference variable indicates the true state of the observation, such as diseased and nondiseased or normal and abnormal, and must be coded as 0 and 1. The rating or outcome of the diagnostic test or test modality is recorded in classvar, which must be at least ordinal, with higher values indicating higher risk.

See [R] roc for other commands designed to perform receiver operating characteristic (ROC) analyses with rating and discrete classification data.

Quick start

Binary true state, true, as a function of classification variable class
   rocfit true class

As above, but with frequency weights wvar
   rocfit true class [fweight = wvar]

Specify that class is continuous and generate v1 containing classification groups
   rocfit true class, continuous(3) generate(v1)

Menu

Statistics > Epidemiology and related > ROC analysis > Parametric ROC analysis without covariates
Syntax

```
rocfit refvar classvar [if] [in] [weight] [, rocfit_options]
```

### rocfit_options

<table>
<thead>
<tr>
<th>Model</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>continuous(#)</code></td>
<td>divide <code>classvar</code> into # groups of approximately equal length</td>
</tr>
<tr>
<td><code>generate(newvar)</code></td>
<td>create <code>newvar</code> containing classification groups</td>
</tr>
</tbody>
</table>

### SE

| `vce(vcetype)` | `vcetype` may be `oim` or `opg` |

### Reporting

| `level(#)` | set confidence level; default is `level(95)` |

### Maximization

| `maximize_options` | control the maximization process; seldom used |

- `fp` is allowed; see [U] 11.1.10 Prefix commands.
- `fweights` are allowed; see [U] 11.1.6 weight.
- See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

**Options**

- **Model**
  - `continuous(#)` specifies that the continuous `classvar` be divided into # groups of approximately equal length. This option is required when `classvar` takes on more than 20 distinct values.
  - `continuous(.)` may be specified to indicate that `classvar` be used as it is, even though it could have more than 20 distinct values.
  - `generate(newvar)` specifies the new variable that is to contain values indicating the groups produced by `continuous(#)`.

- **SE**
  - `vce(vcetype)` specifies the type of standard error reported. `vcetype` may be either `oim` or `opg`; see [R] `vce_option`.

- **Reporting**
  - `level(#)`; see [R] Estimation options.

- **Maximization**
  - `maximize_options`: `difficult`, `technique(algorithm_spec)`, `iterate(#)`, `[no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(init_specs)`; see [R] Maximize. These options are seldom used.

  Setting the optimization type to `technique(bhhh)` resets the default `vcetype` to `vce(opg)`. 
Remarks and examples

Dorfman and Alf (1969) developed a generalized approach for obtaining maximum likelihood estimates of the parameters for a smooth fitting ROC curve. The most commonly used method for ordinal data, and the one implemented here, is based upon the binormal model; see Pepe (2003), Pepe, Longton, and Janes (2009), and Janes, Longton, and Pepe (2009) for methods of ROC analysis for continuous data, including methods for adjusting for covariates.

The model assumes the existence of an unobserved, continuous, latent variable that is normally distributed (perhaps after a monotonic transformation) in both the normal and abnormal populations with means $\mu_n$ and $\mu_a$ and variances $\sigma_n^2$ and $\sigma_a^2$, respectively. The model further assumes that the $K$ categories of the rating variable result from partitioning the unobserved latent variable by $K - 1$ fixed boundaries. The method fits a straight line to the empirical ROC points plotted using normal probability scales on both axes. Maximum likelihood estimates of the line’s slope and intercept and the $K - 1$ boundaries are obtained simultaneously. See Methods and formulas for details.

The intercept from the fitted line is a measurement of $\frac{\mu_a - \mu_n}{\sigma_a}$, and the slope measures $\frac{\sigma_n}{\sigma_a}$.

Thus the intercept is the standardized difference between the two latent population means, and the slope is the ratio of the two standard deviations. The null hypothesis that there is no difference between the two population means is evaluated by testing that the intercept = 0, and the null hypothesis that the variances in the two populations are equal is evaluated by testing that the slope = 1.

Example 1

We use Hanley and McNeil’s (1982) dataset, described in example 1 of [R] roctab, to fit a smooth ROC curve assuming a binormal model.

```
. use https://www.stata-press.com/data/r16/hanley
. rocfit disease rating

Fitting binormal model:
Iteration 0: log likelihood = -123.68069
Iteration 1: log likelihood = -123.64867
Iteration 2: log likelihood = -123.64855
Iteration 3: log likelihood = -123.64855

Binormal model of disease on rating
Number of obs = 109
Goodness-of-fit chi2(2) = 0.21
Prob > chi2 = 0.9006
Log likelihood = -123.64855

|                | Coef.   | Std. Err. | z      | P>|z|   | [95% Conf. Interval] |
|----------------|---------|-----------|--------|-------|----------------------|
| intercept      | 1.656782| 0.310456  | 5.34   | 0.000 | 1.048300 2.265265    |
| slope (*)      | 0.713002| 0.215882  | -1.33  | 0.184 | 0.289881 1.136123    |

| cut2           | 0.463215| 0.167235  | 2.77   | 0.006 | 0.135441 0.790990    |
| cut3           | 0.766860| 0.174808  | 4.39   | 0.000 | 0.424243 1.109477    |
| cut4           | 1.797938| 0.299581  | 6.00   | 0.000 | 1.210770 2.385106    |
```
rocfit outputs the MLE for the intercept and slope of the fitted regression line along with, here, four boundaries (because there are five ratings) labeled /cut1 through /cut4. Also rocfit computes and reports four indices based on the fitted ROC curve: the area under the curve (labeled ROC area), \( \delta(m) \) (labeled delta(m)), \( d_e \) (labeled d(e)), and \( d_a \) (labeled d(a)). More information about these indices can be found in Methods and formulas and in Erdreich and Lee (1981).

### Stored results

rocfit stores the following in e():

Scalars

- e(N): number of observations
- e(k): number of parameters
- e(k_eq): number of equations in e(b)
- e(k_eq_model): number of equations in overall model test
- e(k_dv): number of dependent variables
- e(df_m): model degrees of freedom
- e(ll): log likelihood
- e(chi2_gf): goodness-of-fit \( \chi^2 \)
- e(df_gf): goodness-of-fit degrees of freedom
- e(p_gf): \( p \)-value for goodness-of-fit test
- e(area): area under the ROC curve
- e(se_area): standard error for the area under the ROC curve
- e(deltam): delta(m)
- e(se_delm): standard error for delta(m)
- e(de): d(e) index
- e(se_de): standard error for d(e) index
- e(da): d(a) index
- e(se_da): standard error for d(a) index
- e(rank): rank of e(V)
- e(ic): number of iterations
- e(rc): return code
- e(converged): 1 if converged, 0 otherwise

Macros

- e(cmd): rocfit
- e(cmdline): command as typed
- e(depvar): refvar and classvar
- e(wtype): weight type
- e(wexp): weight expression
- e(title): title in estimation output
- e(chi2type): GOF; type of model \( \chi^2 \) test
- e(vce): vcetype specified in vce()
- e(vcetype): title used to label Std. Err.
- e(opt): type of optimization
- e(which): max or min; whether optimizer is to perform maximization or minimization
- e(ml_method): type of ml method
- e(user): name of likelihood-evaluator program
- e(technique): maximization technique
- e(properties): b V
Methods and formulas

Dorfman and Alf (1969) developed a general procedure for obtaining maximum likelihood estimates of the parameters of a smooth-fitting ROC curve. The most common method, and the one implemented in Stata, is based upon the binormal model.

The model assumes that there is an unobserved continuous latent variable that is normally distributed in both the normal and abnormal populations. The idea is better explained with the following illustration:

The latent variable is assumed to be normally distributed for both the normal and abnormal subjects, perhaps after a monotonic transformation, with means $\mu_n$ and $\mu_a$ and variances $\sigma^2_n$ and $\sigma^2_a$, respectively.

This latent variable is assumed to be partitioned into the $k$ categories of the rating variable by $k-1$ fixed boundaries. In the above figure, the $k=5$ categories of the rating variable identified on the bottom result from the partition of the four boundaries $Z_1$ through $Z_4$.

Let $R_j$ for $j = 1, 2, \ldots, k$ indicate the categories of the rating variable, let $i = 1$ if the subject belongs to the normal group, and let $i = 2$ if the subject belongs to the abnormal group.

Then

$$p(R_j | i = 1) = F(Z_j) - F(Z_{j-1})$$

where $Z_k = (x_k - \mu_n)/\sigma_n$, $F$ is the cumulative normal distribution, $F(Z_0) = 0$, and $F(Z_k) = 1$. Also,

$$p(R_j | i = 2) = F(bZ_j - a) - F(bZ_{j-1} - a)$$

where $b = \sigma_n/\sigma_a$ and $a = (\mu_a - \mu_n)/\sigma_a$.

The parameters $a$, $b$ and the $k-1$ fixed boundaries $Z_j$ are simultaneously estimated by maximizing the log-likelihood function

$$\log L = \sum_{i=1}^{2} \sum_{j=1}^{k} r_{ij} \log \{p(R_j | i)\}$$

where $r_{ij}$ is the number of $R_j$s in group $i$. 
The area under the fitted ROC curve is computed as
\[ \Phi\left(\frac{a}{\sqrt{1+b^2}}\right) \]
where \( \Phi \) is the standard normal cumulative distribution function.

Point estimates for the ROC curve indices are as follows:
\[ \delta(m) = \frac{a}{b} \quad d_e = \frac{2a}{b+1} \quad d_a = \frac{a\sqrt{2}}{\sqrt{1+b^2}} \]

Variances for these indices are computed using the delta method.

The \( \delta(m) \) estimates \((\mu_a - \mu_n)/\sigma_n\), \( d_e \) estimates \(2(\mu_a - \mu_n)/(\sigma_a - \sigma_n)\), and \( d_a \) estimates \(\sqrt{2}(\mu_a - \mu_n)/(\sigma_a^2 - \sigma_n^2)^2\).

Simultaneous confidence bands for the entire curve are obtained, as suggested by Ma and Hall (1993), by first obtaining Working–Hotelling (1929) confidence bands for the fitted straight line in normal probability coordinates and then transforming them back to ROC coordinates.

rocplot

Description for rocplot

rocplot plots the fitted ROC curve and simultaneous confidence bands.

Menu for rocplot

Statistics > Epidemiology and related > ROC analysis > ROC curves after rocfit

Syntax for rocplot

rocplot [, rocplot_options]

rocplot_options | Description
-----------------|--------------------------------------------------
Main
confband | display confidence bands
norefline | suppress plotting the reference line
level(#) | set confidence level; default is level(95)
Plot
plotopts(plot_options) | affect rendition of the ROC points
Fit line
lineopts(cline_options) | affect rendition of the fitted ROC line
Cl plot
ciopts(area_options) | affect rendition of the confidence bands
Reference line
rlopts(cline_options) | affect rendition of the reference line
Add plots
addplot(plot) | add other plots to the generated graph

Y axis, X axis, Titles, Legend, Overall
twoway_options | any options other than by() documented in [G-3] twoway_options

plot_options | Description
--------------|--------------------------------------------------
marker_options | change look of markers (color, size, etc.)
marker_label_options | add marker labels; change look or position
cline_options | change the look of the line
Options for rocplot

---

**Main**

confband specifies that simultaneous confidence bands be plotted around the ROC curve.

noxline suppresses plotting the 45-degree reference line from the graphical output of the ROC curve.

level(##) specifies the confidence level, as a percentage, for the confidence bands. The default is level(95) or as set by set level; see [R] level.

---

**Plot**

plotopts(plot_options) affects the rendition of the plotted ROC points, including the size and color of markers, whether and how the markers are labeled, and whether and how the points are connected. For the full list of available plot_options, see [G-3] marker_options, [G-3] marker_label_options, and [G-3] cline_options.

---

**Fit line**

lineopts(cline_options) affects the rendition of the fitted ROC line; see [G-3] cline_options.

---

**CI plot**

ciopts(area_options) affects the rendition of the confidence bands; see [G-3] area_options.

---

**Reference line**

rlopts(cline_options) affects the rendition of the reference line; see [G-3] cline_options.

---

**Add plots**

addplot(plot) provides a way to add other plots to the generated graph. See [G-3] addplot_option.

---

**Y axis, X axis, Titles, Legend, Overall**

twoway_options are any of the options documented in [G-3] twoway_options, excluding by(). These include options for titling the graph (see [G-3] title_options) and for saving the graph to disk (see [G-3] saving_option).

---

Remarks and examples

Remarks are presented under the following headings:

Using lincom and test
Using rocplot

---

Using lincom and test

intercept, slope, and cut#, shown in example 1 of [R] rocfit, are equation names and not variable names, so they need to be referenced as described in Special syntaxes after multiple-equation estimation of [R] test. For example, instead of typing

```
.test intercept
intercept not found
r(111);
```
you should type

```
.test [intercept]_cons  
( 1) [intercept]_cons = 0  
   chi2( 1) = 28.48 
   Prob > chi2 = 0.0000
```

**Using rocplot**

Example 1

In example 1 of [R] rocfit, we fit a ROC curve by typing `rocfit disease rating`.

In the output table for our model, we are testing whether the variances of the two latent populations are equal by testing that the slope = 1.

We plot the fitted ROC curve.

```
. rocplot, confband
```

![ROC curve with confidence band]

[R] rocfit — Parametric ROC models

[U] 20 Estimation and postestimation commands
Description

The `rocreg` command is used to perform receiver operating characteristic (ROC) analyses with rating and discrete classification data under the presence of covariates.

The two variables `refvar` and `classvar` must be numeric. The reference variable indicates the true state of the observation—such as diseased and nondiseased or normal and abnormal—and must be coded as 0 and 1. The `refvar` coded as 0 can also be called the control population, while the `refvar` coded as 1 comprises the case population. The rating or outcome of the diagnostic test or test modality is recorded in `classvar`, which must be ordinal, with higher values indicating higher risk.

`rocreg` can fit three models: a nonparametric model, a parametric probit model that uses the bootstrap for inference, and a parametric probit model fit using maximum likelihood.

Quick start

Nonparametric estimation with bootstrap resampling

Area under the ROC curve for test classifier `v1` and true state `true` using seed 20547

```
rocreg true v1, bseed(20547)
```

Add `v2` as an additional classifier

```
rocreg true v1 v2, bseed(20547)
```

As above, but estimate ROC value for a false-positive rate of 0.7

```
rocreg true v1 v2, bseed(20547) roc(.7)
```

Covariate stratification of controls by categorical variable `a` using seed 121819

```
rocreg true v1 v2, bseed(121819) ctrlcov(a)
```

Linear control covariate adjustment with binary variable `b` and continuous variable `x`

```
rocreg true v1 v2, bseed(121819) ctrlcov(b x) ctrlmodel(linear)
```

Parametric estimation

Area under the ROC curve for test classifier `v1` and true state `true` by estimating equations using seed 200512

```
rocreg true v1, probit bseed(200512)
```

And save results to `myfile.dta` for use by `rocregplot`

```
rocreg true v1, probit bseed(200512) bsave(myfile)
```
Add v2 as a classifier and x as a control covariate in a linear control covariate-adjustment model
```
rocreg true v1 v2, probit bseed(200512) ctrlcov(x) ctrlmodel(linear)
```
Also treat x as a ROC covariate
```
rocreg true v1 v2, probit bseed(200512) ctrlcov(x) ///
               ctrlmodel(linear) roccov(x)
```
Estimate AUC by maximum likelihood instead of bootstrap resampling
```
rocreg true v1, probit ml
```

| display_options | control column formats, line width, and display of omitted variables |

**Maximization**

| maximize_options | control the maximization process; seldom used |

*probit and ml are required.

fweights, iweights, and pweights are allowed with maximum likelihood estimation; see [U] 11.1.6 weight.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

### Options

Options are presented under the following headings:

- Options for nonparametric ROC estimation, using bootstrap
- Options for parametric ROC estimation, using bootstrap
- Options for parametric ROC estimation, using maximum likelihood

#### Options for nonparametric ROC estimation, using bootstrap

- **auc** estimates the total area under the ROC curve. This is the default summary statistic.
- **roc(numlist)** estimates the ROC corresponding to each of the false-positive rates in numlist. The values of numlist must be in the range (0,1).
- **invroc(numlist)** estimates the false-positive rates corresponding to each of the ROC values in numlist. The values of numlist must be in the range (0,1).
- **pauc(numlist)** estimates the partial area under the ROC curve up to each false-positive rate in numlist. The values of numlist must in the range (0,1).
- **cluster(varname)** specifies the variable identifying resampling clusters.
- **ctrlcov(varlist)** specifies the covariates to be used to adjust the control population.
- **ctrlmodel(strata|linear)** specifies how to model the control population of classifiers on ctrlcov(). When ctrlmodel(linear) is specified, linear regression is used. The default is ctrlmodel(strata); that is, the control population of classifiers is stratified on the control variables.
- **pvc(empirical|normal)** determines how the percentile values of the control population will be calculated. When pvc(normal) is specified, the standard normal cumulative distribution function (CDF) is used for calculation. Specifying pvc(empirical) will use the empirical CDFs of the control population classifiers for calculation. The default is pvc(empirical).
tiecorrected adjusts the percentile values for ties. For each value of the classifier, one half the probability that the classifier equals that value under the control population is added to the percentile value. tiecorrected is not allowed with pvc(normal).

Bootstrap

nobootstrap specifies that bootstrap standard errors not be calculated.
bseed(#) specifies the random-number seed to be used in the bootstrap.
breps(#) sets the number of bootstrap replications. The default is breps(1000).
bootcc performs case–control (stratified on refvar) sampling rather than cohort bootstrap sampling.
nobstrata ignores covariate stratification in bootstrap sampling.
nodots suppresses bootstrap replication dots.

Reporting

level(#); see [R] Estimation options.

Options for parametric ROC estimation, using bootstrap

Model

probit fits the probit model. This option is required and implies parametric estimation.
roccov(varlist) specifies the covariates that will affect the ROC curve.
fprpts(#) sets the number of false-positive rate points to use in modeling the ROC curve. These points form an equispaced grid on (0,1). The default is fprpts(10).
ctrlfprall models the ROC curve at each false-positive rate in the control population.
cluster(varname) specifies the variable identifying resampling clusters.
ctrlcov(varlist) specifies the covariates to be used to adjust the control population.
ctrlmodel(strata|linear) specifies how to model the control population of classifiers on ctrlcov(). When ctrlmodel(linear) is specified, linear regression is used. The default is ctrlmodel(strata); that is, the control population of classifiers is stratified on the control variables.
pvc(empirical|normal) determines how the percentile values of the control population will be calculated. When pvc(normal) is specified, the standard normal CDF is used for calculation. Specifying pvc(empirical) will use the empirical CDFs of the control population classifiers for calculation. The default is pvc(empirical).
tiecorrected adjusts the percentile values for ties. For each value of the classifier, one half the probability that the classifier equals that value under the control population is added to the percentile value. tiecorrected is not allowed with pvc(normal).

Bootstrap

nobootstrap specifies that bootstrap standard errors not be calculated.
bseed(#) specifies the random-number seed to be used in the bootstrap.
breps(#) sets the number of bootstrap replications. The default is breps(1000).
bootcc performs case–control (stratified on refvar) sampling rather than cohort bootstrap sampling.
nobstrata ignores covariate stratification in bootstrap sampling.

nodots suppresses bootstrap replication dots.

bsave(filename, ...) saves bootstrap replicates from parametric estimation in the given filename with specified options (that is, replace). bsave() is only allowed with parametric analysis using bootstrap.

bfile(filename) specifies to use the bootstrap replicates dataset for estimation replay. bfile() is only allowed with parametric analysis using bootstrap.

---

**Options for parametric ROC estimation, using maximum likelihood**

---

Model

probit fits the probit model. This option is required and implies parametric estimation.

ml fits the probit model by maximum likelihood estimation. This option is required and must be specified with probit.

roccov(varlist) specifies the covariates that will affect the ROC curve.

cluster(varname) specifies the variable used for clustering.

ctrlcov(varlist) specifies the covariates to be used to adjust the control population.

---

Reporting

level(#); see [R] Estimation options.

display_options: noomitted, cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch; see [R] Estimation options.

Maximization

maximize_options: difficult, technique(algorithm_spec), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(init_specs); see [R] Maximize. These options are seldom used. The technique(bhhh) option is not allowed.

---

**Remarks and examples**

Remarks are presented under the following headings:

- Introduction
- ROC statistics
- Covariate-adjusted ROC curves
- Parametric ROC curves: Estimating equations
- Parametric ROC curves: Maximum likelihood
Introduction

Receiver operating characteristic (ROC) analysis provides a quantitative measure of the accuracy of diagnostic tests to discriminate between two states or conditions. These conditions may be referred to as normal and abnormal, nondiseased and diseased, or control and case. We will use these terms interchangeably. The discriminatory accuracy of a diagnostic test is measured by its ability to correctly classify known control and case subjects.

The analysis uses the ROC curve, a graph of the sensitivity versus 1 – specificity of the diagnostic test. The sensitivity is the fraction of positive cases that are correctly classified by the diagnostic test, whereas the specificity is the fraction of negative cases that are correctly classified. Thus the sensitivity is the true-positive rate, and the specificity is the true-negative rate. We also call 1 – specificity the false-positive rate.

These rates are functions of the possible outcomes of the diagnostic test. At each outcome, a decision will be made by the user of the diagnostic test to classify the tested subject as either normal or abnormal. The true-positive and false-positive rates measure the probability of correct classification or incorrect classification of the subject as abnormal. Given the classification role of the diagnostic test, we will refer to it as the classifier.

Using this basic definition of the ROC curve, Pepe (2000) and Pepe (2003) describe how ROC analysis can be performed as a two-stage process. In the first stage, the control distribution of the classifier is estimated. The specificity is then determined as the percentiles of the classifier values calculated based on the control population. The false-positive rates are calculated as 1 – specificity. In the second stage, the ROC curve is estimated as the cumulative distribution of the case population’s “false-positive” rates, also known as the survival function under the case population of the previously calculated percentiles. We use the terms ROC value and true-positive value interchangeably.

This formulation of ROC curve analysis provides simple, nonparametric estimates of several ROC curve summary parameters: area under the ROC curve, partial area under the ROC curve, ROC value for a given false-positive rate, and false-positive rate (also known as invROC) for a given ROC value. In the next section, we will show how to use rocreg to compute these estimates with bootstrap inference. There we will also show how rocreg complements the other nonparametric Stata ROC commands roctab and roccomp.

Other factors beyond condition status and the diagnostic test may affect both stages of ROC analysis. For example, a test center may affect the control distribution of the diagnostic test. Disease severity may affect the distribution of the standardized diagnostic test under the case population. Our analysis of the ROC curve in these situations will be more accurate if we take these covariates into account.

In a nonparametric ROC analysis, covariates may only affect the first stage of estimation; that is, they may be used to adjust the control distribution of the classifier. In a parametric ROC analysis, it is assumed that ROC follows a normal distribution, and thus covariates may enter the model at both stages; they may be used to adjust the control distribution and to model ROC as a function of these covariates and the false-positive rate. In parametric models, both sets of covariates need not be distinct but, in fact, they are often the same.

To model covariate effects on the first stage of ROC analysis, Janes and Pepe (2009) propose a covariate-adjusted ROC curve. We will demonstrate the covariate adjustment capabilities of rocreg in Covariate-adjusted ROC curves.

To account for covariate effects at the second stage, we assume a parametric model. Particularly, the ROC curve is a generalized linear model of the covariates. We will thus have a separate ROC curve for each combination of the relevant covariates. In Parametric ROC curves: Estimating equations, we show how to fit the model with estimating equations and bootstrap inference using rocreg.
This method, documented as the “pdf” approach in Alonzo and Pepe (2002), works well with weak assumptions about the control distribution.

Also in Parametric ROC curves: Estimating equations, we show how to fit a constant-only parametric model (involving no covariates) of the ROC curve with weak assumptions about the control distribution. The constant-only model capabilities of rocreg in this context will be compared with those of rocfit. roccomp has the binormal option, which will allow it to compute area under the ROC curve according to a normal ROC curve, equivalent to that obtained by rocfit. We will compare this functionality with that of rocreg.

In Parametric ROC curves: Maximum likelihood, we demonstrate maximum likelihood estimation of the ROC curve model with rocreg. There we assume a normal linear model for the classifier on the covariates and case–control status. This method is documented in Pepe (2003). We will also demonstrate how to use this method with no covariates, and we will compare rocreg under the constant-only model with rocfit and roccomp.

The rocregplot command is used repeatedly in this entry. This command provides graphical output for rocreg and is documented in [R] rocregplot.

ROC statistics

roctab computes the ROC curve by calculating the false-positive rate and true-positive rate empirically at every value of the input classifier. It makes no distributional assumptions about the case or control distributions. We can get identical behavior from rocreg by using the default option settings.

Example 1: Nonparametric ROC, AUC

Hanley and McNeil (1982) presented data from a study in which a reviewer was asked to classify, using a five-point scale, a random sample of 109 tomographic images from patients with neurological problems. The rating scale was as follows: 1 is definitely normal, 2 is probably normal, 3 is questionable, 4 is probably abnormal, and 5 is definitely abnormal. The true disease status was normal for 58 of the patients and abnormal for the remaining 51 patients.
Here we list 9 of the 109 observations:

```
. use https://www.stata-press.com/data/r16/hanley
. list disease rating in 1/9
```

For each observation, `disease` identifies the true disease status of the subject (0 is normal, 1 is abnormal), and `rating` contains the classification value assigned by the reviewer.

We run `roctab` on these data, specifying the `graph` option so that the ROC curve is rendered. We then calculate the false-positive and true-positive rates of the ROC curve by using `rocreg`. We graph the rates with `rocregplot`. Because we focus on `rocreg` output later, for now we use the quietly prefix to omit the output of `rocreg`. Both graphs are combined using `graph combine` (see [G-2] `graph combine`) for comparison. To ease the comparison, we specify the `aspectratio(1)` option in `roctab`; this is the default aspect ratio in `rocregplot`.

```
. roctab disease rating, graph aspectratio(1) name(a) nodraw title("roctab")
. quietly rocreg disease rating
. rocregplot, name(b) nodraw legend(off) title("rocreg")
. graph combine a b
```

Both `roctab` and `rocreg` compute the same false-positive rate and ROC values. The stairstep line connection style of the graph on the right emphasizes the empirical nature of its estimates. The control distribution of the classifier is estimated using the empirical CDF estimate. Similarly, the ROC curve, the distribution of the resulting case observation false-positive rate values, is estimated using the empirical CDF. Note the footnote in the `roctab` plot. By default, `roctab` will estimate the area
under the ROC curve (AUC) using a trapezoidal approximation to the estimated false-positive rate and true-positive rate points.

The AUC can be interpreted as the probability that a randomly selected member of the case population will have a larger classifier value than a randomly selected member of the control population. It can also be viewed as the average ROC value, averaged uniformly over the (0,1) false-positive rate domain (Pepe 2003).

The nonparametric estimator of the AUC (DeLong, DeLong, and Clarke-Pearson 1988; Hanley and Hajian-Tilaki 1997) used by rocreg is equivalent to the sample mean of the percentile values of the case observations. Thus to calculate the nonparametric AUC estimate, we only need to calculate the percentile values of the case observations with respect to the control distribution.

This estimate can differ from the trapezoidal approximation estimate. Under discrete classification data, like we have here, there may be ties between classifier values from case to control. The trapezoidal approximation uses linear interpolation between the classifier values to correct for ties. Correcting the nonparametric estimator involves adding a correction term to each observation’s percentile value, which measures the probability that the classifier is equal to (instead of less than) the observation’s classifier value.

The tie-corrected nonparametric estimate (trapezoidal approximation) is used when we think the true ROC curve is smooth. This means that the classifier we measure is a discretized approximation of a true latent and a continuous classifier.

We now recompute the ROC curve of rating for classifying disease and calculate the AUC. Specifying the tiecorrected option allows tie correction to be used in the rocreg calculation. Under nonparametric estimation, rocreg bootstraps to obtain standard errors and confidence intervals for requested statistics. We use the default 1,000 bootstrap replications to obtain confidence intervals for our parameters. This is a reasonable lower bound to the number of replications (Mooney and Duval 1993) required for estimating percentile confidence intervals. By specifying the summary option in roctab, we will obtain output showing the trapezoidal approximation of the AUC estimate, along with standard error and confidence interval estimates for the trapezoidal approximation suggested by DeLong, DeLong, and Clarke-Pearson (1988).

The estimates of AUC match well. The standard error from roctab is close to the bootstrap standard error calculated by rocreg. The bootstrap standard error generalizes to the more complex models that we consider later, whereas the roctab standard-error calculation does not.

The AUC can be used to compare different classifiers. It is the most popular summary statistic for comparisons (Pepe, Longton, and Janes 2009). roccomp will compute the trapezoidal approximation of the AUC and graph the ROC curves of multiple classifiers. Using the DeLong, DeLong, and Clarke-Pearson (1988) covariance estimates for the AUC estimate, roccomp performs a Wald test of the null hypothesis that all classifier AUC values are equal. rocreg has similar capabilities.

Example 2: Nonparametric ROC, AUC, multiple classifiers

Hanley and McNeil (1983) presented data from an evaluation of two computer algorithms designed to reconstruct CT images from phantoms. We will call these two algorithms modalities 1 and 2. A sample of 112 phantoms was selected; 58 phantoms were considered normal, and the remaining 54 were abnormal. Each of the two modalities was applied to each phantom, and the resulting images were rated by a reviewer using a six-point scale: 1 is definitely normal, 2 is probably normal, 3 is possibly normal, 4 is possibly abnormal, 5 is probably abnormal, and 6 is definitely abnormal. Because each modality was applied to the same sample of phantoms, the two sets of outcomes are correlated.
We list the first seven observations:

```
. use https://www.stata-press.com/data/r16/ct, clear
. list in 1/7, sep(0)
```

<table>
<thead>
<tr>
<th>mod1</th>
<th>mod2</th>
<th>status</th>

<td>1</td>
</tr>
<tr>
<td>2</td>
<td>2</td>
<td>0</td>
</tr>
<tr>
<td>3</td>
<td>2</td>
<td>0</td>
</tr>
</tbody>
</table>

Each observation corresponds to one phantom. The mod1 variable identifies the rating assigned for the first modality, and the mod2 variable identifies the rating assigned for the second modality. The true status of the phantoms is given by status==0 if they are normal and status==1 if they are abnormal. The observations with at least one missing rating were dropped from the analysis.

A fictitious dataset was created from this true dataset, adding a third test modality. We will use roccomp to compute the AUC statistic for each modality in these data and compare the AUC of the three modalities. We obtain the same behavior from rocreg. As before, the tiecorrected option is specified so that the AUC is calculated with the trapezoidal approximation.

Ho: All classifiers have equal AUC values.
Ha: At least one classifier has a different AUC value.
P-value: .0339546 Test based on bootstrap (N) assumptions.

We see that the AUC estimates are equivalent, and the standard errors are quite close as well. The p-value for the tests of equal AUC under rocreg leads to similar inference as the p-value from roccomp. The Wald test performed by rocreg uses the joint bootstrap estimate variance matrix of the three AUC estimators rather than the DeLong, DeLong, and Clarke-Pearson (1988) variance estimate used by roccomp.

roccomp is used here on potentially correlated classifiers that are recorded in wide-format data. It can also be used on long-format data to compare independent classifiers. Further details can be found in [R] roccomp.

Citing the AUC’s lack of clinical relevance, there is argument against using it as a key summary statistic of the ROC curve (Pepe 2003; Cook 2007). Pepe, Longton, and Janes (2009) suggest using the estimate of the ROC curve itself at a particular point, or the estimate of the false-positive rate at a given ROC value, also known as invROC.
Recall from example 1 how nonparametric rocreg graphs look, with the stairstep pattern in the ROC curve. In an ideal world, the graph would be a smooth one-to-one function, and it would be trivial to map a false-positive rate to its corresponding true-positive rate and vice versa.

However, smooth ROC curves can only be obtained by assuming a parametric model that uses linear interpolation between observed false-positive rates and between observed true-positive rates, and rocreg is certainly capable of that; see example 1 of [R] rocregplot. However, under nonparametric estimation, the mapping between false-positive rates and true-positive rates is not one to one, and estimates tend to be less reliable the further you are from an observed data point. This is somewhat mitigated by using tie-corrected rates (the tiecorrected option).

When we examine continuous data, the difference between the tie-corrected estimates and the standard estimates becomes negligible, and the empirical estimate of the ROC curve becomes close to the smooth ROC curve obtained by linear interpolation. So the nonparametric ROC and invROC estimates work well.

Fixing one rate value of interest can be difficult and subjective (Pepe 2003). A compromise measure is the partial area under the ROC curve (pAUC) (McClish 1989; Thompson and Zucchini 1989). This is the integral of the ROC curve from 0 and above to a given false-positive rate (perhaps the largest clinically acceptable value). Like the AUC estimate, the nonparametric estimate of the pAUC can be written as a sample average of the case observation percentiles, but with an adjustment based on the prescribed maximum false-positive rate (Dodd and Pepe 2003). A tie correction may also be applied so that it reflects the trapezoidal approximation.

We cannot compare rocreg with roctab or roccomp on the estimation of pAUC, because pAUC is not computed by the latter two.

Example 3: Nonparametric ROC, other statistics

To see how rocreg estimates ROC, invROC, and pAUC, we will examine a new study. Wieand et al. (1989) examined a pancreatic cancer study with two continuous classifiers, here called y1 (CA 19-9) and y2 (CA 125). This study was also examined in Pepe, Longton, and Janes (2009). The indicator of cancer in a subject is recorded as d. The study was a case–control study, stratifying participants on disease status.

We list the first five observations:

```
. use http://research.fhcrc.org/content/dam/stripe/diagnostic-biomarkers-
    > statistical-center/files/wiedat2b.dta, clear
(S. Wieand - Pancreatic cancer diagnostic marker data)
. list in 1/5
+--------+--------+--------+--------+
| y1     | y2     | d     |
+--------+--------+--------+
| 28     | 13.3   | no    |
| 15.5   | 11.1   | no    |
| 8.2    | 16.7   | no    |
| 3.4    | 12.6   | no    |
| 17.3   | 7.4    | no    |
+--------+--------+--------+
```

We will estimate the ROC curves at a large value (0.7) and a small value (0.2) of the false-positive rate. These values are specified in roc(). The false-positive rate for ROC or sensitivity value of 0.6 will also be estimated by specifying invroc(). Percentile confidence intervals for these parameters are displayed in the graph obtained by rocregplot after rocreg. The pAUC statistic will be calculated for the false-positive rate of 0.5, which is specified as an argument to the pauc() option. Following Pepe, Longton, and Janes (2009), we use a stratified bootstrap, sampling separately from the case
and control populations by specifying the `bootcc` option. This reflects the case–control nature of the study.

All four statistics can be estimated simultaneously by `rocreg`. For clarity, however, we will estimate each statistic with a separate call to `rocreg`. `rocregplot` is used after estimation to graph the ROC and false-positive rate estimates. The display of the individual, observation-specific false-positive rate and ROC values will be omitted in the plot. This is accomplished by specifying `msymbol(i)` in our `plot1opts()` and `plot2opts()` options to `rocregplot`.

  ROC | P-value
  .7  | .5537371
```
In this study, we see that classifier $y_1$ (CA 19-9) is a uniformly better test than is classifier $y_2$ (CA 125) until high levels of false-positive rate and sensitivity or ROC value are reached. At the high level of false-positive rate, 0.7, the ROC value does not significantly differ between the two classifiers. This can be seen in the plot by the overlapping confidence intervals.

We also find significant evidence supporting the hypothesis that the pAUC for \( y_1 \) up to a false-positive rate of 0.5 differs from the area of the same region under the ROC curve of \( y_2 \).

**Covariate-adjusted ROC curves**

When covariates affect the control distribution of the diagnostic test, thresholds for the test being classified as abnormal may be chosen that vary with the covariate values. These conditional thresholds will be more accurate than the marginal thresholds that would normally be used, because they take into account the specific distribution of the diagnostic test under the given covariate values as opposed to the marginal distribution over all covariate values.

By using these covariate-specific thresholds, we are essentially creating new classifiers for each covariate-value combination, and thus we are creating multiple ROC curves. As explained in Pepe (2003), when the case and control distributions of the covariates are the same, the marginal ROC curve will always be bound above by these covariate-specific ROC curves. So using conditional thresholds will never provide a less powerful test diagnostic in this case.
In the marginal ROC curve calculation, the classifiers are standardized to percentiles according to the control distribution, marginalized over the covariates. Thus the ROC curve is the CDF of the standardized case observations. The covariate-adjusted ROC curve is the CDF of one minus the conditional control percentiles for the case observations, and the marginal ROC curve is the CDF of one minus the marginal control percentiles for the case observations (Pepe and Cai 2004). Thus the standardization of classifier to false-positive rate value is conditioned on the specific covariate values under the covariate-adjusted ROC curve.

The covariate-adjusted ROC curve (Janes and Pepe 2009) at a given false-positive rate \( t \) is equivalent to the expected value of the covariate-specific ROC at \( t \) over all covariate combinations. When the covariates in question do not affect the case distribution of the classifier, the covariate-specific ROC will have the same value at each covariate combination. So here the covariate-adjusted ROC is equivalent to the covariate-specific ROC, regardless of covariate values.

When covariates do affect the case distribution of the classifier, users of the diagnostic test would likely want to model the covariate-specific ROC curves separately. Tools to do this can be found in the parametric modeling discussion in the following two sections. Regardless, the covariate-adjusted ROC curve can serve as a meaningful summary of covariate-adjusted accuracy.

Also note that the ROC summary statistics defined in the previous section have covariate-adjusted analogs. These analogs are estimated in a similar manner as under the marginal ROC curve (Janes, Longton, and Pepe 2009). The options for their calculation in \texttt{rocreg} are identical to those given in the previous section. Further details can be found in \textit{Methods and formulas}.

\section*{Example 4: Nonparametric ROC, linear covariate adjustment}

Norton et al. (2000) studied data from a neonatal audiology study on three tests to identify hearing impairment in newborns. These data were also studied in Janes, Longton, and Pepe (2009). Here we list 5 of the 5,058 observations.

The classifiers \(y1\) (DPOAE 65 at 2 kHz), \(y2\) (TEOAE 80 at 2 kHz), and \(y3\) (ABR) and the hearing impairment indicator \(d\) are recorded along with some relevant covariates. The infant’s age is recorded in months as \(currage\), and the infant’s gender is indicated by \(male\). Over 90% of the newborns were tested in each ear (\(ear\)), so we will cluster on infant \(ID\) (\(id\)).

Following the strategy of Janes, Longton, and Pepe (2009), we will first perform ROC analysis for the classifiers while adjusting for the covariate effects of the infant’s gender and age. This is done by specifying these variables in the \texttt{ctrlcov()} option. We adjust using a linear regression rule, by specifying \texttt{ctrlmodel(linear)}. This means that when a user of the diagnostic test chooses a threshold conditional on the age and gender covariates, they assume that the diagnostic test classifier has some linear dependence on age and gender and equal variance as their levels vary. Our cluster adjustment is made by specifying the \texttt{cluster()} option.
We will focus on the first classifier. The percentile, or specificity, values are calculated empirically by default, and thus so are the false-positive rates, \((1 - \text{specificity})\). Also by default, the ROC curve values are empirically defined by the false-positive rates. To draw the ROC curve, we again use \texttt{rocregplot}.

The \texttt{AUC} is calculated by default. For brevity, we specify the \texttt{nobootstrap} option so that bootstrap sampling is not performed. The \texttt{AUC} point estimate will be sufficient for our purposes.

```
. rocreg d y1, ctrlcov(male currage) ctrlmodel(linear) cluster(id) nobootstrap

Our covariate control adjustment model shows that `currage` has a negative effect on `y1` (DPOAE 65 at 2 kHz) under the control population. At the 0.001 significance level, we reject that its contribution to `y1` is zero, and the point estimate has a negative sign. This result does not directly tell us about the effect of `currage` on the ROC curve of `y1` as a classifier of `d`. None of the case observations are used in the linear regression, so information on `currage` for abnormal cases is not used in the model. This result does show us how to calculate false-positive rates for tests that use thresholds conditional on a child’s sex and current age. We will see how `currage` affects the ROC curve when `y1` is used as a classifier and conditional thresholds are used based on `male` and `currage` in the following section, *Parametric ROC curves: Estimating equations*.

#### Technical note

Under this nonparametric estimation, `rocreg` saved the false-positive rate for each observation’s `y1` values in the utility variable `_fpr_y1`. The true-positive rates are stored in the utility variable `_roc_y1`. For other models, say with classifier `yname`, these variables would be named `_fpr_yname` and `_roc_yname`. They will also be overwritten with each call of `rocreg`. The variables `_roc_*` and `_fpr_*` are usually for internal `rocreg` use only and are overwritten with each call of `rocreg`. They are only created for nonparametric models or parametric models that do not involve ROC covariates. In these models, covariates may only affect the first stage of estimation, the control distribution, and not the ROC curve itself. In parametric models that allow ROC covariates, different covariate values would lead to different ROC curves.

To see how the covariate-adjusted ROC curve estimate differs from the standard marginal estimate, we will reestimate the ROC curve for classifier `y1` without covariate adjustment. We rename these variables before the new estimation and then draw an overlaid `twoway line` (see *G-2* `graph twoway line`) plot to compare the two.
Though they are close, particularly in AUC, there are clearly some points of difference between the estimates. So the covariate-adjusted ROC curve may be useful here.

In our examples thus far, we have used the empirical CDF estimator to estimate the control distribution. `rocreg` allows some flexibility here. The `pvc(normal)` option may be specified to calculate the percentile values according to a Gaussian distribution of the control.

Covariate adjustment in `rocreg` may also be performed with stratification instead of linear regression. Under the stratification method, the unique values of the stratified covariates each define separate parameters for the control distribution of the classifier. A user of the diagnostic test chooses a threshold based on the control distribution conditioned on the unique covariate value parameters.

We will demonstrate the use of normal percentile values and covariate stratification in our next example.
Example 5: Nonparametric ROC, covariate stratification

The hearing test study of Stover et al. (1996) examined the effectiveness of negative signal-to-noise ratio, \( nsnr \), as a classifier of hearing loss. The test was administered under nine different settings, corresponding to different frequency, \( xf \), and intensity, \( xl \), combinations. Here we list 10 of the 1,848 observations.

Hearing loss is represented by \( d \). The covariate \( xd \) is a measure of the degree of hearing loss. We will use this covariate in later analysis, because it only affects the case distribution of the classifier. Multiple measurements are taken for each individual, \( id \), so we will cluster by individual.

We evaluate the effectiveness of \( nsnr \) using \( xf \) and \( xl \) as stratification covariates with \texttt{rocreg}; the default method of covariate adjustment.

As mentioned before, the default false-positive rate calculation method in \texttt{rocreg} estimates the conditional control distribution of the classifiers empirically. For comparison, we will also estimate a separate ROC curve using false-positive rates assuming the conditional control distribution is normal. This behavior is requested by specifying the \texttt{pvc(normal)} option. Using the \texttt{rocregplot} option \texttt{name()} to store the ROC plots and using the \texttt{graph combine} command, we are able to compare the Gaussian and empirical ROC curves side by side. As before, for brevity we specify the \texttt{nobootstrap} option to suppress bootstrap sampling.

. graph combine a b, xsize(5)

On cursory visual inspection, we see little difference between the two curves. The AUC values are close as well. So it is sensible to assume that we have Gaussian percentile values for control standardization.

### Parametric ROC curves: Estimating equations

We now assume a parametric model for covariate effects on the second stage of ROC analysis. Particularly, the ROC curve is a probit model of the covariates. We will thus have a separate ROC curve for each combination of the relevant covariates.

Under weak assumptions about the control distribution of the classifier, we can fit this model by using estimating equations as described in Alonzo and Pepe (2002). This method can be also be used without covariate effects in the second stage, assuming a parametric model for the single (constant only) ROC curve. Covariates may still affect the first stage of estimation, so we parametrically model the single covariate-adjusted ROC curve (from the previous section). The marginal ROC curve, involving no covariates in either stage of estimation, can be fit parametrically as well.
In addition to the Alonzo and Pepe (2002) explanation, further details are given in Pepe, Longton, and Janes (2009); Janes, Longton, and Pepe (2009); Pepe (2003); and Janes and Pepe (2009).

The parametric models that we consider assume that the ROC curve is a cumulative distribution function $g$ invoked with input of a linear polynomial in the corresponding quantile function invoked on the false-positive rate $u$. In this context, we assume that $g$ corresponds to a standard normal cumulative distribution function, $\Phi$. So the corresponding quantile function is $\Phi^{-1}$. The constant intercept of the polynomial may depend on covariates, but the slope term $\alpha$ (the quantile coefficient) may not.

$$
\text{ROC}(u) = g\{x'\beta + \alpha g^{-1}(u)\}
$$

The first step of the algorithm involves the choice of false-positive rates to use in the parametric fit. These are typically a set of equispaced points spanning the interval (0,1). Alonzo and Pepe (2002) examined the effect of fitting large and small sets of points, finding that relatively small sets could be used with little loss of efficiency. Alternatively, the set can be formed by using the observed false-positive rates in the data (Pepe 2003). Further details on the algorithm are provided in Methods and formulas.

Under parametric estimation, all the summary measures we defined earlier, except the AUC, are not calculated until postestimation. In models with covariates, each covariate combination would yield a different ROC curve and thus different summary parameters, so no summary parameters are initially estimated. In marginal parametric models (where there are no ROC covariates, but there are potentially control covariates), we will calculate the AUC and leave the other measures for postestimation; see [R] rocreg postestimation. As with the other parameters, we bootstrap for standard errors and inference.

We will now demonstrate how rocreg performs the Alonzo and Pepe (2002) algorithm using the previous section’s examples and others.

Example 6: Parametric ROC, linear covariate adjustment

We return to the neonatal audiology study with gender and age covariates (Norton et al. 2000), which we discussed in example 4. Janes, Longton, and Pepe (2009) suspected the current age of the infant would play a role in the case distribution of the classifier $y_1$ (DPOAE 65 at 2 kHz). They postulated a probit link between the ROC curve and the covariate-adjusted false-positive rates. We follow their investigation and reach similar results.

In example 4, we saw the results of adjusting for the currage and male variables in the control population for classifier $y_1$. Now we see how currage affects the ROC curve when $y_1$ is used with thresholds conditioned on male and currage.

We specify the covariates that should affect the ROC curve in the roccov() option. By default, rocreg will choose 10 equally spaced false-positive rates in the (0,1) interval as fitting points. The fprpts() option allows the user to specify more or fewer points. We specify the bsave() option with the nnhs2y1 dataset so that we can use the bootstrap resamples in postestimation.
. use https://www.stata-press.com/data/r16/nnhs, clear

Note how the number of clusters—here infants—changes from the covariate control adjustment model fit to the ROC model. The control fit is limited to control cases and thus fewer infants. The ROC is fit on all the data, so the variance is adjusted for all clustering on all infants.

With a 0.05 level of statistical significance, we cannot reject the null hypothesis that currage has no effect on the ROC curve at a given false-positive rate. This is because each of our 95% bootstrap confidence intervals contains 0. This corresponds with the finding in Janes, Longton, and Pepe (2009) where the reported 95% intervals each contained 0. We cannot reject that the intercept parameter \( \beta_0 \), reported as _cons in the main table, is 0 at the 0.05 level either. The slope parameter \( \alpha \), reported
as _cons in the probit table, is close to 1 and cannot be rejected as being 1 at the 0.05 level. Under the assumption that the ROC coefficients except $\alpha$ are 0 and that $\alpha = 1$, the ROC curve at false-positive rate $u$ is equal to $u$. In other words, we cannot reject that the false-positive rate is equal to the true-positive rate, and so the test is noninformative. Further investigation of the results requires postestimation; see [R] rocreg postestimation.

The fitting point set can be formed by using the observed false-positive rates (Pepe 2003). Our next example will illustrate this.

Example 7: Parametric ROC, covariate stratification

We return to the hearing test study of Stover et al. (1996), which we discussed in example 5. Pepe (2003) suspected that intensity, $x_d$, would play a role in the case distribution of the negative signal-to-noise ratio ($nsnr$) classifier. A ROC regression was fit with covariate adjustment for $x_f$ and $x_l$ with stratification, and for ROC covariates $x_f$, $x_l$, and $x_d$. There is no prohibition against the same covariate being used in the first and second stages of ROC calculation. The false-positive rate fitting point set was composed of all observed false-positive rates in the control data.

We fit the model with rocreg here. Using observed false-positive rates as the fitting point set can make the dataset very large, so fitting the model is computationally intensive. We demonstrate the fitting algorithm without precise confidence intervals, focusing instead on the coefficient estimates and standard errors. We will thus perform only 50 bootstrap replications, a reasonable number to obtain accurate standard error estimates (Mooney and Duval 1993). The number of replications is specified in the breps() option.

The ROC covariates are specified in roccov(). We specify that all observed false-positive rates in the control observations be used as fitting points with the ctrlfprall option. The nobstrata option specifies that the bootstrap is not stratified. The covariate stratification in the first stage of estimation does not affect the resampling. We will return to this example in postestimation, so we save the bootstrap results in the nsnrf dataset with the bsave() option.
We obtain results similar to those reported in Pepe (2003, 159). We find that the coefficients for $x_l$ and $x_d$ differ from 0 at the 0.05 level of significance. So over certain covariate combinations, we can have a variety of informative tests using $nsnr$ as a classifier.

As mentioned before, when there are no covariates, rocreg can still fit a parametric model for the ROC curve of a classifier by using the Alonzo and Pepe (2002) method. roccomp and rocfit can fit marginal probit models as well. We will compare the behavior of rocreg with that of roccomp and rocfit for probit models without covariates.

When the binormal option is specified, roccomp calculates the AUC for input classifiers according to the maximum likelihood algorithm of rocfit. The rocfit algorithm expects discrete classifiers but can slice continuous classifiers into discrete partitions. Further, the case and control distributions are both assumed normal. Actually, the observed classification values are taken as discrete indicators.
of the latent normally distributed classification values. This method is documented in Dorfman and Alf (1969).

Alonzo and Pepe (2002) compared their estimating equations probability density function method (with empirical estimation of the false-positive rates) to the maximum likelihood approach of Dorfman and Alf (1969) and found that they had similar efficiency and mean squared error. So we should expect rocfit and rocreg to give similar results when fitting a simple probit model.

Example 8: Parametric ROC, marginal model

We return to the Hanley and McNeil (1982) data. We will fit a probit model to the ROC curve, assuming that the rating variable is a discrete indicator of an underlying latent normal random variable in both the case and control populations of disease. We invoke rocfit with the default options. rocreg is invoked with the probit option. The percentile values are calculated empirically. Because there are fewer categories than 10, there will be fewer than 10 false-positive rates that trigger a different true-positive rate value. So for efficiency, we invoke rocreg with the ctrlfprall option.

We see that the intercept and slope parameter estimates are close. The intercept (_cons in the main table) is clearly nonzero. Under rocreg, the slope (_cons in the probit table) and its percentile and bias-corrected confidence intervals are close to those of rocfit. The area under the ROC curve for each of the rocreg and rocfit estimators also matches closely.

Now we will compare the parametric fit of rocreg under the constant probit model with roccomp.

Example 9: Parametric ROC, marginal model, multiple classifiers

We now use the fictitious dataset generated from Hanley and McNeil (1983). To fit a probit model using roccomp, we specify the binormal option. Our specification of rocreg remains the same as before.

rocregplot is used to render the model produced by rocreg. We specify several graph options to both roccomp and rocregplot to ease comparison. When the binormal option is specified along with graph, roccomp will draw the binormal fitted lines in addition to connected line plots of the empirical false-positive and true-positive rates.

In this plot, we overlay scatterplots of the empirical false-positive rates (because percentile value calculation defaulted to pvc(empirical)) and the parametric true-positive rates.

Ho: All classifiers have equal AUC values.
Ha: At least one classifier has a different AUC value.
P-value: .0599896 Test based on bootstrap (N) assumptions.

```
. rocregplot, title(rocreg) nodraw name(b)
> plot1opts(msymbol(o)) plot2opts(msymbol(s)) plot3opts(msymbol(t))
```
We see differing true-positive rate values in the scattered points, which is expected because \texttt{roccomp} gives the empirical estimate and \texttt{rocreg} gives the parametric estimate. However, the estimated curves and areas under the ROC curve look similar. Using the Wald test based on the bootstrap covariance, \texttt{rocreg} rejects the null hypothesis that each test has the same AUC at the 0.1 significance level. \texttt{roccomp} formulates the asymptotic covariance using the \texttt{rocfit} estimates of AUC. Examination of its output leads to rejection of the null hypothesis that the AUCs are equal across each test at the 0.05 significance level.

**Parametric ROC curves: Maximum likelihood**

The Alonzo and Pepe (2002) method of fitting a parametric model to the ROC curve is powerful because it can be generally applied, but that can be a limitation as well. Whenever we invoke the method and want anything other than point estimates of the parameters, we must perform bootstrap resampling.

An alternative is to use maximum likelihood inference to fit the ROC curve. This method can save computational time by avoiding the bootstrap.

\texttt{rocreg} implements maximum likelihood estimation for ROC curve analysis when both the case and control populations are normal. Particularly, the classifier is a normal linear model on certain covariates, and the covariate effect and variance of the classifier may change between the case and control populations. This model is defined in Pepe (2003, 145).

\[ y = z' \beta_0 + D x' \beta_1 + \sigma(D) \epsilon \]

Our error term, $\epsilon$, is a standard normal random variable. The variable $D$ is our true status variable, being 1 for the case population observations and 0 for the control population observations. The variance function $\sigma$ is defined as

\[ \sigma(D) = \sigma_0(D = 0) + \sigma_1(D = 1) \]

This provides two variance parameters in the model and does not depend on covariate values.
Suppose a covariate \( x_i \) is present in \( z \) and \( x \). The coefficient \( \beta_{1i} \) represents the interaction effect of the \( x_i \) and \( D \). It is the extra effect that \( x_i \) has on classifier \( y \) under the case population, \( D = 1 \), beyond the main effect \( \beta_{0i} \). These \( \beta_1 \) coefficients are directly related to the ROC curve of \( y \).

Under this model, the ROC curve is derived to be

\[
\text{ROC}(u) = \Phi \left( \frac{1}{\sigma_1} \{ x' \beta_1 + \sigma_0 \Phi^{-1}(u) \} \right)
\]

For convenience, we reparameterize the model at this point, creating the parameters \( \beta_i = \sigma_1^{-1} \beta_{1i} \) and \( \alpha = \sigma_1^{-1} \sigma_0 \). We refer to \( \beta_0 \) as the constant intercept, \( \text{i\_cons} \). The parameter \( \alpha \) is referred to as the constant slope, \( \text{s\_cons} \).

\[
\text{ROC}(u) = \Phi \{ x' \beta + \alpha \Phi^{-1}(u) \}
\]

We may interpret the final coefficients as the standardized linear effect of the ROC covariate on the classifier under the case population. The marginal effect of the covariate on the classifier in the control population is removed, and it is rescaled by the case population standard deviation of the classifier when all ROC covariate effects are removed. An appreciable effect on the classifier by a ROC covariate in this measure leads to an appreciable effect on the classifier’s ROC curve by the ROC covariate.

The advantage of estimating the control coefficients \( \beta_0 \) is similar to the gains of estimating the covariate control models in the estimating equations ROC method and nonparametric ROC estimation. This model would similarly apply when evaluating a test that is conditioned on control covariates.

Again we note that under parametric estimation, all the summary measures we defined earlier except the AUC are not calculated until postestimation. In models with covariates, each covariate combination would yield a different ROC curve and thus different summary parameters, so no summary parameters are estimated initially. In marginal parametric models, we will calculate the AUC and leave the other measures for postestimation. There is a simple closed-form formula for the AUC under the probit model. Using this formula, the delta method can be invoked for inference on the AUC. Details on AUC estimation for probit marginal models are found in *Methods and formulas*.

We will demonstrate the maximum likelihood method of *rocreg* by revisiting the models of the previous section.

> **Example 10: Maximum likelihood ROC, single classifier**

Returning to the hearing test study of Stover et al. (1996), we use a similar covariate grouping as before. The frequency \( x_f \) and intensity \( x_l \) are control covariates (\( z \)), while all three covariates \( x_f, x_l, \) and hearing loss degree \( x_d \) are case covariates (\( x \)). In example 7, we fit this model using the Alonzo and Pepe (2002) method. Earlier we stratified on the control covariates and estimated the conditioned control distribution of \( \text{nsnr} \) empirically. Now we assume a normal linear model for \( \text{nsnr} \) on \( x_f \) and \( x_l \) under the control population.

We fit the model by specifying the control covariates in the `ctrlcov()` option and the case covariates in the `roccov()` option. The `ml` option tells `rocreg` to perform maximum likelihood estimation.

We find the results are similar to those of example 7. Frequency (xf) and intensity (xl) have a negative effect on the classifier nsnr in the control population.

The negative control effect is mitigated for xf in the case population, but the effect for xl is even more negative there. Hearing loss severity, xd, has a positive effect on nsnr in the case population, and it is undefined in the control population.

The ROC coefficients are shown in the ROC Model table. Each are different from 0 at the 0.05 level. At this level, we also cannot conclude that the variances differ from case to control populations,
because 1 is in the 95% confidence interval for `s_cons`, the ratio of the case to control standard deviation parameters.

Both frequency (xf) and hearing loss severity (xd) make a positive contribution to the ROC curve and thus make the test more powerful. Intensity (xl) has a negative effect on the ROC curve and weakens the test. We previously saw in example 5 that the control distribution appears to be normal, so using maximum likelihood to fit this model is a reasonable approach.

This model was also fit in Pepe (2003, 147). Pepe used separate least-squares estimates for the case and control samples. We obtain similar results for the coefficients, but the maximum likelihood fitting yields slightly different standard deviations by considering both case and control observations concurrently. In addition, a misprint in Pepe (2003, 147) reports a coefficient of $-4.91$ for xl in the case population instead of $-3.19$ as reported by Stata.

Inference on multiple classifiers using the Alonzo and Pepe (2002) estimating equation method is performed by fitting each model separately and bootstrapping to determine the dependence of the estimates. Using the maximum likelihood method, we also fit each model separately. We use `suest` (see [R] `suest`) to estimate the joint variance–covariance of our parameter estimates.

For our models, we can view the score equation for each model as an estimating equation. The estimate that solves the estimating equation (that makes the score 0) is asymptotically normal with a variance matrix that can be estimated using the inverse of the squared scores. By stacking the score equations of the separate models, we can estimate the variance matrix for all the parameter estimates by using this rule. This is an informal explanation; further details can be found in [R] `suest` and in the references Rogers (1993); White (1982 and 1996).

Now we will examine a case with multiple classification variables.

Example 11: Maximum likelihood ROC, multiple classifiers

We return to the neonatal audiology study with gender and age covariates (Norton et al. 2000). In example 6, we fit a model with `male` and `currage` as control covariates, and `currage` as a ROC covariate for the classifier y1 (DPOAE 65 at 2 kHz). We will refit this model, extending it to include the classifier y2 (TEOAE 80 at 2 kHz).
. use https://www.stata-press.com/data/r16/nnhs

| _cons        | 6.986167 | .0705206 | 99.07 | 0.000 | 6.84795 7.124385    |
Both classifiers have similar results. The results for \( y_1 \) show the same direction as the estimating equation results in example 6. However, we can now reject the null hypothesis that the ROC currage coefficient is 0 at the 0.05 level.

In example 6, we could not reject that the slope parameter \( \text{s_cons} \) was 1 and that the constant intercept or ROC coefficient for current age was 0. The resulting ROC curve implied a noninformative test using \( y_1 \) as a classifier. This is not the case with our current results. As \( \text{currage} \) increases, we expect a steeper ROC curve and thus a more powerful test, for both classifiers \( y_1 \) (DPOAE 65 at 2 kHz) and \( y_2 \) (TEOAE 80 at 2 kHz).

In example 10, the clustering of observations within infant \( \text{id} \) was adjusted in the individual fit of \( \text{nsnr} \). In our current example, the adjustment for the clustering of observations within \( \text{id} \) is performed during concurrent estimation, as opposed to during the individual classifier fits (as in example 10). This adjustment, performed by \text{suest}, is still accurate.

Now we will fit constant probit models and compare \text{rocreg} with \text{rocfit} and \text{roccomp} with the \text{binormal} option. Our first applications of \text{rocfit} and \text{roccomp} are taken directly from examples 8 and 9. The Dorfman and Alf (1969) algorithm that \text{rocfit} works with uses discrete classifiers or uses slicing to make a classifier discrete. So we are applying the maximum likelihood method of \text{rocreg} on discrete classification data here, where it expects continuous data. We expect to see some discrepancies, but we do not find great divergence in the estimates. After revisiting examples 8 and 9, we will fit a probit model with a continuous classifier and no covariates using \text{rocreg}, and we will compare the results with those from \text{rocfit}.

\section*{Example 12: Maximum likelihood ROC, marginal model}

Using the Hanley and McNeil (1982) data, discussed in example 1 and in example 8, we fit a constant probit model of the classifier \text{rating} with true status \text{disease}. \text{rocreg} is invoked with the \text{ml} option and compared with \text{rocfit}.

We find that both the intercept and the slope are estimated as higher with the maximum likelihood method under `rocreg` than with `roccfit`. The AUC (ROC area in `roccfit`) is close for both commands. We find that the standard errors of each of these estimates is slightly lower under `rocreg` than `roccfit` as well.

Both `roccfit` and `rocreg` suggest that the slope parameter of the ROC curve (slope in `roccfit` and `s_cons` in `rocreg`) is not significantly different from 1. Thus we cannot reject that the classifier has the same variance in both case and control populations. There is, however, significant evidence that the intercepts (i_cons in `rocreg` and intercept in `roccfit`) differ from 0. Because of the positive direction of the intercept estimates, the ROC curve for rating as a classifier of disease suggests that rating provides an informative test. This is also suggested by the high AUC, which is significantly different from 0.5, that is, a flip of a coin.

> Example 13: Maximum likelihood ROC, marginal model, multiple classifiers

We use the fictitious dataset generated from Hanley and McNeil (1983), which we previously used in example 2 and in example 9. To fit a probit model using `roccomp`, we specify the binormal option. We perform parametric, maximum likelihood ROC analysis using `rocreg`. We use `rocregplot` to plot the ROC curves created by `rocreg`.

<td>0.9580</td>
</tr>
<tr>
<td>mod3</td>
<td>0.9376</td>
<td>0.9453</td>
</tr>
</tbody>
</table>

Each classifier has a higher estimated AUC under `rocreg` than `roccomp`. Each curve appears to be raised and smoothed in the `rocreg` fit as compared with `roccomp`. They are different, but not drastically different. The inference on whether the curve areas are the same is similar to example 9. We reject equality at the 0.10 level under `rocreg` and at the 0.05 level under `roccomp`.

Each intercept is significantly different from 0 at the 0.05 level and is estimated in a positive direction. Though all but classifier `mod2` has 1 in their slope confidence intervals, the high intercepts suggest steep ROC curves and powerful tests.

Also note that the false-positive and true-positive rate points are calculated empirically in the `roccomp` graph and parametrically in `rocreg`. In example 9, the false-positive rates calculated by `rocreg` were calculated empirically, similar to `roccomp`. But in this example, the rates are calculated based on normal percentiles.

Now we will generate an example to compare `rocfit` and `rocreg` under maximum likelihood estimation of a continuous classifier.

**Example 14: Maximum likelihood ROC, graphical comparison with rocfit**

We generate 500 realizations of a population under threat of disease. One quarter of the population has the disease. A classifier $x$ is measured, which has a control distribution of $N(1, 3)$ and a case distribution of $N(1 + 5, 2)$. We will invoke `rocreg` with the `ml` option on this generated data. We specify the `continuous()` option for `rocfit` and invoke it on the data as well. The `continuous()` option tells `rocfit` how many discrete slices to partition the data into before fitting.
For comparison of the two curves, we will use the `rocfit` postestimation command, `rocplot`; see [R] `rocfit postestimation`. This command graphs the empirical false-positive and true-positive rates with an overlaid fit of the binormal curve estimated by `rocfit`. `rocplot` also supports an `addplot()` option. We use the saved variables from `rocreg` in this option to overlay a line plot of the `rocreg` fit.

> norefline addplot(line _roc_x _fpr_x, sort(_fpr_x _roc_x)
> lpattern(solid)) aspectratio(1) legend(off)

We find that the curves are close. As before, the rocfit estimates are lower for the slope and intercept than under rocreg. The AUC estimates are close. Though the slope confidence interval contains 1, a high ROC intercept suggests a steep ROC curve and thus a powerful test.
Nonparametric `rocreg` stores the following in `e()`:

Scalars

- `e(N)` number of observations
- `e(N_strata)` number of covariate strata
- `e(N_clust)` number of clusters
- `e(level)` confidence level for bootstrap CIs
- `e(rank)` rank of `e(V)`

Macros

- `e(cmd)` `rocreg`
- `e(cmdline)` command as typed
- `e(classvars)` classification variable list
- `e(refvar)` status variable, reference variable
- `e(ctrlmodel)` covariate-adjustment specification
- `e(ctrlcov)` covariate-adjustment variables
- `e(pvc)` percentile value calculation method
- `e(title)` title in estimation output
- `e(tiecorrected)` `tiecorrected`, if specified
- `e(nobootstrap)` `nobootstrap`, if specified
- `e(rngstate)` random-number state used in bootstrap, if bootstrap was performed
- `e(breps)` number of bootstrap resamples, if bootstrap performed
- `e(bootcc)` `bootcc`, if specified
- `e(nobstrata)` `nobstrata`, if specified
- `e(clustvar)` name of cluster variable
- `e(exp#)` expression for the #th statistic
- `e(roc)` false-positive rates where ROC was estimated
- `e(invroc)` ROC values where false-positive rates were estimated
- `e(pauc)` false-positive rates where pAUC was estimated
- `e(auc)` indicates that AUC was calculated
- `e(vce)` `bootstrap`
- `e(properties)` `b V` (or `b` if bootstrap not performed)

Matrices

- `e(b)` coefficient vector
- `e(V)` variance–covariance matrix of the estimators
- `e(b_bs)` bootstrap estimates
- `e(reps)` number of nonmissing results
- `e(bias)` estimated biases
- `e(se)` estimated standard errors
- `e(zo)` median biases
- `e(ci_normal)` normal-approximation confidence intervals
- `e(ci_percentile)` percentile confidence intervals
- `e(ci_bc)` bias-corrected confidence intervals

Functions

- `e(sample)` marks estimation sample
Parametric, bootstrap `rocreg` stores the following in `e()`:

Scalars
- `e(N)` number of observations
- `e(N_strata)` number of covariate strata
- `e(N_clust)` number of clusters
- `e(level)` confidence level for bootstrap CIs
- `e(rank)` rank of `e(V)`

Macros
- `e(cmd)` `rocreg`
- `e(cmdline)` command as typed

Methods and formulas

Assume that we applied a diagnostic test to each of \( N_0 \) control and \( N_1 \) case subjects. Further assume that the higher the outcome value of the diagnostic test, the higher the risk of the subject being abnormal. Let \( y_{1i}, i = 1, 2, \ldots, N_1 \), and \( y_{0j}, j = 1, 2, \ldots, N_0 \), be the values of the diagnostic test for the case and control subjects, respectively. The true status variable \( D \) identifies an observation as case \( D = 1 \) or control \( D = 0 \). The CDF of the classifier \( Y \) is \( F \). Conditional on \( D \), we write the CDF as \( F_D \).

Methods and formulas are presented under the following headings:

- **ROC statistics**
- **Covariate-adjusted ROC curves**
- **Parametric ROC curves: Estimating equations**
- **Parametric ROC curves: Maximum likelihood**
ROC statistics

We obtain these definitions and their estimates from Pepe (2003) and Pepe, Longton, and Janes (2009). The false-positive and true-positive rates at cutoff $c$ are defined as

$$FPR(y) = P(Y \geq y | D = 0)$$
$$TPR(y) = P(Y \geq y | D = 1)$$

The true-positive rate, or ROC value at false-positive rate $u$, is given by

$$ROC(u) = P(1 - F_0(Y) \leq u | D = 1)$$

When $Y$ is continuous, the false-positive rate can be written as

$$FPR(y) = 1 - F_0(y)$$

The empirical CDF for the sample $z_1, \ldots, z_n$ is given by

$$\hat{F}(z) = \frac{1}{n} \sum_{i=1}^{n} I(z < z_i)$$

The empirical estimates $\hat{FPR}$ and $\hat{ROC}$ both use this empirical CDF estimator.

The area under the ROC curve is defined as

$$AUC = \int_0^1 ROC(u) du$$

The partial area under the ROC curve for false-positive rate $a$ is defined as

$$pAUC(a) = \int_0^a ROC(u) du$$

The nonparametric estimate for the AUC is given by

$$\hat{AUC} = \sum_{i=1}^{N_1} \frac{1 - \hat{FPR}(y_{1i})}{N_1}$$

The nonparametric estimate of pAUC is given by

$$\hat{pAUC}(a) = \sum_{i=1}^{N_1} \max\{1 - \hat{FPR}(y_{1i}) - (1 - a), 0\} \frac{1}{N_1}$$

For discrete classifiers, a correction term is subtracted from the false-positive rate estimate so that the $\hat{AUC}$ and $\hat{pAUC}$ estimates correspond with a trapezoidal approximation to the area of the ROC curve.

$$FPR_c(y) = 1 - \hat{F}_0(y) - \frac{1}{2} \sum_{j=1}^{N_0} \frac{I(y = y_{0j})}{N_0}$$

In the nonparametric estimation of the ROC curve, all inference is performed using the bootstrap command (see \texttt{R bootstrap}). \texttt{rocreg} also allows users to calculate the ROC curve and related statistics by assuming a normal control distribution. So these formulas are updated by replacing $F_0$ by $\Phi$ (with adjustment of the marginal mean and variance of the control distribution).
Covariate-adjusted ROC curves

Suppose we observe covariate vector $Z$ in addition to the classifier $Y$. Let $Z_{1i}, i = 1, 2, \ldots, N_1$, and $Z_{0j}, j = 1, 2, \ldots, N_0$, be the values of the covariates for the case and control subjects, respectively.

The covariate-adjusted ROC curve is defined by Janes and Pepe (2009) as

$$\text{AROC}(t) = E\{\text{ROC}(t|Z_0)\}$$

It is calculated by replacing the marginal control CDF estimate, $\hat{F}_0$, with the conditional control CDF estimate, $\hat{F}_{0Z}$. If we used a normal control CDF, then we would replace the marginal control mean and variance with the conditional control mean and variance. The formulas of the previous section can be updated for covariate-adjustment by making this substitution of the conditional CDF for the marginal CDF in the false-positive rate calculation.

Because the calculation of the ROC value is now performed based on the conditionally calculated false-positive rate, no further conditioning is made in its calculation under nonparametric estimation.

rocreg supports covariate adjustment with stratification and linear regression. Under stratification, separate parameters are estimated for the control distribution at each level of the covariates. Under linear regression, the classifier is regressed on the covariates over the control distribution, and the resulting coefficients serve as parameters for $\hat{F}_{0Z}$.

Parametric ROC curves: Estimating equations

Under nonparametric estimation of the ROC curve with covariate adjustment, no further conditioning occurs in the ROC curve calculation beyond the use of covariate-adjusted false-positive rates as inputs.

Under parametric estimation of the ROC curve, we can relax this restriction. We model the ROC curve as a cumulative distribution function $g$ (standard normal $\Phi$) invoked with input of a linear polynomial in the corresponding quantile function (here $\Phi^{-1}$) invoked on the false-positive rate $u$. The constant intercept of the polynomial may depend on covariates; the slope term $\alpha$ (quantile coefficient) may not.

$$\text{ROC}(u) = g\{x'\beta + \alpha g^{-1}(u)\}$$

Pepe (2003) notes that having a binormal ROC ($g = \Phi$) is equivalent to specifying that some monotone transformation of the data exists to make the case and control classifiers normally distributed. This specification applies to the marginal case and control.

Under weak assumptions about the control distribution of the classifier, we can fit this model by using estimating equations (Alonzo and Pepe 2002). The method can be used without covariate effects in the second stage, assuming a parametric model for the single ROC curve. Using the Alonzo and Pepe (2002) method, the covariate-adjusted ROC curve may be fit parametrically. The marginal ROC curve, involving no covariates in either stage of estimation, can be fit parametrically as well. In addition to the Alonzo and Pepe (2002) explanation, further details are given in Pepe, Longton, and Janes (2009); Janes, Longton, and Pepe (2009); Pepe (2003); and Janes and Pepe (2009).

The algorithm can be described as follows:

1. Estimate the false-positive rates of the classifier $\text{fpr}$. These may be computed in any fashion outlined so far: covariate-adjusted, empirically, etc.

2. Determine a set of $n_p$ false-positive rates to use as fitting points $f_1, \ldots, f_{n_p}$. These may be an equispaced grid on $(0, 1)$ or the set of observed false-positive rates from part 1.
3. Expand the case observation portion of the data to include a subobservation for each fitting point. So there are now \( N_1(n_p - 1) \) additional observations in the data.

4. Generate a new dummy variable \( u \). For subobservation \( j \), \( u = I(\text{fpr} \leq f_j) \).

5. Generate a new variable \( \text{quant} \) containing the quantiles of the false-positive rate fitting points. For subobservation \( j \), \( \text{quant} = g^{-1}(f_j) \).

6. Perform a binary regression (probit, \( g = \Phi \)) of \( \text{fpr} \) on the covariates \( x \) and quantile variable \( \text{quant} \).

The coefficients of part 6 are the coefficients of the ROC model. The coefficients of the covariates coincide naturally with estimates of \( \beta \), and the \( \alpha \) parameter is estimated by the coefficient on \( \text{quant} \). Because the method is so general and makes few distributional assumptions, bootstrapping must be performed for inference. If multiple classifiers are to be fit, the algorithm is performed separately for each in each bootstrap, and the bootstrap is used to estimate covariances.

We mentioned earlier that in parametric estimation, the AUC was the only summary parameter that could be estimated initially. This is true when we fit the marginal probit model because there are no covariates in part 6 of the algorithm.

To calculate the AUC statistic under a marginal probit model, we use the formula

\[
AUC = \Phi \left( \frac{\beta_0}{\sqrt{1 + \alpha^2}} \right)
\]

Alternatively, the AUC for the probit model can be calculated as \( p\text{AUC}(1) \) in postestimation. Under both models, bootstrapping is performed for inference on the AUC.

**Parametric ROC curves: Maximum likelihood**

`rocreg` supports another form of parametric ROC estimation: maximum likelihood with a normally distributed classifier. This method assumes that the classifier is a normal linear model on certain covariates, and the covariate effect and variance of the classifier may change between the case and control populations. The model is defined in Pepe (2003, 145).

\[
y = z'\beta_0 + Dx'\beta_1 + \sigma(D) \epsilon
\]

Our error term, \( \epsilon \), is a standard normal random variable. The variable \( D \) is our true status variable, being 1 for the case population observations and 0 for the control population observations. The variance function \( \sigma \) is defined as

\[
\sigma(D) = \sigma_0(D = 0) + \sigma_1(D = 1)
\]

This provides two variance parameters in the model and does not depend on covariate values.

Under this model, the ROC curve is easily derived to be

\[
\text{ROC}(u) = \Phi \left[ \frac{1}{\sigma_1} \left\{ x'\beta_1 + \sigma_0 \Phi^{-1}(u) \right\} \right]
\]

We reparameterize the model, creating the parameters \( \beta_i = \sigma_1^{-1}\beta_1i \) and \( \alpha = \sigma_1^{-1}\sigma_0 \). We refer to \( \beta_0 \) as the constant intercept, \texttt{i_cons}. The parameter \( \alpha \) is referred to as the constant slope, \texttt{s_cons}.

\[
\text{ROC}(u) = \Phi \left\{ x'\beta + \alpha \Phi^{-1}(u) \right\}
\]
The original model defining the classifier $y$ leads to the following single observation likelihoods for $D = 0$ and $D = 1$:

$$L(\beta_0, \beta_1, \sigma_1, \sigma_0, \mid D = 0, y, z, x) = \frac{1}{\sqrt{2\pi\sigma_0}} \exp\left(-\frac{(y - z'\beta_0)^2}{2\sigma_0^2}\right)$$

$$L(\beta_0, \beta_1, \sigma_1, \sigma_0, \mid D = 1, y, z, x) = \frac{1}{\sqrt{2\pi\sigma_1}} \exp\left(-\frac{(y - z'\beta_0 - x'\beta_1)^2}{2\sigma_1^2}\right)$$

These can be combined to yield the observation-level log likelihood:

$$\ln L(\beta_0, \beta_1, \sigma_1, \sigma_0, \mid D, y, z, x) = -\frac{\ln 2\pi}{2} - I(D = 0) \left\{ \ln \sigma_0 + \frac{(y - z'\beta_0)^2}{2\sigma_0^2} \right\}$$

$$- I(D = 1) \left\{ \ln \sigma_1 + \frac{(y - z'\beta_0 - x'\beta_1)^2}{2\sigma_1^2} \right\}$$

When there are multiple classifiers, each classifier is fit separately with maximum likelihood. Then the results are combined by stacking the scores and using the sandwich variance estimator. For more information, see \texttt{[R] suest} and the references White (1982); Rogers (1993); and White (1996).

Acknowledgments

We thank Margaret S. Pepe, Holly Janes, and Gary Longton of the Fred Hutchinson Cancer Research Center for providing the inspiration for the \texttt{rocreg} command and for illuminating many useful datasets for its documentation.

predict

Description for predict

Use of `predict` after fitting a parametric model with `rocreg` allows calculation of all the ROC curve summary statistics for covariate-specific ROC curves. The ROC values for given false-positive rates, false-positive rate for given ROC values, area under the ROC curve (AUC), and partial areas under the ROC curve (pAUC) for a given false-positive rate can all be calculated.

* `bfile()` and `btype()` are only allowed with parametric analysis using bootstrap inference.

Options for predict

```
at(varname)
```

`at(varname)` records the variable to be used as input for the above predictions.
auc predicts the total area under the ROC curve defined by the covariate values in the data. This is the default statistic.

roc predicts the ROC values for false-positive rates stored in `varname` specified in `at()`.

invroc predicts the false-positive rates for given ROC values stored in `varname` specified in `at()`.

pauc predicts the partial area under the ROC curve up to each false-positive rate stored in `varname` specified in `at()`.

classvar(`varname`) performs the prediction for the specified classifier.

---

**Options**

- `intpts(#)` specifies that # points be used in the pAUC calculation.
- `se(newvar)` specifies that standard errors be produced and stored in `newvar`.
- `ci(stubname)` requests that confidence intervals be produced and the lower and upper bounds be stored in `stubname_l` and `stubname_u`, respectively.
- `level(#)` specifies the confidence level, as a percentage, for confidence intervals. The default is `level(95)` or as set by `set level`; see [U] 20.8 Specifying the width of confidence intervals.
- `bfile(filename, ...)` uses bootstrap replicates of parameters from rocreg stored in `filename` to estimate standard errors and confidence intervals of predictions.
- `btype(n | p | bc)` specifies whether to produce normal-based (n), percentile (p), or bias-corrected (bc) confidence intervals. The default is `btype(n)`.
estat

Description for estat

estat nproc allows calculation of all the ROC curve summary statistics for covariate-specific ROC curves, as well as for a nonparametric ROC estimation. Under nonparametric estimation, a single ROC curve is estimated by rocreg. Covariates can affect this estimation, but there are no separate covariate-specific ROC curves. Thus the input arguments for estat nproc are taken in the command line rather than from the data as variable values.

Menu for estat

Statistics > Postestimation

Syntax for estat nproc

estat nproc [, estat_nproc_options]

<table>
<thead>
<tr>
<th>estat_nproc_options</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>auc</td>
<td>estimate total area under the ROC curve</td>
</tr>
<tr>
<td>roc(numlist)</td>
<td>estimate ROC values for given false-positive rates</td>
</tr>
<tr>
<td>invroc(numlist)</td>
<td>estimate false-positive rate for given ROC values</td>
</tr>
<tr>
<td>pauc(numlist)</td>
<td>estimate partial area under the ROC curve up to each false-positive rate</td>
</tr>
</tbody>
</table>

At least one option must be specified.

Options for estat nproc

- **auc** estimates the total area under the ROC curve.
- **roc(numlist)** estimates the ROC for each of the false-positive rates in *numlist*. The values in *numlist* must be in the range (0,1).
- **invroc(numlist)** estimates the false-positive rate for each of the ROC values in *numlist*. The values in *numlist* must be in the range (0,1).
- **pauc(numlist)** estimates the partial area under the ROC curve up to each false-positive rate in *numlist*. The values in *numlist* must be in the range (0,1).

Remarks and examples

Remarks are presented under the following headings:

- Using predict after rocreg
- Using estat nproc
Using predict after rocreg

predict, after parametric rocreg, predicts the AUC, the ROC value, the false-positive rate (invROC), or the pAUC value. The default is auc.

We begin by estimating the area under the ROC curve for each of the three age-specific ROC curves in example 1 of [R] rocregplot: 30, 40, and 50 months.

Example 1: Parametric ROC, AUC

In example 6 of [R] rocreg, a probit ROC model was fit to audiology test data from Norton et al. (2000). The estimating equations method of Alonzo and Pepe (2002) was used to fit the model. Gender and age were covariates that affected the control distribution of the classifier y1 (DPOAE 65 at 2 kHz). Age was a ROC covariate for the model, so we fit separate ROC curves at each age.

Following Janes, Longton, and Pepe (2009), we drew the ROC curves for ages 30, 40, and 50 months in example 1 of [R] rocregplot. Now we use predict to estimate the AUC for the ROC curve at each of those ages.

The bootstrap dataset saved by rocreg in example 6 of [R] rocreg, nnhs2y1.dta, is used in the bfile() option.

We will store the AUC prediction in the new variable predAUC. We specify the se() option with the new variable name seAUC to produce an estimate of the prediction’s standard error. By specifying the stubname cin in ci(), we tell predict to create normal-based confidence intervals (the default) as new variables cin_l and cin_u.

```
use https://www.stata-press.com/data/r16/nnhs
(Norton - neonatal audiology data)
. rocreg d y1, probit ctrlcov(currage male) ctrlmodel(linear) roccov(currage)
. cluster(id) bseed(56930) bsave(nnhs2y1)
(output omitted)
. set obs 5061
number of observations (_N) was 5,058, now 5,061
. quietly replace currage = 30 in 5059
. quietly replace currage = 40 in 5060
. quietly replace currage = 50 in 5061
. predict predAUC in 5059/5061, auc se(seAUC) ci(cin) bfile(nnhs2y1)
. list currage predAUC seAUC cin* in 5059/5061
```

<table>
<thead>

</tr>
</tbody>
</table>

As expected, we find the AUC to increase with age.

Essentially, we have a stored bootstrap sample of ROC covariate coefficient estimates in nnhs2y1.dta. We calculate the AUC using each set of coefficient estimates, resulting in a sample of AUC estimates. Then the bootstrap standard error and confidence intervals are calculated based on this AUC sample. Further details of the computation of the standard error and percentile confidence intervals can be found in Methods and formulas and in [R] bootstrap.

We can also produce percentile or bias-corrected confidence intervals by specifying btype(p) or btype(bc), which we now demonstrate.
predict can also estimate the ROC value and the false-positive rate (invROC).

Example 2: Parametric ROC, invROC, and ROC value

In example 7 of [R] rocreg, we fit the ROC curve for status variable hearing loss (d) and classifier negative signal-to-noise ratio nsnr with ROC covariates frequency (xf), intensity (xl), and hearing loss severity (xd). The data were obtained from Stover et al. (1996). The model fit was probit with bootstrap resampling. We saved 50 bootstrap replications in the dataset nsnrf.dta.

The covariate value combinations xf = 10.01, xl = 5.5, and xd = .5, and xf = 10.01, xl = 6.5, and xd = 4 are of interest. In example 3 of [R] rocregplot, we estimated the ROC values for false-positive rates 0.2 and 0.7 and the false-positive rate for a ROC value of 0.5 by using rocregplot. We will use predict to replicate the estimation.

We begin by appending observations with our desired covariate combinations to the data. We also create two new variables: rocinp, which contains the ROC values for which we wish to predict the corresponding invROC values, and invrocinp, which contains the invROC values corresponding to the ROC values we wish to predict.
. clear
. input xf xl xd rocinp invrocinp
   xf     xl     xd     rocinp     invrocinp

<td>10.01</td>
<td>5.5</td>
<td>.5</td>
<td>.7</td>
</tr>
<tr>
<td>1852.</td>
<td>10.01</td>
<td>6.5</td>
<td>4</td>
<td>.7</td>
</tr>
</tbody>
</table>

Now we will use predict to estimate the ROC value for the false-positive rates stored in rocinp. We specify the roc option, and we specify rocinp in the at() option. The other options, se() and ci(), are used to obtain standard errors and confidence intervals, respectively. The dataset of bootstrap samples, nsnrf.dta, is specified in bfile(). After prediction, we list the point estimates and standard errors.

. predict rocit in 1849/1852, roc at(rocinp) se(seroc) ci(cin) bfile(nsnrf)
. list xf xl xd rocinp rocit seroc if !missing(rocit)

<table>
<thead>
<tr>
<th>xf</th>
<th>xl</th>
<th>xd</th>
<th>rocinp</th>
<th>rocit</th>
<th>seroc</th>
</tr>
</thead>
<tbody>
<tr>
<td>1849.</td>
<td>10.01</td>
<td>5.5</td>

<td>.7652956</td>
<td>.0624187</td>
</tr>
<tr>
<td>1850.</td>
<td>10.01</td>
<td>6.5</td>
<td>4</td>
<td>.9672505</td>
<td>.0162785</td>
</tr>
<tr>
<td>1851.</td>
<td>10.01</td>
<td>5.5</td>
<td>.5</td>
<td>.9835816</td>
<td>.0133583</td>
</tr>
<tr>
<td>1852.</td>
<td>10.01</td>
<td>6.5</td>
<td>4</td>
<td>.999428</td>
<td>.0007784</td>
</tr>
</tbody>
</table>

These results match example 3 of [R] rocregplot. We list the confidence intervals next. These also conform to the rocregplot results from example 3 in [R] rocregplot. We begin with the confidence intervals for ROC under the covariate values xf=10.01, xl=5.5, and xd=.5.
Now we list the ROC confidence intervals under the covariate values \(xf=10.01\), \(xl=6.5\), and \(xd=4\).

\[
\begin{array}{cccccccc}
1849. & & & & & & & \\
10.01 & 6.5 & 4 & .2 & .9672505 & .9353452 & .9991558 \\
1852. & & & & & & & \\
10.01 & 6.5 & 4 & .5 & .0043298 & .003835 \\
\end{array}
\]

Now we will predict the false-positive rate for a ROC value by specifying the \texttt{invroc} option. We pass the \texttt{invrocinp} variable as an argument to the \texttt{at()} option. Again we list the point estimates and standard errors first.

\[
\begin{array}{cccccccc}
1851. & & & & & & & \\
10.01 & 5.5 & .5 & .5 & .0615144 & .0209516 & & \\
1852. & & & & & & & \\
10.01 & 6.5 & 4 & .5 & .0043298 & .003835 & & \\
\end{array}
\]

These also match those of example 3 of \cite{R} \texttt{rocregplot}. Listing the confidence intervals shows identical results as well. First we list the confidence intervals under the covariate values \(xf=10.01\), \(xl=5.5\), and \(xd=.5\).

\[
\begin{array}{cccccccc}
1851. & & & & & & & \\
10.01 & 5.5 & .5 & .5 & .0615144 & .0209516 & & \\
1852. & & & & & & & \\
10.01 & 6.5 & 4 & .5 & .0043298 & .003835 & & \\
\end{array}
\]

Now we list the confidence intervals for false-positive rate under the covariate values \(xf=10.01\), \(xl=6.5\), and \(xd=4\).

\[
\begin{array}{cccccccc}

\]

The \texttt{predict} command can also be used after a maximum-likelihood ROC model is fit.
Example 3: Maximum likelihood ROC, invROC, and ROC value

In the previous example, we revisited the estimating equations fit of a probit model with ROC covariates frequency (xf), intensity (xl), and hearing loss severity (xd) to the Stover et al. (1996) audiology study data. A maximum likelihood fit of the same model was performed in example 10 of [R] rocreg. In example 2 of [R] rocregplot, we used rocregplot to estimate ROC values and false-positive rates for this model under two covariate configurations. We will use predict to obtain the same estimates. We will also estimate the partial area under the ROC curve.

We append the data as in the previous example. This leads to the following four final observations in the data.

```
use https://www.stata-press.com/data/r16/dp, clear
(Stover - DPOAE test data)
rocreg d nsnr, probit ctrlcov(xf xl) roccov(xf xl xd) ml cluster(id)
(output omitted)
append using newdata
list xf xl xd invrocinv rocinp in 1849/1852
```

<table>
<thead>
<tr>

</table>

Now we predict the ROC value for false-positive rates of 0.2 and 0.7. Under maximum likelihood prediction, only Wald-type confidence intervals are produced. We specify a new variable name for the standard error in the se() option and a stubname for the confidence interval variables in the ci() option.

```
predict rocit in 1849/1852, roc at(rocinp) se(seroc) ci(ci)

</tbody>
</table>
Example 4: Maximum likelihood ROC, pAUC, and ROC value

In example 13 of [R] rocreg, we fit a maximum-likelihood marginal probit model to each classifier of the fictitious dataset generated from Hanley and McNeil (1983). In example 5 of [R] rocregplot, rocregplot was used to draw the ROC for the mod1 and mod3 classifiers. Estimates of the ROC value and false-positive rate were also obtained with Wald-type confidence intervals.

We return to this example, this time using predict to estimate the ROC value and false-positive rate. We will also estimate the pAUC for the false-positive rates of 0.3 and 0.8.

First, we add the input variables to the data. The variable paucinp will hold the 0.3 and 0.8 false-positive rates that we will input to pAUC. The variable invrocinp holds the ROC value of 0.8 for which we will estimate the false-positive rate. Finally, the variable rocinp holds the false-positive rates of 0.15 and 0.75 for which we will estimate the ROC value.

```
use https://www.stata-press.com/data/r16/ct2, clear
rocreg status mod1 mod2 mod3, probit ml
(predict output omitted)
quietly generate paucinp = .3 in 111
quietly replace paucinp = .8 in 112
quietly generate invrocinp = .8 in 112
quietly generate rocinp = .15 in 111
quietly replace rocinp = .75 in 112
```

Then, we estimate the ROC value for false-positive rates 0.15 and 0.75 under classifier mod1. The point estimate is stored in roc1. Wald confidence intervals and standard errors are also estimated. We find that these results match those of example 5 of [R] rocregplot.

```
predict roc1 in 111/112, classvar(mod1) roc at(rocinp) se(sr1) ci(cir1)
list rocinp roc1 sr1 cir1* in 111/112
```

<table>
<thead>
<tr>
<th>rocinp</th>
<th>roc1</th>
<th>sr1</th>
<th>cir1_l</th>
<th>cir1_u</th>
</tr>
</thead>
<tbody>
<tr>
<td>0.15</td>
<td>0.7934935</td>
<td>0.0801363</td>
<td>0.6364293</td>
<td>0.9505678</td>
</tr>
<tr>
<td>0.75</td>
<td>0.9931655</td>
<td>0.0069689</td>
<td>0.9795067</td>
<td>1.006824</td>
</tr>
</tbody>
</table>

Next we perform the same estimation under the classifier mod3.

```
predict roc3 in 111/112, classvar(mod3) roc at(rocinp) se(sr3) ci(cir3)
list rocinp roc3 sr3 cir3* in 111/112
```

<table>
<thead>
<tr>
<th>rocinp</th>
<th>roc3</th>
<th>sr3</th>

<td>0.75</td>
<td>0.9953942</td>
<td>0.0043435</td>
<td>0.9868811</td>
<td>1.003907</td>
</tr>
</tbody>
</table>

Now we estimate the false-positive rate for the ROC value of 0.8. These results also match example 5 of [R] rocregplot.

```
predict invroc1 in 112, classvar(mod1) invroc at(invrocinp) se(sir1) ci(cir1)
list invrocinp invroc1 sir1 cir1* in 112
```

<table>
<thead>

Using `estat nproc`

When you initially use `rocreg` to fit a nonparametric ROC curve, you can obtain bootstrap estimates of a ROC value, false-positive rate, area under the ROC curve, and partial area under the ROC curve. The `estat nproc` command allows the user to estimate these parameters after `rocreg` has originally been used.

The seed and resampling settings used by `rocreg` are used by `estat nproc`. So the results for these new statistics are identical to what they would be if they had been initially estimated in the `rocreg` command. These new statistics, together with those previously estimated in `rocreg`, are returned in `r()`.

We demonstrate with an example.

Example 5: Nonparametric ROC, invROC, and pAUC

In example 3 of [R] `rocreg`, we examined data from a pancreatic cancer study (Wieand et al. 1989). Two continuous classifiers, \(y_1\) (CA 19-9) and \(y_2\) (CA 125), were used for the true status variable \(d\). In that example, we estimated various quantities including the false-positive rate for a ROC value of 0.6 and the pAUC for a false-positive rate of 0.5. Here we replicate that estimation with a call to `rocreg` to estimate the former and follow that with a call to `estat nproc` to estimate the latter. For simplicity, we restrict estimation to classifier \(y_1\) (CA 19-9).

We start by executing `rocreg`, estimating the false-positive rate for a ROC value of 0.6. This value is specified in `invroc()`. Case–control resampling is used by specifying the `bootcc` option.

</tbody>
</table>
The advantages of using estat nproc are twofold. First, you can estimate additional parameters of interest without having to respecify the bootstrap settings you did with rocreg; instead estat nproc uses the bootstrap settings that were stored by rocreg. Second, parameters estimated with estat nproc are added to those parameters estimated by rocreg and returned in the matrices \( r(b) \) (parameter estimates) and \( r(V) \) (variance–covariance matrix). Thus you can also obtain correlations between any quantities you wish to estimate.

### Stored results

estat nproc stores the following in \( r() \):

- **Matrices**
  - \( r(b) \): coefficient vector
  - \( r(V) \): variance–covariance matrix of the estimators
  - \( r(ci\text{\_normal}) \): normal-approximation confidence intervals
  - \( r(ci\text{\_percentile}) \): percentile confidence intervals
  - \( r(ci\text{\_bc}) \): bias-corrected confidence intervals

### Methods and formulas

Details on computation of the nonparametric ROC curve and the estimation of the parametric ROC curve model coefficients can be found in [R] rocreg. Here we describe how to estimate the ROC curve summary statistics for a parametric model. The cumulative distribution function, \( g \), can be the standard normal cumulative distribution function, \( \Phi \).

Methods and formulas are presented under the following headings:

- **Parametric model: Summary parameter definition**
- **Maximum likelihood estimation**
- **Estimating equations estimation**
Parametric model: Summary parameter definition

Conditioning on covariates \( x \), we have the following ROC curve model:

\[
\text{ROC} (u) = g \{ x'\beta + \alpha g^{-1} (u) \}
\]

\( x \) can be constant, and \( \beta = \beta_0 \), the constant intercept.

We can solve this equation to obtain the false-positive rate value \( u \) for a ROC value of \( r \):

\[
u = g \left[ \{ g^{-1} (r) - x'\beta \} \alpha^{-1} \right] \]

The partial area under the ROC curve for the false-positive rate \( u \) is defined by

\[
pAUC (u) = \int_o^u g \{ x'\beta + \alpha g^{-1} (t) \} dt \]

The area under the ROC curve is defined by

\[
\text{AUC} = \int_o^1 g \{ x'\beta + \alpha g^{-1} (t) \} dt \]

When \( g \) is the standard normal cumulative distribution function \( \Phi \), we can express the AUC as

\[
\text{AUC} = \Phi \left( \frac{x'\beta}{\sqrt{1+\alpha^2}} \right) \]

Maximum likelihood estimation

We allow maximum likelihood estimation under probit parametric models, so \( g = \Phi \). The ROC value, false-positive rate, and AUC parameters all have closed-form expressions in terms of the covariate values \( x \), coefficient vector \( \beta \), and slope parameter \( \alpha \). So to estimate these three types of summary parameters, we use the delta method (Oehlert 1992; Phillips and Park 1988). Particularly, we use the \texttt{nlcom} command (see \texttt{R nlcom}) to implement the delta method.

To estimate the partial area under the ROC curve for false-positive rate \( u \), we use numeric integration. A trapezoidal approximation is used in calculating the integrals. A numeric integral of the \text{ROC}(t) function conditioned on the covariate values \( x \), coefficient vector estimate \( \hat{\beta} \), and slope parameter estimate \( \hat{\alpha} \) is computed over the range \( t = [0, u] \). This gives us the point estimate of \( p\text{AUC}(u) \).

To calculate the standard error and confidence intervals for the point estimate of \( p\text{AUC}(u) \), we again use the delta method. Details on the delta method algorithm can be found in \textit{Methods and formulas} of \texttt{R nlcom} and the earlier mentioned references.

Under maximum likelihood estimation, the coefficient estimates \( \hat{\beta} \) and slope estimate \( \hat{\alpha} \) are asymptotically normal with variance matrix \( V \). For convenience, we rename the parameter vector \([\beta', \alpha]\) to the \( k \)-parameter vector \( \theta = [\theta_1, \ldots, \theta_k] \). We will also explicitly refer to the conditioning of the ROC curve by \( \theta \) in its mention as \( \text{ROC}(t, \theta) \).

Under the delta method, the continuous scalar function of the estimate \( \hat{\theta} \), \( f(\hat{\theta}) \) has asymptotic mean \( f(\theta) \) and asymptotic covariance

\[
\text{Var} \left\{ f(\hat{\theta}) \right\} = \mathbf{f}V\mathbf{f}'
\]
where \( f \) is the \( 1 \times k \) matrix of derivatives for which

\[
f_{1j} = \frac{\partial f(\theta)}{\partial \theta_j} \quad j = 1, \ldots, k
\]

The asymptotic covariance of \( f(\hat{\theta}) \) is estimated and then used in conjunction with \( f(\hat{\theta}) \) for further inference, including Wald confidence intervals, standard errors, and hypothesis testing.

In the case of \( \text{pAUC}(u) \) estimation, our \( f(\hat{\theta}) \) is the aforementioned numeric integral of the ROC curve. It estimates \( f(\theta) \), the true integral of the ROC curve on the \([0, u]\) range. The \( V \) variance matrix is estimated using the likelihood information that \text{rocreg} calculated, and the estimation is performed by \text{rocreg} itself.

The partial derivatives of \( f(\theta) \) can be determined by using Leibniz’s rule (Weisstein 2011):

\[
f_{1j} = \frac{\partial}{\partial \theta_j} \int_0^u \text{ROC}(t, \theta)dt = \int_0^u \frac{\partial}{\partial \theta_j} \text{ROC}(t, \theta)dt \quad j = 1, \ldots, k
\]

When \( \theta_j \) corresponds with the slope parameter \( \alpha \), we obtain the following partial derivative:

\[
\frac{\partial}{\partial \alpha} \text{pAUC}(u) = \int_0^u \phi\{x'\beta + \alpha \Phi^{-1}(t)\} \Phi^{-1}(t) dt
\]

The partial derivative of \( f(\theta) \) [\( \text{pAUC}(u) \)] for \( \beta_0 \) is the following:

\[
\frac{\partial}{\partial \beta_0} \text{pAUC}(u) = \int_0^u \phi\{x'\beta + \alpha \Phi^{-1}(t)\} dt
\]

For a nonintercept coefficient, we obtain the following:

\[
\frac{\partial}{\partial \beta_i} \text{pAUC}(u) = \int_0^u x_i \phi\{x'\beta + \alpha \Phi^{-1}(t)\} dt
\]

We can estimate each of these integrals by numeric integration, plugging in the estimates \( \hat{\beta} \) and \( \hat{\alpha} \) for the parameters. This, together with the previously calculated estimate \( \hat{V} \), provides an estimate of the asymptotic covariance of \( f(\hat{\theta}) = \text{pAUC}(u) \), which allows us to perform further statistical inference on \( \text{pAUC}(u) \).

**Estimating equations estimation**

When we fit a model using the Alonzo and Pepe (2002) estimating equations method, we use the bootstrap to perform inference on the ROC curve summary parameters. Each bootstrap sample provides a sample of the coefficient estimates \( \hat{\beta} \) and the slope estimates \( \hat{\alpha} \). Using the formulas in **Parametric model: Summary parameter definition** under *Methods and formulas*, we can obtain an estimate of the ROC, false-positive rate, or AUC for each resample. Using numeric integration (with the trapezoidal approximation), we can also estimate the \( \text{pAUC} \) of the resample.
By making these calculations, we obtain a bootstrap sample of our summary parameter estimate. We then obtain bootstrap standard errors, normal approximation confidence intervals, percentile confidence intervals, and bias-corrected confidence intervals using this bootstrap sample. Further details can be found in [R] bootstrap.

[U] 20 Estimation and postestimation commands
**rocregplot — Plot marginal and covariate-specific ROC curves after rocreg**

### Description

Under parametric estimation, rocregplot plots the fitted ROC curves for specified covariate values and classifiers. If rocreg, probit or rocreg, probit ml were previously used, the false-positive rates (for specified ROC values) and ROC values (for specified false-positive rates) for each curve may also be plotted, along with confidence intervals.

Under nonparametric estimation, rocregplot will plot the fitted ROC curves using the _fpr_* and _roc_* variables produced by rocreg. Point estimates and confidence intervals for false-positive rates and ROC values that were computed in rocreg may be plotted as well.

### Quick start

**Plot ROC curve after any rocreg command**

```
rocregplot
```

Name graph mygraph and save as myfile.gph

```
rocregplot, name(mygraph) saving(myfile)
```

**Plot ROC curve only for v2 after fitting a model with v1 and v2**

```
rocregplot, classvars(v2)
```

Add bias-corrected CI for the ROC value at a false-positive rate of 0.7 from estimation with bootstrap resampling that specified roc(.7)

```
rocregplot, btype(bc)
```

**Plots following parametric estimation only**

Plot curve evaluated at $x = 30$ and $x = 50$

```
rocregplot, at1(x=30) at2(x=50)
```

After bootstrap resampling with resampled observations saved in myfile.dta

```
rocregplot, at1(x=30) at2(x=50) bfile(myfile)
```

And draw CI for ROC values at false-positive rates 0.1, 0.2, and 0.3

```
rocregplot, at1(x=30) at2(x=50) roc(.1 .2 .3) bfile(myfile)
```

Bootstrap
† bfile(filename) | load dataset containing bootstrap replicates from rocreg
btype(n|p|bc) | plot normal-based (n), percentile (p), or bias-corrected (bc) confidence intervals; default is btype(n)
† bfile() is only allowed with parametric analysis using bootstrap inference; in which case this option is required with roc() or invroc().
probit_options
Main
at(varname=# ... | requests that the covariates specified by varname be set to #. By default, rocregplot evaluates the function by setting each covariate to its mean value. This option causes the ROC curve to be evaluated at the value of the covariates listed in at() and at the mean of all unlisted covariates.

at1(varname=# ...), at2(varname=# ...), ..., at10(varname=# ...) | specify that ROC curves (up to 10) be plotted on the same graph. at1(), at2(), ..., at10() work like the at() option. They request that the function be evaluated at the values of the covariates specified and at the mean of all unlisted covariates. at1() specifies the values of the covariates for the first curve, at2() specifies the values of the covariates for the second curve, and so on.
roc(numlist) | specifies that estimated ROC values for given false-positive rates be graphed.
invroc(numlist) | specifies that estimated false-positive rates for given ROC values be graphed.
level(#) | specifies the confidence level, as a percentage, for confidence intervals. The default is level(95) or as set by set level; see [U] 20.8 Specifying the width of confidence intervals.
level() may be specified with either roc() or invroc().
Curve
line#opts(cline_options) | affects the rendition of ROC curve #. See [G-3] cline_options.
### common_options

**Main**

- `classvars(varlist)` restricts plotting ROC curves to specified classification variables.
- `norefline` suppresses plotting the reference line.

**Scatter**

- `plot#opts(scatter_options)` affects the rendition of classifier #’s false-positive rate and ROC scatter points. This option applies only to non-ROC covariate estimation graphing. See [G-2] `graph twoway scatter`.

**Reference line**

- `rlopts(cline_options)` affects the rendition of the reference line. See [G-3] `cline_options`.

**Y axis, X axis, Titles, Legend, Overall**

- `twoway_options` are any of the options documented in [G-3] `twoway_options`, excluding `by()`. These include options for titling the graph (see [G-3] `title_options`) and options for saving the graph to disk (see [G-3] `saving_option`).

### boot_options

**Bootstrap**

- `bfile(filename)` uses bootstrap replicates of parameters from `rocreg` stored in `filename` to estimate standard errors and confidence intervals of predictions. `bfile()` must be specified with either `roc()` or `invroc()` if parametric estimation with bootstrapping was used.
- `btype(n|p|bc)` indicates the desired type of confidence interval rendering. `n` draws normal-based, `p` draws percentile, and `bc` draws bias-corrected confidence intervals for specified false-positive rates and ROC values in `roc()` and `invroc()`. The default is `btype(n)`.

### Remarks and examples

Remarks are presented under the following headings:

- *Plotting covariate-specific ROC curves*
- *Plotting marginal ROC curves*

### Plotting covariate-specific ROC curves

The `rocregplot` command is also demonstrated in [R] `rocreg`. We will further demonstrate its use with several examples. Particularly, we will show how `rocregplot` can draw the ROC curves of covariate models that have been fit using `rocreg`. 
Example 1: Parametric ROC

In example 6 of [R] `rocreg`, we fit a probit ROC model to audiology test data from Norton et al. (2000). The estimating equation method of Alonzo and Pepe (2002) was used to fit the model. Gender and age were covariates that affected the control distribution of the classifier $y_1$ (DPOAE 65 at 2 kHz). Age was a ROC covariate for the model, so we fit separate ROC curves at each age.

Following Janes, Longton, and Pepe (2009), we draw the ROC curves for ages 30, 40, and 50 months. The `at1()`, `at2()`, and `at3()` options are used to specify the age covariates.

```
. use https://www.stata-press.com/data/r16/nnhs
    (Norton - neonatal audiology data)
. rocreg d y1, probit ctrlcov(currage male) ctrlmodel(linear) roccov(currage)
    > cluster(id) bseed(56930) bsave(nnhs2y1, replace)
    (output omitted)
. rocregplot, at1(currage=30) at2(currage=40) at3(currage=50)
```

Here we use the default entries of the legend, which indicate the “at #” within the specified `at*` options and the classifier to which the curve corresponds. ROC curve one corresponds with `currage=30`, two with `currage=40`, and three with `currage=50`. The positive effect of age on the ROC curve is evident. At an age of 30 months (`currage=30`), the ROC curve of $y_1$ (DPOAE 65 at 2 kHz) is nearly equivalent to that of a noninformative test that gives equal probability to hearing loss. At age 50 months (`currage=50`), corresponding to some of the oldest children in the study, the ROC curve shows that test $y_1$ (DPOAE 65 at 2 kHz) is considerably more powerful than the noninformative test.

You may create your own legend by specifying the `legend()` option. The default legend is designed for the possibility of multiple covariates. Here we could change the legend entries to `currage` values and gain some extra clarity. However, this may not be feasible when there are many covariates present.

We can also use `rocregplot` after maximum likelihood estimation.
Example 2: Maximum likelihood ROC

We return to the audiology study with frequency ($xf$), intensity ($xl$), and hearing loss severity ($xd$) covariates from Stover et al. (1996) that we examined in example 10 of [R] rocreg. Negative signal-to-noise ratio is again used as a classifier. Using maximum likelihood, we fit a probit model to these data with the indicated ROC covariates.

After fitting the model, we wish to compare the ROC curves of two covariate combinations. The first has an intensity value of 5.5 (the lowest intensity, corresponding to 55 decibels) and a frequency of 10.01 (the lowest frequency, corresponding to 1001 hertz). We give the first combination a hearing loss severity value of 0.5 (the lowest). The second covariate combination has the same frequency, but the highest intensity value of 6.5 (65 decibels). We give this second covariate set a higher severity value of 4. We will visually compare the two ROC curves resulting from these two covariate value combinations.

We specify false-positive rates of 0.7 first followed by 0.2 in the `roc()` option to visually compare the size of the ROC curve at large and small false-positive rates. Because maximum likelihood estimation was used to fit the model, a Wald confidence interval is produced for the estimated ROC value and false-positive rate parameters. Further details are found in Methods and formulas.

```
  . use https://www.stata-press.com/data/r16/dp
  (Stover - DPOAE test data)
  . rocreg d nsnr, probit ctrlcov(xf xl) roccov(xf xl xd) ml cluster(id)
  (output omitted)
```
At the higher false-positive rate value of 0.7, we see little difference in the ROC values and note that the confidence intervals nearly overlap. Now we view the same curves with the lower false-positive rate compared.
The lower false-positive rate of 0.2 shows clearly distinguishable ROC values. Now we specify option `invroc(.5)` to view how the false-positive rates vary at a ROC value of 0.5.
. rocregplot, at1(xf=10.01, xl=5.5, xd=.5) at2(xf=10.01, xl=6.5, xd=4) invroc(.5)

invROC Coef. Std. Err. [95% Conf. Interval]
.5  .0055624 .0032645 -.0008359 .0119607

At a ROC value of 0.5, the false-positive rates for both curves are small and close to one another.

Technical note
We can use the `testnl` command to support our visual observations with statistical inference. We use it to perform a Wald test of the null hypothesis that the two ROC curves just rendered are equal at a false-positive rate of 0.7.
The test is significant at the 0.05 level, and thus we find that the two curves are significantly different. Now we will use `testnl` again to test equality of the false-positive rates for each curve with a ROC value of 0.5. The inverse ROC formula used is derived in Methods and formulas.

```plaintext
. testnl normal((invnormal(.5)-(_b[i_cons]+10.01*_b[xf]+5.5*_b[xl]+.5*_b[xd])) /_b[s_cons]) = normal((invnormal(.5)-(_b[i_cons]+10.01*_b[xf]+6.5*_b[xl]+4*_b[xd])) /_b[s_cons])

(1) normal((invnormal(.5)-(_b[i_cons]+10.01*_b[xf]+5.5*_b[xl]+.5*_b[xd])) /_b[s_cons]) = normal((invnormal(.5)-(_b[i_cons]+10.01*_b[xf]+6.5*_b[xl]+4*_b[xd])) /_b[s_cons])

chi2(1) = 8.01
Prob > chi2 = 0.0046
```

We again reject the null hypothesis that the two curves are equal at the 0.05 level.

The model of our last example was also fit using the estimating equations method in example 7 of [R] rocreg. We will demonstrate rocregplot after that model fit as well.

Example 3: Parametric ROC, invROC, and ROC value

In example 2, we used rocregplot after a maximum likelihood model fit of the ROC curve for classifier nsnr and covariates frequency (xf), intensity (xl), and hearing loss severity (xd). The data were obtained from the audiology study described in Stover et al. (1996). In example 7 of [R] rocreg, we fit the model using the estimating equations method of Alonzo and Pepe (2002). Under this method, bootstrap resampling is used to make inferences. We saved 50 bootstrap replications in nsnrf.dta, which we re-create below.

We use rocregplot to draw the ROC curves for nsnr under the covariate values xf = 10.01, xl = 5.5, and xd = .5, and xf = 10.01, xl = 6.5, and xd = 4. The at#() options are used to specify the covariate values. The previous bootstrap results are made available to rocregplot with the bfile() option. As before, we will specify 0.2 and 0.7 as false-positive rates in the roc() option and 0.5 as a ROC value in the invroc() option. We do not specify btype() and thus our graph will contain normal-based bootstrap confidence bands, the default.

As shown in the graph, we find that the ROC values at a false-positive rate of 0.7 are close together, as they were in the maximum likelihood estimation in example 2. We now repeat this process for the lower false-positive rate of 0.2 by using the `roc(.2)` option.

```
. rocregplot, at1(xf=10.01, xl=5.5, xd=.5) at2(xf=10.01, xl=6.5, xd=4) > roc(.2) bfile(nsnrf)

The point estimates of the ROC value and false-positive rate are both computed directly using the point estimates of the ROC coefficients. Calculation of the standard errors and confidence intervals is slightly more complicated. Essentially, we have stored a sample of our ROC covariate coefficient estimates in `nsnrf.dta`. We then calculate the ROC value or false-positive rate estimates using each set of coefficient estimates, resulting in a sample of point estimates. Then the bootstrap standard error and confidence intervals are calculated based on these bootstrap samples. Details of the computation of the standard error and percentile confidence intervals can be found in *Methods and formulas* and in [R] bootstrap.

As mentioned in [R] rocreg, 50 resamples is a reasonable lower bound for obtaining bootstrap standard errors (Mooney and Duval 1993). However, it may be too low for obtaining percentile and bias-corrected confidence intervals. Normal-based confidence intervals are valid when the bootstrap distribution exhibits normality. See [R] bootstrap postestimation for more details.

We can assess the normality of the bootstrap distribution by using a normal probability plot. Stata provides this in the `pnorm` command (see [R] Diagnostic plots). We will use `nsnrf.dta` to draw a normal probability plot for the ROC estimate corresponding to a false-positive rate of 0.2. We use the covariate values `xf = 10.01`, `xl = 6.5`, and `xd = 4`.

```stata
use nsnrf
(bootstrap: rocregstat)
generate double rocp2 = nsnr_b_i_cons + 10.01*nsnr_b_xf + 6.5*nsnr_b_xl + 4*nsnr_b_xd+nsnr_b_s_cons*invnormal(.2)
replace rocp2 = normal(rocp2)
(50 real changes made)
```
The closeness of the points to the horizontal line on the normal probability plot shows us that the bootstrap distribution is approximately normal. So it is reasonable to use the normal-based confidence intervals for ROC at a false-positive rate of 0.2 under covariate values $x_f = 10.01$, $x_l = 6.5$, and $x_d = 4$.

## Plotting marginal ROC curves

The `rocregplot` command can also be used after fitting models with no covariates. We will demonstrate this with an empirical ROC model fit in `R rocreg`.

### Example 4: Nonparametric ROC

We run `rocregplot` after fitting the single-classifier, empirical ROC model shown in example 1 of `R rocreg`. There we empirically predicted the ROC curve of the classifier `rating` for the true status variable `disease` from the Hanley and McNeil (1982) data. The `rocreg` command saves variables `_roc_rating` and `_fpr_rating`, which give the ROC values and false-positive rates, respectively, for every value of `rating`. These variables are used by `rocregplot` to render the ROC curve.

```
. use https://www.stata-press.com/data/r16/hanley, clear
. rocreg disease rating, noboot
```

<table>

</tr>
<tr>
<td></td>
<td></td>
<td></td>
<td></td>
<td>(BC)</td>
</tr>
</tbody>
</table>
```
We end our discussion of rocregplot by showing its use after a marginal probit model.

Example 5: Maximum likelihood ROC, invROC, and ROC value

In example 13 of [R] rocreg, we fit a maximum-likelihood probit model to each classifier of the fictitious dataset generated from Hanley and McNeil (1983).

We use rocregplot after the original rocreg command to draw the ROC curves for classifiers mod1 and mod3. This is accomplished by specifying the two variables in the classvars() option. We will use the roc() option to obtain confidence intervals for ROC values at false-positive rates of 0.15 and 0.75. We will specify the invroc() option to obtain false-positive rate confidence intervals for a ROC value of 0.8. As mentioned previously, these are Wald confidence intervals.

First, we will view results for a false-positive rate of 0.75.

```
. use https://www.stata-press.com/data/r16/ct2, clear
. rocreg status mod1 mod2 mod3, probit ml
(output omitted)
. rocregplot, classvars(mod1 mod3) roc(.75)
```

<table>
<thead>
<tr>
<th>ROC</th>
<th>Coef.</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>.75</td>
<td>.9931655</td>
<td>.0069689</td>
<td>.9795067 1.006824</td>
</tr>
</tbody>
</table>

```
use https://www.stata-press.com/data/r16/ct2, clear
. rocreg status mod1 mod2 mod3, probit ml
(output omitted)
. rocregplot, classvars(mod1 mod3) invroc(0.75) roc(0.8)
```

<table>
<thead>
<tr>
<th>ROC</th>
<th>Coef.</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>.75</td>
<td>.9953942</td>
<td>.0043435</td>
<td>.9868811 1.003907</td>
</tr>
</tbody>
</table>
We see that the estimates for each of the two ROC curves are close. Because this is a marginal model, the actual false-positive rate and the true-positive rate for each observation are plotted in the graph. The added point estimates of the ROC value at false-positive rate 0.75 are shown as diamond (mod3) and circle (mod1) symbols in the upper-right-hand corner of the graph at $FPR = 0.75$. Confidence bands are also plotted at $FPR = 0.75$ but are so narrow that they are barely noticeable. Under both classifiers, the ROC value at 0.75 is very high. Now we will compare these results to those with a lower false-positive rate of 0.15.

```
   rocregplot, classvars(mod1 mod3) roc(.15)
   ROC curve
   Status : status
   Classifier: mod1

<table>
<thead>
<tr>
<th>ROC</th>
<th>Coef.</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>.15</td>
<td>0.7934935</td>
<td>0.0801363</td>
<td>0.6364292   0.9505578</td>
</tr>
</tbody>
</table>

   Status : status

<td>0.0520118</td>
<td>0.7869184   0.9908008</td>
</tr>
</tbody>
</table>
```
The ROC value for the false-positive rate of 0.15 is more separated in the two classifiers. Here we see that mod3 has a larger ROC value than mod1 for this false-positive rate, but the confidence intervals of the estimates overlap.

By specifying `invroc(.8)`, we obtain invROC confidence intervals corresponding to a ROC value of 0.8.

```
. rocregplot, classvars(mod1 mod3) invroc(.8)
```

<table>
<thead>
<tr>

</tr>
<tr>
<td>Classifier: mod3</td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
```
For estimation of the false-positive rate at a ROC value of 0.8, the confidence intervals overlap. Both classifiers require only a small false-positive rate to achieve a ROC value of 0.8.

Methods and formulas

Details on computation of the nonparametric ROC curve and the estimation of the parametric ROC curve model coefficients can be found in [R] rocreg. Here we describe how to estimate the ROC values and false-positive rates of a parametric model. The cumulative distribution function $g$ can be the standard normal cumulative distribution function.

Methods and formulas are presented under the following headings:

- Parametric model: Summary parameter definition
- Maximum likelihood estimation
- Estimating equations estimation

Parametric model: Summary parameter definition

Conditioning on covariates $x$, we have the following ROC curve model:

$$\text{ROC} (u) = g\{x'\beta + \alpha g^{-1} (u)\}$$

$x$ can be constant, and $\beta = \beta_0$, the constant intercept.

With simple algebra, we can solve this equation to obtain the false-positive rate value $u$ for a ROC value of $r$:

$$u = g \left[ \{g^{-1} (r) - x'\beta\} \alpha^{-1} \right]$$
Maximum likelihood estimation

We allow maximum likelihood estimation under probit parametric models, so \( g = \Phi \). The ROC value and false-positive rate parameters all have closed-form expressions in terms of the covariate values \( x \), coefficient vector \( \beta \), and slope parameter \( \alpha \). Thus to estimate these two types of summary parameters, we use the delta method (Oehlert 1992; Phillips and Park 1988). Particularly, we use the \texttt{nlcom} command (see \texttt{[R] nlcom}) to implement the delta method.

Under maximum likelihood estimation, the coefficient estimates \( \hat{\beta} \) and slope estimate \( \hat{\alpha} \) are asymptotically normal with variance matrix \( V \). For convenience, we rename the parameter vector \( [\beta', \alpha] \) to the \( k \)-parameter vector \( \theta = [\theta_1, \ldots, \theta_k] \). We will also explicitly refer to the conditioning of the ROC curve by \( \theta \) in its mention as \( \text{ROC}(i, \theta) \).

Under the delta method, the continuous scalar function of the estimate \( \hat{\theta} \), \( f(\hat{\theta}) \) has asymptotic mean \( f(\theta) \) and asymptotic covariance

\[
\text{Var}\left\{ f(\hat{\theta}) \right\} = fVf'
\]

where \( f \) is the \( 1 \times k \) matrix of derivatives for which

\[
f_{1j} = \frac{\partial f(\theta)}{\partial \theta_j} \quad j = 1, \ldots, k
\]

The asymptotic covariance of \( f(\hat{\theta}) \) is estimated and then used in conjunction with \( f(\hat{\theta}) \) for further inference, including Wald confidence intervals, standard errors, and hypothesis testing.

Estimating equations estimation

When we fit a model using the Alonzo and Pepe (2002) estimating equations method, we use the bootstrap to perform inference on the ROC curve summary parameters. Each bootstrap sample provides a sample of the coefficient estimates \( \beta \) and the slope estimates \( \alpha \). Using the formulas above, we can obtain an estimate of the ROC value or false-positive rate for each resample.

By making these calculations, we obtain a bootstrap sample of our summary parameter estimate. We then obtain bootstrap standard errors, normal approximation confidence intervals, percentile confidence intervals, and bias-corrected confidence intervals using this bootstrap sample. Further details can be found in \texttt{[R] bootstrap}.

[U] 20 Estimation and postestimation commands
### Description

The above command is used to perform receiver operating characteristic (ROC) analyses with rating and discrete classification data.

The two variables `refvar` and `classvar` must be numeric. The reference variable indicates the true state of the observation, such as diseased and nondiseased or normal and abnormal, and must be coded as 0 and 1. The rating or outcome of the diagnostic test or test modality is recorded in `classvar`, which must be at least ordinal, with higher values indicating higher risk.

`roctab` performs nonparametric ROC analyses. By default, `roctab` calculates the area under the ROC curve. Optionally, `roctab` can plot the ROC curve, display the data in tabular form, and produce Lorenz-like plots.

See [R] `rocfit` for a command that fits maximum-likelihood ROC models.

### Quick start

AUC, standard error, and CI for ROC curve of binary true state, `true`, as a function of classification variable `v`

```
roctab true v
```

Also plot the ROC curve

```
roctab true v, graph summary
```

As above, but plot sensitivity versus specificity instead of the ROC curve

```
roctab true v, specificity summary
```

Exact binomial CI instead of asymptotic normal CI for AUC estimate

```
roctab true v, binomial
```

Gini and Pietra indices

```
roctab true v, lorenz
```

### Menu

- Statistics > Epidemiology and related > ROC analysis > Nonparametric ROC analysis without covariates
Syntax

roctab refvar classvar [if] [in] [weight] [, options]

Description

Main

lorenz      report Gini and Pietra indices
binomial    calculate exact binomial confidence intervals
nolabel     display numeric codes rather than value labels
detail      show details on sensitivity/specificity for each cutpoint
table       display the raw data in a $2 \times k$ contingency table
bamber      calculate standard errors by using the Bamber method
hanley      calculate standard errors by using the Hanley method
graph       graph the ROC curve
norefline   suppress plotting the 45-degree reference line
summary     report the area under the ROC curve
specificity graph sensitivity versus specificity
level(#)    set confidence level; default is level(95)

Plot

plotopts(plot_options)       affect rendition of the ROC curve

Reference line

rlopts(cline_options)        affect rendition of the reference line

Add plots

addplot(plot)                add other plots to the generated graph

Y axis, X axis, Titles, Legend, Overall

twoway_options              any options other than by() documented in [G-3] twoway_options

Options

fweights are allowed; see [U] 11.1.6 weight.

plot_options               Description

marker_options             change look of markers (color, size, etc.)
marker_label_options       add marker labels; change look or position
cline_options              change the look of the line

Options

Main

lorenz specifies that the Gini and Pietra indices be reported. Optionally, graph will plot the Lorenz-like curve.

binomial specifies that exact binomial confidence intervals be calculated.

nolabel specifies that numeric codes be displayed rather than value labels.

detail outputs a table displaying the sensitivity, specificity, the percentage of subjects correctly classified, and two likelihood ratios for each possible cutpoint of classvar.
roctab — Nonparametric ROC analysis 2377

Table outputs a $2 \times k$ contingency table displaying the raw data.

bamber specifies that the standard error for the area under the ROC curve be calculated using the method suggested by Bamber (1975). Otherwise, standard errors are obtained as suggested by DeLong, DeLong, and Clarke-Pearson (1988).

hanley specifies that the standard error for the area under the ROC curve be calculated using the method suggested by Hanley and McNeil (1982). Otherwise, standard errors are obtained as suggested by DeLong, DeLong, and Clarke-Pearson (1988).

graph produces graphical output of the ROC curve. If lorenz is specified, graphical output of a Lorenz-like curve will be produced.

norefline suppresses plotting the 45-degree reference line from the graphical output of the ROC curve.

summary reports the area under the ROC curve, its standard error, and its confidence interval. If lorenz is specified, Lorenz indices are reported. This option is needed only when also specifying graph.

specificity produces a graph of sensitivity versus specificity instead of sensitivity versus $(1 - \text{specificity})$. specificity implies graph.

level(#) specifies the confidence level, as a percentage, for the confidence intervals. The default is level(95) or as set by set level; see [R] level.

plotopts(plot_options) affects the rendition of the plotted ROC curve—the curve’s plotted points connected by lines. The plot_options can affect the size and color of markers, whether and how the markers are labeled, and whether and how the points are connected; see [G-3] marker_options, [G-3] marker_label_options, and [G-3] cline_options.

rlopts(cline_options) affects the rendition of the reference line; see [G-3] cline_options.

addplot(plot) provides a way to add other plots to the generated graph; see [G-3] addplot_option.

twoway_options are any of the options documented in [G-3] twoway_options, excluding by(). These include options for titling the graph (see [G-3] title_options) and for saving the graph to disk (see [G-3] saving_option).

Remarks and examples

Remarks are presented under the following headings:

Introduction
Nonparametric ROC curves
Lorenz-like curves
Introduction

The `roctab` command provides nonparametric estimation of the ROC for a given classifier and true-status reference variable. The Lorenz curve functionality of `roctab`, which provides an alternative to standard ROC analysis, is discussed in *Lorenz-like curves*.

Nonparametric ROC curves

The points on the nonparametric ROC curve are generated using each possible outcome of the diagnostic test as a classification cutpoint and computing the corresponding sensitivity and $1 - \text{specificity}$. These points are then connected by straight lines, and the area under the resulting ROC curve is computed using the trapezoidal rule.

Example 1

Hanley and McNeil (1982) presented data from a study in which a reviewer was asked to classify, using a five-point scale, a random sample of 109 tomographic images from patients with neurological problems. The rating scale was as follows: 1 = definitely normal, 2 = probably normal, 3 = questionable, 4 = probably abnormal, and 5 = definitely abnormal. The true disease status was normal for 58 of the patients and abnormal for the remaining 51 patients.

Here we list 9 of the 109 observations:

```
. use https://www.stata-press.com/data/r16/hanley
. list disease rating in 1/9
```

<table>
<thead>
<tr>

</tr>
</tbody>
</table>

For each observation, `disease` identifies the true disease status of the subject (0 = normal, 1 = abnormal), and `rating` contains the classification value assigned by the reviewer.

We can use `roctab` to calculate and plot the nonparametric ROC curve by specifying both the `summary` and `graph` options. By also specifying the `table` option, we obtain a contingency table summarizing our dataset.
. roctab disease rating, table graph summary

By default, `roctab` reports the area under the curve, its standard error, and its confidence interval. The graph option can be used to plot the ROC curve.

The ROC curve is plotted by computing the sensitivity and specificity using each value of the rating variable as a possible cutpoint. A point is plotted on the graph for each of the cutpoints. These plotted points are joined by straight lines to form the ROC curve, and the area under the ROC curve is computed using the trapezoidal rule.
We can tabulate the computed sensitivities and specificities for each of the possible cutpoints by specifying `detail`.

```
. roctab disease rating, detail
```

</tbody>
</table>

Each cutpoint in the table indicates the ratings used to classify tomographs as being from an abnormal subject. For example, the first cutpoint (>= 1) indicates that all tomographs rated as 1 or greater are classified as coming from abnormal subjects. Because all tomographs have a rating of 1 or greater, all are considered abnormal. Consequently, all abnormal cases are correctly classified (sensitivity = 100%), but none of the normal patients is classified correctly (specificity = 0%). For the second cutpoint (>=2), tomographs with ratings of 1 are classified as normal, and those with ratings of 2 or greater are classified as abnormal. The resulting sensitivity and specificity are 94.12% and 56.90%, respectively. Using this cutpoint, we correctly classified 74.31% of the 109 tomographs. Similar interpretations can be used on the remaining cutpoints. As mentioned, each cutpoint corresponds to a point on the nonparametric ROC curve. The first cutpoint (>=1) corresponds to the point at (1,1), and the last cutpoint (> 5) corresponds to the point at (0,0).

`detail` also reports two likelihood ratios suggested by Choi (1998): the likelihood ratio for a positive test result (LR+) and the likelihood ratio for a negative test result (LR–). The LR+ is the ratio of the probability of a positive test among the truly positive subjects to the probability of a positive test among the truly negative subjects. The LR– is the ratio of the probability of a negative test among the truly positive subjects to the probability of a negative test among the truly negative subjects. Choi points out that LR+ corresponds to the slope of the line from the origin to the point on the ROC curve determined by the cutpoint. Similarly, LR– corresponds to the slope from the point (1,1) to the point on the ROC curve determined by the cutpoint.

By default, `roctab` calculates the standard error for the area under the curve by using an algorithm suggested by DeLong, DeLong, and Clarke-Pearson (1988) and asymptotic normal confidence intervals. Optionally, standard errors based on methods suggested by Bamber (1975) or Hanley and McNeil (1982) can be computed by specifying `bamber` or `hanley`, respectively, and an exact binomial confidence interval can be obtained by specifying `binomial`.
Lorenz-like curves

For applications where it is known that the risk status increases or decreases monotonically with increasing values of the diagnostic test, the ROC curve and associated indices are useful in assessing the overall performance of a diagnostic test. When the risk status does not vary monotonically with increasing values of the diagnostic test, however, the resulting ROC curve can be nonconvex and its indices can be unreliable. For these situations, Lee (1999) proposed an alternative to the ROC analysis based on Lorenz-like curves and the associated Pietra and Gini indices.

Lee (1999) mentions at least three specific situations where results from Lorenz curves are superior to those obtained from ROC curves: 1) a diagnostic test with similar means but very different standard deviations in the abnormal and normal populations, 2) a diagnostic test with bimodal distributions in either the normal or abnormal population, and 3) a diagnostic test distributed symmetrically in the normal population and skewed in the abnormal.

When the risk status increases or decreases monotonically with increasing values of the diagnostic test, the ROC and Lorenz curves yield interchangeable results.

Example 2

To illustrate the use of the `lorenz` option, we constructed a fictitious dataset that yields results similar to those presented in Table III of Lee (1999). The data assume that a 12-point rating scale was used to classify 442 diseased and 442 healthy subjects. We list a few of the observations.

```
use https://www.stata-press.com/data/r16/lorenz, clear
list in 1/7, noobs sep(0)
```

<table>
<thead>
<tr>

<td>0</td>
<td>2</td>
<td>7</td>
</tr>
<tr>
<td>1</td>
<td>4</td>
<td>16</td>
</tr>
</tbody>
</table>
```

The data consist of 24 observations: 12 observations from diseased individuals and 12 from nondiseased individuals. Each observation corresponds to one of the 12 classification values of the rating-scale variable, `class`. The number of subjects represented by each observation is given by the `pop` variable, making this a frequency-weighted dataset. The data were generated assuming a binormal distribution of the latent variable with similar means for the normal and abnormal populations but with the standard deviation for the abnormal population five times greater than that of the normal population.
The resulting ROC curve is nonconvex or, as termed by Lee, “wiggly”. Lee argues that for this and similar situations, the Lorenz curve and indices are preferred.

Like ROC curves, a more bowed Lorenz curve suggests a better diagnostic test. This bowedness is quantified by the Pietra index, which is geometrically equivalent to twice the largest triangle that can be inscribed in the area between the curve and the diagonal line, and the Gini index, which is
equivalent to twice the area between the Lorenz curve and the diagonal. Lee (1999) provides several additional interpretations for the Pietra and Gini indices.

Stored results

roctab stores the following in r():

Scalars
r(N)  number of observations
r(se)  standard error for the area under the ROC curve
r(lb)  lower bound of CI for the area under the ROC curve
r(ub)  upper bound of CI for the area under the ROC curve
r(level)  confidence level
r(area)  area under the ROC curve
r(pietra)  Pietra index
r(gini)  Gini index

Macros
r(cutpoints)  description of cutpoints (detail only)

Matrices
r(detail)  matrix with details on sensitivity and specificity for each cutpoint (detail only)

Methods and formulas

Assume that we applied a diagnostic test to each of \( N_a \) normal and \( N_a \) abnormal subjects. Further assume that the higher the outcome value of the diagnostic test, the higher the risk of the subject being abnormal. Let \( \hat{\theta} \) be the estimated area under the curve, and let \( X_i, i = 1, 2, \ldots, N_a \) and \( Y_j, j = 1, 2, \ldots, N_n \) be the values of the diagnostic test for the abnormal and normal subjects, respectively.

The points on the nonparametric ROC curve are generated using each possible outcome of the diagnostic test as a classification cutpoint and computing the corresponding sensitivity and 1—specificity. These points are then connected by straight lines, and the area under the resulting ROC curve is computed using the trapezoidal rule.

The default standard error for the area under the ROC curve is computed using the algorithm described by DeLong, DeLong, and Clarke-Pearson (1988). For each abnormal subject, \( i \), define

\[
V_{10}(X_i) = \frac{1}{N_n} \sum_{j=1}^{N_n} \psi(X_i, Y_j)
\]

and for each normal subject, \( j \), define

\[
V_{01}(Y_j) = \frac{1}{N_a} \sum_{i=1}^{N_a} \psi(X_i, Y_j)
\]

where

\[
\psi(X, Y) = \begin{cases} 
1 & Y < X \\
\frac{1}{2} & Y = X \\
0 & Y > X 
\end{cases}
\]
Define
\[
S_{10} = \frac{1}{N_a - 1} \sum_{i=1}^{N_a} (V_{10}(X_i) - \hat{\theta})^2
\]
and
\[
S_{01} = \frac{1}{N_n - 1} \sum_{j=1}^{N_n} (V_{01}(Y_j) - \hat{\theta})^2
\]

The variance of the estimated area under the ROC curve is given by
\[
\text{var}(\hat{\theta}) = \frac{1}{N_a} S_{10} + \frac{1}{N_n} S_{01}
\]

The Hanley standard error for the area under the ROC curve is computed using the algorithm described by Hanley and McNeil (1982). It requires the calculation of two quantities: \(Q_1\) is \(\Pr(\text{two randomly selected abnormal subjects will both have a higher score than a randomly selected normal subject})\), and \(Q_2\) is \(\Pr(\text{one randomly selected abnormal subject will have a higher score than any two randomly selected normal subjects})\). The Hanley and McNeil variance of the estimated area under the ROC curve is
\[
\text{var}(\hat{\theta}) = \hat{\theta} (1 - \hat{\theta}) + \frac{(N_a - 1)(Q_1 - \hat{\theta}^2) + (N_n - 1)(Q_2 - \hat{\theta}^2)}{N_a N_n}
\]

The Bamber standard error for the area under the ROC curve is computed using the algorithm described by Bamber (1975). For any two \(Y\) values, \(Y_j\) and \(Y_k\), and any \(X_i\) value, define
\[
b_{yyx} = p(Y_j, Y_k < X_i) + p(X_i < Y_j, Y_k) - 2p(Y_j < X_i < Y_k)
\]
and similarly, for any two \(X\) values, \(X_i\) and \(X_l\), and any \(Y_j\) value, define
\[
b_{xxy} = p(X_i, X_l < Y_j) + p(Y_j < X_i, X_l) - 2p(X_i < Y_j < X_l)
\]

Bamber’s unbiased estimate of the variance for the area under the ROC curve is
\[
\text{var}(\hat{\theta}) = \frac{1}{4}(N_a - 1)(N_n - 1)\{p(X \neq Y) + (N_a - 1)b_{xxy} + (N_n - 1)b_{yyx} - 4(N_a + N_n - 1)(\hat{\theta} - 0.5)^2\}
\]

Asymptotic confidence intervals are constructed and reported by default, assuming a normal distribution for the area under the ROC curve.

Exact binomial confidence intervals are calculated as described in [R] ci, with \(p\) equal to the area under the ROC curve.

rreg — Robust regression

Description

rreg performs one version of robust regression of depvar on indepvars.

Also see Robust standard errors in [R] regress for standard regression with robust variance estimates and [R] qreg for quantile (including median or least-absolute-residual) regression.

Quick start

Robust regression of y on x

- rreg y x

Add a categorical covariate a using factor-variable syntax

- rreg y x i.a

As above, but set the tuning parameter to 8

- rreg y x i.a, tune(8)

Generate a new variable wvar containing the final weight for each observation

- rreg y x i.a, genwt(wvar)

Set confidence level to 99%

- rreg y x i.a, level(99)

Menu

Statistics > Linear models and related > Other > Robust regression
Syntax

```
rreg depvar [ indepvars ] [ if ] [ in ] [ , options ]
```

</tbody>
</table>

**Options**

- **tune(#)**: is the biweight tuning constant. The default is 7, meaning seven times the median absolute deviation (MAD) from the median residual; see Methods and formulas. Lower tuning constants downweight outliers rapidly but may lead to unstable estimates (less than 6 is not recommended). Higher tuning constants produce milder downweighting.

- **level(#)**: see [R] Estimation options.

- **genwt(newvar)** creates the new variable newvar containing the weights assigned to each observation.

- **display_options**: noci, nopvalues, noomitted, vsquish, noemptycells, baselevels, allbaselevels, noflabel, fwrap(#), fwrapon(style), cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch; see [R] Estimation options.

- **optimization_options**: iterate(#), tolerance(#), [no]log. iterate() specifies the maximum number of iterations; iterations stop when the maximum change in weights drops below tolerance(); and log/nolog specifies whether to show the iteration log (see set iterlog in [R] set iter). These options are seldom used.
graph allows you to graphically watch the convergence of the iterative technique. The weights obtained from the most recent round of estimation are graphed against the weights obtained from the previous round.

The following option is available with `rreg` but is not shown in the dialog box: `coeflegend`; see [R] Estimation options.

### Remarks and examples

`rreg` first performs an initial screening based on Cook’s distance > 1 to eliminate gross outliers before calculating starting values and then performs Huber iterations followed by biweight iterations, as suggested by Li (1985).

#### Example 1

We wish to examine the relationship between mileage rating, weight, and location of manufacture for the 74 cars in the `auto.dta`. As a point of comparison, we begin by fitting an ordinary regression:

```
. use https://www.stata-press.com/data/r16/auto
(1978 Automobile Data)
. regress mpg weight foreign
```

```
| Source | SS  | df  | MS   | Number of obs = 74
|--------|-----|-----|------|-------------------
| Model  | 1619.2877 | 2  | 809.643849 | F(2, 71) = 69.75 Prob > F = 0.0000
| Residual | 824.171761 | 71 | 11.608053  | R-squared = 0.6627 Adj R-squared = 0.6532
| Total   | 2443.45946 | 73 | 33.4720474 | Root MSE = 3.4071
```

```
mpg | Coef.  | Std. Err.  | t    | P>|t|  | [95% Conf. Interval]
---|--------|------------|------|------|-----------------------
weight | -.0065879 | .0006371  | -10.34 | 0.000 | -.0078583 -.0053175
foreign | -1.650029 | 1.075994  | -1.53 | 0.130 | -3.7955 .4954422
_cons   | 41.6797 | 2.165547  | 19.25 | 0.000 | 37.36172 45.99768
```

We now compare this with the results from `rreg`:

```
. rreg mpg weight foreign
```

```
Huber iteration 1: maximum difference in weights = .80280176
Huber iteration 2: maximum difference in weights = .2915438
Huber iteration 3: maximum difference in weights = .08911171
Huber iteration 4: maximum difference in weights = .02697328
Biweight iteration 5: maximum difference in weights = .29186818
Biweight iteration 6: maximum difference in weights = .11988101
Biweight iteration 7: maximum difference in weights = .03315872
Biweight iteration 8: maximum difference in weights = .00721325

Robust regression Number of obs = 74 F( 2, 71) = 168.32 Prob > F = 0.0000

```

```
| mpg | Coef.  | Std. Err.  | t    | P>|t|  | [95% Conf. Interval]
---|--------|------------|------|------|-----------------------
weight | -.0063976 | .0003718  | -17.21 | 0.000 | -.007139 -.0056562
foreign | -3.182639 | .627964  | -5.07 | 0.000 | -4.434763 -1.930514
_cons   | 40.64022 | 1.263841  | 32.16 | 0.000 | 38.1202 43.16025
```

Note the large change in the `foreign` coefficient.
Technical note

It would have been better if we had fit the previous robust regression by typing `rreg mpg weight foreign, genwt(w)`. The new variable, `w`, would then contain the estimated weights. Let’s pretend that we did this:

```
.rreg mpg weight foreign, genwt(w)
(output omitted)
.summarize w, detail
```

<table>

</tr>
</tbody>
</table>

Being familiar with the automobile data, we immediately spotted two things: the VW is the only diesel car in our data, and the weight recorded for the Plymouth Arrow is incorrect.
Example 2

If we specify no explanatory variables, *rreg* produces a robust estimate of the mean:

```
.rreg mpg
Huber iteration 1:  maximum difference in weights =  0.64471879
Huber iteration 2:  maximum difference in weights =  0.05088336
Huber iteration 3:  maximum difference in weights =  0.0099887
Biweight iteration 4: maximum difference in weights =  0.25197391
Biweight iteration 5: maximum difference in weights =  0.00358606

Robust regression
Number of obs =  74
F(    0,    73) =  0.00
Prob > F      =   .

mpg             Coef.   Std. Err.     t     P>|t|     [95% Conf. Interval]
_cons           20.68825   .6418135   32.23   0.000      19.40912    21.96738
```

The estimate is given by the coefficient on `_cons`. The mean is 20.69 with an estimated standard error of 0.6418. The 95% confidence interval is [19.4, 22.0]. By comparison, *ci means* (see [R] ci) gives us the standard calculation:

```
.ci means mpg
Variable |    Obs   Mean   Std. Err.  [95% Conf. Interval]
mpg      |    74   21.2973   .6725511     19.9569    22.63769
```

Stata has an active user community working in the area of robust statistics. You may also be interested in robust estimators and outlier detection tools from Verardi and McCathie (2012), Verardi and Dehon (2010), Jann (2010), and Verardi and Croux (2009), to name a few. See [R] ssc for how to install community-contributed packages.
Stored results

`rreg` stores the following in `e()`: 

Scalars
- `e(N)` number of observations
- `e(mss)` model sum of squares
- `e(df_m)` model degrees of freedom
- `e(rss)` residual sum of squares
- `e(df_r)` residual degrees of freedom
- `e(r2)` $R^2$
- `e(r2_a)` adjusted $R^2$
- `e(F)` $F$ statistic
- `e(rmse)` root mean squared error
- `e(rank)` rank of `e(V)`

Macros
- `e(cmd)` `rreg`
- `e(cmdline)` command as typed
- `e(depvar)` name of dependent variable
- `e(genwt)` variable containing the weights
- `e(title)` title in estimation output
- `e(model)` ols
- `e(properties)` b V
- `e(predict)` program used to implement `predict`
- `e(marginsok)` predictions allowed by `margins`
- `e(asbalanced)` factor variables `fvset` as `asbalanced`
- `e(asobserved)` factor variables `fvset` as `asobserved`

Matrices
- `e(b)` coefficient vector
- `e(V)` variance–covariance matrix of the estimators

Functions
- `e(sample)` marks estimation sample

Methods and formulas

`rreg` begins by fitting the regression (see [R] `regress`), calculating Cook’s $D$ (see [R] `predict` and [R] `regress postestimation`), and excluding any observation for which $D > 1$.

Thereafter `rreg` works iteratively: it performs a regression, calculates case weights from absolute residuals, and regresses again using those weights. Iterations stop when the maximum change in weights drops below `tolerance()`. Weights derive from one of two weight functions, Huber weights and biweights. Huber weights (Huber 1964) are used until convergence, and then, from that result, biweights are used until convergence. The biweight was proposed by Beaton and Tukey (1974, 151–152) after the Princeton robustness study (Andrews et al. 1972) had compared various estimators. Both weighting functions are used because Huber weights have problems dealing with severe outliers, whereas biweights sometimes fail to converge or have multiple solutions. The initial Huber weighting should improve the behavior of the biweight estimator.

In Huber weighting, cases with small residuals receive weights of 1; cases with larger residuals receive gradually smaller weights. Let $e_i = y_i - X_i b$ represent the $i$th-case residual. The $i$th scaled residual $u_i = e_i / s$ is calculated, where $s = M / 0.6745$ is the residual scale estimate and $M = \text{med}(|e_i - \text{med}(e_i)|)$ is the median absolute deviation from the median residual. Huber estimation obtains case weights:
\[
    w_i = \begin{cases} 
        1 & \text{if } |u_i| \leq ch \\
        c_h/|u_i| & \text{otherwise}
    \end{cases}
\]

`rreg` defines \( ch = 1.345 \), so downweighting begins with cases whose absolute residual exceeds \((1.345/0.6745)M \approx 2M\).

With biweights, all cases with nonzero residuals receive some downweighting, according to the smoothly decreasing biweight function

\[
    w_i = \begin{cases} 
        (1 - (u_i/c_b)^2)^2 & \text{if } |u_i| \leq c_b \\
        0 & \text{otherwise}
    \end{cases}
\]

where \( c_b = 4.685 \times \text{tune()}/7 \). Thus when \( \text{tune()} = 7 \), cases with absolute residuals of \((4.685/0.6745)M \approx 7M\) or more are assigned 0 weight and thus are effectively dropped. Goodall (1983, 377) suggests using a value between 6 and 9, inclusive, for `tune()` in the biweight case and states that performance is good between 6 and 12, inclusive.

The tuning constants \( ch = 1.345 \) and \( c_b = 4.685 \) (assuming `tune()` is set at the default 7) give `rreg` about 95% of the efficiency of OLS when applied to data with normally distributed errors (Hamilton 1991b). Lower tuning constants downweight outliers more drastically (but give up Gaussian efficiency); higher tuning constants make the estimator more like OLS.

Standard errors are calculated using the pseudovalues approach described in Street, Carroll, and Ruppert (1988).

* `forecast` is not appropriate with `mi` estimation results.
predict

Description for predict

predict creates a new variable containing predictions such as linear predictions, standard errors, residuals, and diagonal elements of the hat matrix.

Menu for predict

Statistics > Postestimation

Syntax for predict

predict [type] newvar [if] [in] [, statistic]

statistic Description
---
Main
xb      linear prediction; the default
stdp    standard error of the linear prediction
residuals residuals
hat     diagonal elements of the hat matrix

These statistics are available both in and out of sample; type predict ... if e(sample) ... if wanted only for the estimation sample.

Options for predict

xb, the default, calculates the linear prediction.
stdp calculates the standard error of the linear prediction.
residuals calculates the residuals.
hat calculates the diagonal elements of the hat matrix. You must have run the rreg command with the genwt() option.
margins

Description for margins

margins estimates margins of response for linear predictions.

Menu for margins

Statistics  >  Postestimation

Syntax for margins

margins [ marginlist ] [, options ]

margins [ marginlist ] , predict( statistic ... ) [ options ]

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>xb</td>
<td>linear prediction; the default</td>
</tr>
<tr>
<td>stdp</td>
<td>not allowed with margins</td>
</tr>
<tr>
<td>residuals</td>
<td>not allowed with margins</td>
</tr>
<tr>
<td>hat</td>
<td>not allowed with margins</td>
</tr>
</tbody>
</table>

Statistics not allowed with margins are functions of stochastic quantities other than e(b).

For the full syntax, see [R] margins.

[R] rreg — Robust regression

[U] 20 Estimation and postestimation commands
runtest tests whether the observations of varname are serially independent—that is, whether they occur in a random order—by counting how many runs there are above and below a threshold. By default, the median is used as the threshold. A small number of runs indicates positive serial correlation; a large number indicates negative serial correlation.

Quick start

Run test for the serial independence of the observations of v1
runtest v1

Use the mean of v1, rather than the median, as the threshold for counting runs
runtest v1, mean

Use 10 as the threshold for counting runs
runtest v1, threshold(10)

As above, but ignore any values of v1 equal to the threshold when counting runs
runtest v1, threshold(10) drop

Menu

Statistics > Nonparametric analysis > Tests of hypotheses > Test for random order
Syntax

```
runtest varname [in] [ , options ]
```

<table>
<thead>
<tr>
<th>options</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>continuity</td>
<td>continuity correction</td>
</tr>
<tr>
<td>drop</td>
<td>ignore values equal to the threshold</td>
</tr>
<tr>
<td>split</td>
<td>randomly split values equal to the threshold as above or below the threshold; default is to count as below</td>
</tr>
<tr>
<td>mean</td>
<td>use mean as threshold; default is median</td>
</tr>
<tr>
<td>threshold(#)</td>
<td>assign arbitrary threshold; default is median</td>
</tr>
</tbody>
</table>

Options

- `continuity` specifies a continuity correction that may be helpful in small samples. If there are fewer than 10 observations either above or below the threshold, however, the tables in Swed and Eisenhart (1943) provide more reliable critical values. By default, no continuity correction is used.

- `drop` directs `runtest` to ignore any values of `varname` that are equal to the threshold value when counting runs and tabulating observations. By default, `runtest` counts a value as being above the threshold when it is strictly above the threshold and as being below the threshold when it is less than or equal to the threshold.

- `split` directs `runtest` to randomly split values of `varname` that are equal to the threshold. In other words, when `varname` is equal to threshold, a “coin” is flipped. If it comes up heads, the value is counted as above the threshold. If it comes up tails, the value is counted as below the threshold.

- `mean` directs `runtest` to tabulate runs above and below the mean rather than the median.

- `threshold(#)` specifies an arbitrary threshold to use in counting runs. For example, if `varname` has already been coded as a 0/1 variable, the median generally will not be a meaningful separating value.

Remarks and examples

`runtest` performs a nonparametric test of the hypothesis that the observations of `varname` occur in a random order by counting how many runs there are above and below a threshold. If `varname` is positively serially correlated, it will tend to remain above or below its median for several observations in a row; that is, there will be relatively few runs. If, on the other hand, `varname` is negatively serially correlated, observations above the median will tend to be followed by observations below the median and vice versa; that is, there will be relatively many runs.

By default, `runtest` uses the median for the threshold, and this is not necessarily the best choice. If `mean` is specified, the mean is used instead of the median. If `threshold(#)` is specified, # is used. Because `runtest` divides the data into two states—above and below the threshold—it is appropriate for data that are already binary; for example, win or lose, live or die, rich or poor, etc. Such variables are often coded as 0 for one state and 1 for the other. Here you should specify `threshold(0)` because, by default, `runtest` separates the observations into those that are greater than the threshold and those that are less than or equal to the threshold.
As with most nonparametric procedures, the treatment of ties complicates the test. Observations equal to the threshold value are ties and can be treated in one of three ways. By default, they are treated as if they were below the threshold. If `drop` is specified, they are omitted from the calculation and the total number of observations is adjusted. If `split` is specified, each is randomly assigned to the above- and below-threshold groups. The random assignment is different each time the procedure is run unless you specify the random-number seed; see [R] set seed.

Example 1

We can use `runtest` to check regression residuals for serial correlation.

```
. use https://www.stata-press.com/data/r16/run1
. scatter resid year, connect(l) yline(0) title(Regression residuals)
```

![Regression residuals graph](image)

The graph gives the impression that these residuals are positively correlated. Excursions above or below zero—the natural threshold for regression residuals—tend to last for several observations. `runtest` can evaluate the statistical significance of this impression.

```
. runtest resid, thresh(0)
N(resid <= 0) = 8
N(resid > 0) = 8
obs = 16
N(runs) = 5
z = -2.07
Prob>|z| = .04
```

There are five runs in these 16 observations. Using the normal approximation to the true distribution of the number of runs, the five runs in this series are fewer than would be expected if the residuals were serially independent. The $p$-value is 0.04, indicating a two-sided significant result at the 5% level. If the alternative hypothesis is positive serial correlation, rather than any deviation from randomness, then the one-sided $p$-value is $0.04/2 = 0.015$. With so few observations, however, the normal approximation may be inaccurate. (Tables compiled by Swed and Eisenhart list five runs as the 5% critical value for a one-sided test.)

`runtest` is a nonparametric test. It ignores the magnitudes of the observations and notes only whether the values are above or below the threshold. We can demonstrate this feature by reducing the information about the regression residuals in this example to a 0/1 variable that indicates only whether a residual is positive or negative.
As expected, `runtest` produces the same answer as before.

### Technical note

The run test can also be used to test the null hypothesis that two samples are drawn from the same underlying distribution. The run test is sensitive to differences in the shapes, as well as the locations, of the empirical distributions.

Suppose, for example, that two different additives are added to the oil in 10 different cars during an oil change. The cars are run until a viscosity test determines that another oil change is needed, and the number of miles traveled between oil changes is recorded. The data are

```stata
. use https://www.stata-press.com/data/r16/additive, clear
. list
```

<table>
<thead>
<tr>
<th>additive</th>
<th>miles</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>4024</td>
</tr>
<tr>
<td>2</td>
<td>4756</td>
</tr>
<tr>
<td>3</td>
<td>7993</td>
</tr>
<tr>
<td>4</td>
<td>5025</td>
</tr>
<tr>
<td>5</td>
<td>4188</td>
</tr>
<tr>
<td>6</td>
<td>3007</td>
</tr>
<tr>
<td>7</td>
<td>1988</td>
</tr>
<tr>
<td>8</td>
<td>1051</td>
</tr>
<tr>
<td>9</td>
<td>4478</td>
</tr>
<tr>
<td>10</td>
<td>4232</td>
</tr>
</tbody>
</table>

To test whether the additives generate different distributions of miles between oil changes, we sort the data by `miles` and then use `runtest` to see whether the marker for each additive occurs in random order:

```stata
. sort miles
. runtest additive, thresh(1)
```

```
<table>
<thead>
<tr>
<th>additive &lt;= 1</th>
<th>additive &gt; 1</th>
</tr>
</thead>
<tbody>
<tr>
<td>N</td>
<td>N</td>
</tr>
<tr>
<td>N(&lt;= 1)</td>
<td>N(&gt; 1)</td>
</tr>
<tr>
<td>N(&lt;= 1) = 5</td>
<td>N(&gt; 1) = 5</td>
</tr>
<tr>
<td>obs = 10</td>
<td>N(runs) = 4</td>
</tr>
<tr>
<td>z = -1.34</td>
<td>Prob&gt;</td>
</tr>
</tbody>
</table>
```

Here the additives do not produce statistically different results.
A test that is related to the run test is the runs up-and-down test. In the latter test, the data are classified not by whether they lie above or below a threshold but by whether they are steadily increasing or decreasing. Thus an unbroken string of increases in the variable of interest is counted as one run, as is an unbroken string of decreases. According to Madansky (1988), the run test is superior to the runs up-and-down test for detecting trends in the data, but the runs up-and-down test is superior for detecting autocorrelation.

`runtest` can be used to perform a runs up-and-down test. Using the regression residuals from the example above, we can perform a `runtest` on their first differences:

```stata
use https://www.stata-press.com/data/r16/run1
generate resid_D = resid - resid[_n-1]
runtest resid_D, thresh(0)
```

```
N(resid_D <= 0) = 7
N(resid_D > 0) = 8
obs = 15
N(runs) = 6
z = -1.33
Prob>|z| = .18
```

Edgington (1961) has compiled a table of the small-sample distribution of the runs up-and-down statistic, and this table is reprinted in Madansky (1988). For large samples, the $z$ statistic reported by `runtest` is incorrect for the runs up-and-down test. Let $N$ be the number of observations (15 here), and let $r$ be the number of runs (6). The expected number of runs in the runs up-and-down test is

$$
\mu_r = \frac{2N - 1}{3}
$$

the variance is

$$
\sigma_r^2 = \frac{16N - 29}{90}
$$

and the correct $z$ statistic is

$$
\hat{z} = \frac{r - \mu_r}{\sigma_r}
$$

`runtest` will tolerate missing values at the beginning or end of a series, as occurred in the technical note above (generating first differences resulted in a missing value for the first observation). `runtest`, however, will issue an error message if there are any missing observations in the interior of the series (in the portion covered by the `in` `range` qualifier). To perform the test anyway, simply drop the missing observations before using `runtest`.
Stored results

runtest stores the following in r():

Scalars
- r(N) number of observations
- r(N_below) number below the threshold
- r(N_above) number above the threshold
- r(mean) expected number of runs
- r(p) p-value of z
- r(z) z statistic
- r(n_runs) number of runs
- r(Var) variance of the number of runs

Methods and formulas

runtest begins by calculating the number of observations below the threshold, \( n_0 \); the number of observations above the threshold, \( n_1 \); the total number of observations, \( N = n_0 + n_1 \); and the number of runs, \( r \). These statistics are always reported, so the exact tables of critical values in Swed and Eisenhart (1943) may be consulted if necessary.

The expected number of runs under the null is

\[
\mu_r = \frac{2n_0n_1}{N} + 1
\]

the variance is

\[
\sigma_r^2 = \frac{2n_0n_1(2n_0n_1 - N)}{N^2(N - 1)}
\]

and the normal approximation test statistic is

\[
\hat{z} = \frac{r - \mu_r}{\sigma_r}
\]

Acknowledgment

runtest was written by Sean Becketti, a past editor of the Stata Technical Bulletin and author of the Stata Press book Introduction to Time Series Using Stata.

**Options**

- `depvar` may contain factor variables; see [U] 11.4.3 Factor variables.
- bootstrap, by, fp, jackknife, nestreg, rolling, statsby, stepwise, and svy are allowed; see [U] 11.1.10 Prefix commands.
- `vce()` and weights are not allowed with the `svy` prefix; see [SVY] svy.
- `fe`weights, `i`weights, and `p`weights are allowed; see [U] 11.1.6 weight.
- `collinear` and `coeflegend` do not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

- `noconstant`, `offset(varname)`, `constraints(constraints)`; see [R] Estimation options.

- `asis` forces retention of perfect predictor variables and their associated perfectly predicted observations and may produce instabilities in maximization; see [R] probit.
vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim, opg), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.

Reporting

level(#) ; see [R] Estimation options.

or reports the estimated coefficients transformed to odds ratios, that is, \( e^b \) rather than \( b \). Standard errors and confidence intervals are similarly transformed. This option affects how results are displayed, not how they are estimated. or may be specified at estimation or when replaying previously estimated results.

nocnsreport; see [R] Estimation options.

display_options: noci, nopvalues, noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(#) , fvwrapon(style), cformat(%,fmt), pformat(%,fmt), sformat(%,fmt), and nolstretch; see [R] Estimation options.

Maximization

maximize_options: difficult, technique(algorithm_spec), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(init_specs); see [R] Maximize. These options are seldom used.

Setting the optimization type to technique(bhhh) resets the default vcetype to vce(opg).

The following options are available with scobit but are not shown in the dialog box:
collinear, coeflegend; see [R] Estimation options.

Remarks and examples

Remarks are presented under the following headings:

Skewed logistic model
Robust standard errors

Skewed logistic model

scobit fits maximum likelihood models with dichotomous dependent variables coded as 0/1 (or, more precisely, coded as 0 and not 0).

Example 1

We have data on the make, weight, and mileage rating of 22 foreign and 52 domestic automobiles. We wish to fit a model explaining whether a car is foreign based on its mileage. Here is an overview of our data:
. use https://www.stata-press.com/data/r16/auto
(1978 Automobile Data)
. keep make mpg weight foreign
. describe
Contains data from https://www.stata-press.com/data/r16/auto.dta
obs: 74 1978 Automobile Data
vars: 4 13 Apr 2018 17:45
(_dta has notes)

(2 unique values)

foreign is labeled and all values are documented in the label.

The variable foreign takes on two unique values, 0 and 1. The value 0 denotes a domestic car, and 1 denotes a foreign car.

The model that we wish to fit is

$$\Pr(\text{foreign} = 1) = F(\beta_0 + \beta_1 \text{mpg})$$

where $F(z) = 1 - 1/(1 + \exp(z))$. 

To fit this model, we type

. scobit foreign mpg
Fitting logistic model:
Iteration 0:  log likelihood =  -45.03321
Iteration 1:  log likelihood = -39.380959
Iteration 2:  log likelihood = -39.288802
Iteration 3:  log likelihood = -39.28864
Iteration 4:  log likelihood = -39.28864

Fitting full model:
Iteration 0:  log likelihood =  -39.28864
Iteration 1:  log likelihood = -39.286393
Iteration 2:  log likelihood = -39.284415
Iteration 3:  log likelihood = -39.284234
Iteration 4:  log likelihood = -39.284197
Iteration 5:  log likelihood = -39.284196
Skewed logistic regression
Number of obs = 74
Zero outcomes = 52
Nonzero outcomes = 22
Log likelihood = -39.2842

| foreign | Coef.  | Std. Err. | z     | P>|z| | [95% Conf. Interval] |
|---------|--------|-----------|-------|------|----------------------|
| mpg     | 0.1813879 | 0.2407362 | 0.75  | 0.451 | -0.2904463 - 0.6532222 |
| _cons   | -4.274883  | 1.399305  | -3.06 | 0.002 | -7.017471 - 1.532295 |
| /lnalpha| -0.4450405 | 3.879885  | -0.11 | 0.909 | -8.049476  7.159395  |
| alpha   | 0.6407983  | 2.486224  | 0.00  | 0.925 | 0.0003193  1286.133  |

LR test of alpha=1: chi2(1) = 0.01  Prob > chi2 = 0.9249
Note: Likelihood-ratio tests are recommended for inference with scobit models.

We find that cars yielding better gas mileage are less likely to be foreign. The likelihood-ratio test at the bottom of the output indicates that the model is not significantly different from a logit model. Therefore, we should use the more parsimonious model.

Technical note

Stata interprets a value of 0 as a negative outcome (failure) and treats all other values (except missing) as positive outcomes (successes). Thus if the dependent variable takes on the values 0 and 1, then 0 is interpreted as failure and 1 as success. If the dependent variable takes on the values 0, 1, and 2, then 0 is still interpreted as failure, but both 1 and 2 are treated as successes.

Formally, when we type `scobit y x`, Stata fits the model

$$\Pr(y_j \neq 0 \mid x_j) = 1 - \frac{1}{\left\{1 + \exp(x_j \beta)\right\}^{\alpha}}$$

Robust standard errors

If you specify the `vce(robust)` option, scobit reports robust standard errors as described in [U] 20.22 Obtaining robust variance estimates. For the model of foreign on mpg, the robust calculation increases the standard error of the coefficient on mpg by around 25%:

```
. scobit foreign mpg, vce(robust) nolog
```

| foreign | Coef.  | Std. Err. | z     | P>|z| | [95% Conf. Interval] |
|---------|--------|-----------|-------|------|----------------------|
| mpg     | 0.1813879 | 0.3028487 | 0.60  | 0.549 | -0.4121847 - 0.7749606 |
| _cons   | -4.274883  | 1.335521  | -3.20 | 0.001 | -6.892455 - 1.657311 |
| /lnalpha| -0.4450405 | 4.71561   | -0.09 | 0.925 | -9.687466  8.797385  |
| alpha   | 0.6407983  | 3.021755  | 0.00  | 0.925 | 0.000621  6616.919  |
Without \texttt{vce(robust)}, the standard error for the coefficient on mpg was reported to be 0.241, with a resulting confidence interval of $[-0.29, 0.65]$.

Specifying the \texttt{vce(cluster clustvar)} option relaxes the independence assumption required by the skewed logit estimator to being just independence between clusters. To demonstrate this, we will switch to a different dataset.

\textbf{Example 2}

We are studying the unionization of women in the United States and have a dataset with 26,200 observations on 4,434 women between 1970 and 1988. For our purposes, we will use the variables age (the women were 14–26 in 1968 and the data thus span the age range of 16–46), grade (years of schooling completed, ranging from 0 to 18), not_smsa (28% of the person-time was spent living outside an SMSA—standard metropolitan statistical area), south (41% of the person-time was in the South), and year. Each of these variables is included in the regression as a covariate along with the interaction between south and year. This interaction, along with the south and year variables, is specified in the \texttt{scobit} command using factor-variables notation, \texttt{south##c.year}. We also have variable union. Overall, 22% of the person-time is marked as time under union membership and 44% of these women have belonged to a union.

We fit the following model, ignoring that women are observed an average of 5.9 times each in these data:

\begin{verbatim}
  . use https://www.stata-press.com/data/r16/union, clear
  (NLS Women 14-24 in 1968)
  . scobit union age grade not_smsa south##c.year, nrtol(1e-3)

  Skewed logistic regression

  Number of obs = 26,200
  Zero outcomes = 20,389
  Log likelihood = -13540.61

  union     Coef.     Std. Err.      z    P>|z|     [95% Conf. Interval]

   _cons     -10.3557     68.97573    -0.15   0.881   -145.5456    124.8342
   /lnalpha   9.136018    68.97398     0.13   0.895   -126.0505    144.3225
  alpha        9283.72    640335.1    1.81e-55        4.77e+62

  LR test of alpha=1: chi2(1) = 3.76     Prob > chi2 = 0.0524

  Note: Likelihood-ratio tests are recommended for inference with \texttt{scobit} models.
\end{verbatim}

The reported standard errors in this model are probably meaningless. Women are observed repeatedly, so the observations are not independent. Looking at the coefficients, we find a large southern effect against unionization and a different time trend for the south. The \texttt{vce(cluster clustvar)} option provides a way to fit this model and obtains correct standard errors:
. scobit union age grade not_smsa south##c.year, vce(cluster id) nrtol(1e-3)
(output omitted)
Skewed logistic regression
Number of obs = 26,200
Zero outcomes = 20,389
Log pseudolikelihood = -13540.61
Nonzero outcomes = 5,811
(Std. Err. adjusted for 4,434 clusters in idcode)

scobit, vce(cluster clustvar) is robust to assumptions about within-cluster correlation. That is, it inefficiently sums within cluster for the standard error calculation rather than attempting to exploit what might be assumed about the within-cluster correlation (as do the xtgee population-averaged models; see [XT] xtgee).

Technical note
The scobit model can be difficult to fit because of the functional form. Often it requires many iterations, or the optimizer prints out warning and informative messages during the optimization. For example, without the nrtol(1e-3) option, the model using the union dataset will not converge. See [R] Maximize for details about the optimizer.

Technical note
The main reason for using scobit rather that logit is that the effects of the regressors on the probability of success are not constrained to be the largest when the probability is 0.5. Rather, the independent variables might show their largest impact when the probability of success is 0.3 or 0.6. This added flexibility results because the scobit function, unlike the logit function, can be skewed and is not constrained to be mirror symmetric about the 0.5 probability of success.

As Nagler (1994) pointed out, the point of maximum impact is constrained under the scobit model to fall within the interval \((0, 1 - e^{(-1)})\) or approximately \((0, 0.63)\). Achen (2002) notes that if we believe the maximum impact to be outside that range, we can instead estimate the “power logit” model by simply reversing the 0s and 1s of our outcome variable and estimating a scobit model on failure, rather than success. We would need to reverse the signs of the coefficients if we wanted to interpret them in terms of impact on success, or we could leave them as they are and interpret them in terms of impact on failure. The important thing to remember is that the scobit model, unlike the logit model, is not invariant to the choice of which result is assigned to success.
scobit stores the following in e():

Scalars
- **e(N)**: number of observations
- **e(k)**: number of parameters
- **e(k_eq)**: number of equations in e(b)
- **e(k_aux)**: number of auxiliary parameters
- **e(k_dv)**: number of dependent variables
- **e(ll)**: log likelihood
- **e(ll_c)**: log likelihood, comparison model
- **e(N_f)**: number of failures (zero outcomes)
- **e(N_s)**: number of successes (nonzero outcomes)
- **e(alpha)**: alpha
- **e(N_clust)**: number of clusters
- **e(chi2_c)**: $\chi^2$ for comparison test
- **e(rank)**: rank of e(V)
- **e(ic)**: number of iterations
- **e(rc)**: return code
- **e(converged)**: 1 if converged, 0 otherwise

Macros
- **e(cmd)**: scobit
- **e(cmdline)**: command as typed
- **e(depvar)**: name of dependent variable
- **e(wtype)**: weight type
- **e(wexp)**: weight expression
- **e(title)**: title in estimation output
- **e(clustvar)**: name of cluster variable
- **e(offset)**: linear offset variable
- **e(chi2_ct)**: Wald or LR; type of model $\chi^2$ test corresponding to e(chi2_c)
- **e(vce)**: vcetype specified in vce()
- **e(vcetype)**: title used to label Std. Err.
- **e(opt)**: type of optimization
- **e(which)**: max or min; whether optimizer is to perform maximization or minimization
- **e(ml_method)**: type of ml method
- **e(user)**: name of likelihood-evaluator program
- **e(technique)**: maximization technique
- **e(properties)**: b V
- **e(predict)**: program used to implement predict
- **e(footnote)**: program used to implement the footnote display
- **e(asbalanced)**: factor variables fvset as asbalanced
- **e(asobserved)**: factor variables fvset as asobserved

Matrices
- **e(b)**: coefficient vector
- **e(Cns)**: constraints matrix
- **e(ilog)**: iteration log (up to 20 iterations)
- **e(gradient)**: gradient vector
- **e(V)**: variance–covariance matrix of the estimators
- **e(V_modelbased)**: model-based variance

Functions
- **e(sample)**: marks estimation sample
Methods and formulas

Skewed logit analysis is an alternative to logit that relaxes the assumption that individuals with initial probability of 0.5 are most sensitive to changes in independent variables.

The log-likelihood function for skewed logit is

\[
\ln L = \sum_{j \in S} w_j \ln F(x_j b) + \sum_{j \notin S} w_j \ln \{1 - F(x_j b)\}
\]

where \(S\) is the set of all observations \(j\) such that \(y_j \neq 0\), \(F(z) = 1 - 1/(1 + \exp(z))^{\alpha}\), and \(w_j\) denotes the optional weights. \(\ln L\) is maximized as described in [R] Maximize.

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using \(\text{vce(robust)}\) and \(\text{vce(cluster clustvar)}\), respectively. See [P] \_robust, particularly Maximum likelihood estimators and Methods and formulas.

\text{scobit} also supports estimation with survey data. For details on VCEs with survey data, see [SVY] Variance estimation.

* `forecast` and `lrtest` are not appropriate with `svy` estimation results.
predict

Description for predict

predict creates a new variable containing predictions such as probabilities, linear predictions, and standard errors.

Menu for predict

Statistics > Postestimation

Syntax for predict

```
predict [type] newvar [if] [in] [, statistic nooffset]
predict [type] { stub* newvar_reg newvar_inalpha } [if] [in] , scores
```

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>pr</td>
<td>probability of a positive outcome; the default</td>
</tr>
<tr>
<td>xb</td>
<td>$x_j \beta$, linear prediction</td>
</tr>
<tr>
<td>stdp</td>
<td>standard error of the linear prediction</td>
</tr>
</tbody>
</table>

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

Options for predict

- **Main**
  - **pr**, the default, calculates the probability of a positive outcome.
  - **xb** calculates the linear prediction.
  - **stdp** calculates the standard error of the linear prediction.

- **nooffset** is relevant only if you specified `offset(varname)` for `scobit`. It modifies the calculations made by `predict` so that they ignore the offset variable; the linear prediction is treated as $x_j \beta$ rather than as $x_j \beta + \text{offset}_j$.

- **scores** calculates equation-level score variables.
  The first new variable will contain $\partial \ln L / \partial (x_j \beta)$.
  The second new variable will contain $\partial \ln L / \partial \ln \alpha$. 
margins

Description for margins

margins estimates margins of response for probabilities and linear predictions.

Menu for margins

Statistics > Postestimation

Syntax for margins

margins [marginlist] [, options]

margins [marginlist], predict(statistic ...) [predict(statistic ...) ...] [options]

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>pr</td>
<td>probability of a positive outcome; the default</td>
</tr>
<tr>
<td>xb</td>
<td>$x_j b$, linear prediction</td>
</tr>
<tr>
<td>stdp</td>
<td>not allowed with margins</td>
</tr>
</tbody>
</table>

Statistics not allowed with margins are functions of stochastic quantities other than $e(b)$.
For the full syntax, see [R] margins.

Remarks and examples

Once you have fit a model, you can obtain the predicted probabilities by using the predict command for both the estimation sample and other samples; see [U] 20 Estimation and postestimation commands and [R] predict. Here we will make only a few additional comments.

predict without arguments calculates the predicted probability of a positive outcome. With the xb option, it calculates the linear combination $x_j b$, where $x_j$ are the independent variables in the $j$th observation and $b$ is the estimated parameter vector.

With the stdp option, predict calculates the standard error of the prediction, which is not adjusted for replicated covariate patterns in the data.
Example 1

In example 1 of [R] scobit, we fit the model `scobit foreign mpg`. To obtain predicted probabilities, we type

```
. use https://www.stata-press.com/data/r16/auto
   (1978 Automobile Data)
. keep make mpg weight foreign
. scobit foreign mpg
   (output omitted)
. predict p
   (option `pr' assumed; Pr(foreign))
. summarize foreign p
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>foreign</td>
<td>74</td>
<td>.2972973</td>
<td>.4601885</td>
<td>0</td>
<td>1</td>
</tr>
<tr>
<td>p</td>
<td>74</td>
<td>.297405</td>
<td>.182352</td>
<td>.0714664</td>
<td>.871624</td>
</tr>
</tbody>
</table>

[U] 20 Estimation and postestimation commands
**sdtest** — Variance-comparison tests

### Description

sdtest performs tests on the equality of standard deviations (variances). In the first form, sdtest tests that the standard deviation of *varname* is #. In the second form, sdtest performs the same test, using the standard deviations of the two groups defined by *groupvar*. In the third form, sdtest tests that *varname*₁ and *varname*₂ have the same standard deviation.

sdtesti is the immediate form of sdtest; see [U] 19 Immediate commands.

Both the traditional *F* test for the homogeneity of variances and Bartlett’s generalization of this test to *K* samples are sensitive to the assumption that the data are drawn from an underlying Gaussian distribution. See, for example, the cautionary results discussed by Markowski and Markowski (1990). Levene (1960) proposed a test statistic for equality of variance that was found to be robust under nonnormality. Then Brown and Forsythe (1974) proposed alternative formulations of Levene’s test statistic that use more robust estimators of central tendency in place of the mean. These reformulations were demonstrated to be more robust than Levene’s test when dealing with skewed populations.

robvar reports Levene’s robust test statistic (*W*₀) for the equality of variances between the groups defined by *groupvar* and the two statistics proposed by Brown and Forsythe that replace the mean in Levene’s formula with alternative location estimators. The first alternative (*W*₅₀) replaces the mean with the median. The second alternative replaces the mean with the 10% trimmed mean (*W*₁₀).

### Quick start

Test that the standard deviation of *v*₁ is equal to 2  

```
  sdtest v1=2
```

Equality of standard deviations (variances) test for *v*₁ comparing the two groups defined by *catvar*₁  

```
  sdtest v1, by(catvar1)
```

Robust equality of variances test for *v*₁ comparing the groups defined by *catvar*₁  

```
  robvar v1, by(catvar1)
```

Compare the variances of *v*₂ and *v*₃  

```
  sdtest v2 == v3
```

As above, but with separate tests for each group defined by *catvar*₂  

```
  by catvar2, sort: sdtest v2 == v3
```

Test *sd*₁ = *sd*₂ for *sd*₁ = 34, *sd*₂ = 45, *N*₁ = 143, and *N*₂ = 184  

```
  sdtesti 143 . 34 184 . 45
```

sdtesti
Statistics > Summaries, tables, and tests > Classical tests of hypotheses > Variance-comparison test calculator

robvar
Statistics > Summaries, tables, and tests > Classical tests of hypotheses > Robust equal-variance test

Syntax

One-sample variance-comparison test

```
sdtest varname == # [if] [in] [, level(#)]
```

Two-sample variance-comparison test using groups

```
sdtest varname [if] [in], by(groupvar) [level(#)]
```

Two-sample variance-comparison test using variables

```
sdtest varname1 == varname2 [if] [in] [, level(#)]
```

Immediate form of one-sample variance-comparison test

```
sdtesti #obs { #mean | . } #sd #val [, level(#)]
```

Immediate form of two-sample variance-comparison test

```
sdtesti #obs,1 { #mean,1 | . } #sd,1 #obs,2 { #mean,2 | . } #sd,2 [, level(#)]
```

Robust tests for equality of variances

```
robvar varname [if] [in], by(groupvar)
```

by is allowed with sdtest and robvar; see [D] by.

Options

`level(#)` specifies the confidence level, as a percentage, for confidence intervals of the means. The default is `level(95)` or as set by `set level`; see [U] 20.8 Specifying the width of confidence intervals.

`by(groupvar)` specifies the `groupvar` that defines the groups to be compared. For `sdtest`, there should be two groups, but for `robvar` there may be more than two groups. Do not confuse the `by()` option with the `by` prefix; both may be specified.
Remarks and examples

Remarks are presented under the following headings:

- Basic form
- Immediate form
- Robust test

Basic form

`sdtest` performs two different statistical tests: one testing equality of variances and the other testing that the standard deviation is equal to a known constant. Which test it performs is determined by whether you type a variable name or a number to the right of the equal sign.

Example 1: One-sample test of variance

We have a sample of 74 automobiles. For each automobile, we know the mileage rating. We wish to test whether the overall standard deviation is 5 mpg:

```
. use https://www.stata-press.com/data/r16/auto
   (1978 Automobile Data)
. sdtest mpg == 5
One-sample test of variance
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>Std. Dev.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>mpg</td>
<td>74</td>
<td>21.2973</td>
<td>.6725511</td>
<td>5.785503</td>
<td>19.9569   22.63769</td>
</tr>
</tbody>
</table>

\[
\text{sd} = \text{sd(mpg)} \\
\text{c} = \text{chi2} = 97.7384 \\
\text{Ho: sd} = 5 \\
\text{degrees of freedom} = 73 \\
\text{Ha: sd} < 5 \\
\text{Pr(C < c)} = 0.9717 \\
\text{2*Pr(C > c)} = 0.0565 \\
\text{Pr(C > c)} = 0.0283
\]

Example 2: Variance ratio test

We are testing the effectiveness of a new fuel additive. We run an experiment on 12 cars, running each without and with the additive. The data can be found in [R] `ttest`. The results for each car are stored in the variables `mpg1` and `mpg2`:

```
. use https://www.stata-press.com/data/r16/fuel
. sdtest mpg1==mpg2
Variance ratio test
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>Std. Dev.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>mpg1</td>
<td>12</td>
<td>21</td>
<td>.7881701</td>
<td>2.730301</td>
<td>19.26525  22.73475</td>
</tr>
<tr>
<td>mpg2</td>
<td>12</td>
<td>22.75</td>
<td>.9384465</td>
<td>3.250874</td>
<td>20.68449  24.81551</td>
</tr>
<tr>
<td>combined</td>
<td>24</td>
<td>21.875</td>
<td>.6264476</td>
<td>3.068954</td>
<td>20.57909  23.17091</td>
</tr>
</tbody>
</table>

\[
\text{combined} = \frac{\text{sd(mpg1)}}{\text{sd(mpg2)}} \\
\text{f} = 0.7054 \\
\text{degrees of freedom} = 11, 11 \\
\text{Ha: ratio} < 1 \\
\text{Pr(F < f)} = 0.2862 \\
\text{2*Pr(F < f)} = 0.5725 \\
\text{Pr(F > f)} = 0.7138
\]

We cannot reject the hypothesis that the standard deviations are the same.
In [R] `ttest`, we draw an important distinction between paired and unpaired data, which, in this example, means whether there are 12 cars in a before-and-after experiment or 24 different cars. For `sdtest`, on the other hand, there is no distinction. If the data had been unpaired and stored as described in [R] `ttest`, we could have typed `sdtest mpg, by(treated)`, and the results would have been the same.

**Immediate form**

> **Example 3: sdtesti**

Immediate commands are used not with data, but with reported summary statistics. For instance, to test whether a variable on which we have 75 observations and a reported standard deviation of 6.5 comes from a population with underlying standard deviation 6, we would type

```
    . sdtesti 75 . 6.5 6
    One-sample test of variance

    | Obs  | Mean  | Std. Err. | Std. Dev. | [95% Conf. Interval] |
    |------|-------|-----------|-----------|----------------------|
    | x    | 75    | 0.7505553 | 6.5       | .                    |

    sd = sd(x)       c = chi2 = 86.8472
    Ho: sd = 6       degrees of freedom = 74
    Ha: sd < 6       Ha: sd != 6          Ha: sd > 6
    Pr(C < c) = 0.8542 2*Pr(C > c) = 0.2916 Pr(C > c) = 0.1458
```

The mean plays no role in the calculation, so it may be omitted.

To test whether the variable comes from a population with the same standard deviation as another for which we have a calculated standard deviation of 7.5 over 65 observations, we would type

```
    . sdtesti 75 . 6.5 65 . 7.5
    Variance ratio test

    | Obs  | Mean  | Std. Err. | Std. Dev. | [95% Conf. Interval] |
    |------|-------|-----------|-----------|----------------------|
    | x    | 75    | 0.7505553 | 6.5       | .                    |
    | y    | 65    | 0.9302605 | 7.5       | .                    |
    | combined | 140 | .       | .       | .                   |

    ratio = sd(x) / sd(y)   f = 0.7511
    Ho: ratio = 1           degrees of freedom = 74, 64
    Ha: ratio < 1           Ha: ratio != 1          Ha: ratio > 1
    Pr(F < f) = 0.1172      2*Pr(F < f) = 0.2344 Pr(F > f) = 0.8828
```
Robust test

Example 4: robvar

We wish to test whether the standard deviation of the length of stay for patients hospitalized for a given medical procedure differs by gender. Our data consist of observations on the length of hospital stay for 1778 patients: 884 males and 894 females. Length of stay, \texttt{lengthstay}, is highly skewed (skewness coefficient = 4.912591) and thus violates Bartlett’s normality assumption. Therefore, we use \texttt{robvar} to compare the variances.

\begin{verbatim}
. use https://www.stata-press.com/data/r16/stay
. robvar lengthstay, by(sex)
\end{verbatim}

\begin{verbatim}
<table>
<thead>
<tr>
<th>Gender</th>
<th>Summary of Length of stay in days</th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Mean</td>
<td>Std. Dev.</td>
<td>Freq.</td>
</tr>
<tr>
<td>male</td>
<td>9.0874434</td>
<td>9.7884747</td>
<td>884</td>
</tr>
<tr>
<td>female</td>
<td>8.800671</td>
<td>9.1081478</td>
<td>894</td>
</tr>
<tr>
<td>Total</td>
<td>8.9432508</td>
<td>9.4509466</td>
<td>1778</td>
</tr>
</tbody>
</table>
\end{verbatim}

\[ W_0 = 0.55505315 \quad df(1, 1776) \quad Pr > F = 0.45635888 \]
\[ W_{50} = 0.42714734 \quad df(1, 1776) \quad Pr > F = 0.51347664 \]
\[ W_{10} = 0.44577674 \quad df(1, 1776) \quad Pr > F = 0.50443411 \]

For these data, we cannot reject the null hypothesis that the variances are equal. However, Bartlett’s test yields a significance probability of 0.0319 because of the pronounced skewness of the data.

Technical note

\texttt{robvar} implements both the conventional Levene’s test centered at the mean and a median-centered test. In a simulation study, Conover, Johnson, and Johnson (1981) compare the properties of the two tests and recommend using the median test for asymmetric data, although for small sample sizes the test is somewhat conservative. See Carroll and Schneider (1985) for an explanation of why both mean- and median-centered tests have approximately the same level for symmetric distributions, but for asymmetric distributions the median test is closer to the correct level.

Stored results

\texttt{sdtest} and \texttt{sdtesti} store the following in \texttt{r()}:  

 Scalars  
 \( r(N) \) number of observations  
 \( r(p_{-1}) \) lower one-sided \( p \)-value  
 \( r(p_{-u}) \) upper one-sided \( p \)-value  
 \( r(p) \) two-sided \( p \)-value  
 \( r(F) \) \( F \) statistic  
 \( r(sd) \) standard deviation  
 \( r(sd_{-1}) \) standard deviation for first variable  
 \( r(sd_{-2}) \) standard deviation for second variable  
 \( r(df) \) degrees of freedom  
 \( r(df_{-1}) \) numerator degrees of freedom  
 \( r(df_{-2}) \) denominator degrees of freedom  
 \( r(chi2) \) \( \chi^2 \)
robvar stores the following in r():

Scalars

- \text{r(N)}: number of observations
- \text{r(w50)}: Brown and Forsythe’s F statistic (median)
- \text{r(p_w50)}: Brown and Forsythe’s p-value
- \text{r(w0)}: Levene’s F statistic
- \text{r(p_w0)}: Levene’s p-value
- \text{r(w10)}: Brown and Forsythe’s F statistic (trimmed mean)
- \text{r(p_w10)}: Brown and Forsythe’s p-value (trimmed mean)
- \text{r(df_1)}: numerator degrees of freedom
- \text{r(df_2)}: denominator degrees of freedom

Methods and formulas

See Armitage et al. (2002, 149–153) or Bland (2015, 144–145) for an introduction and explanation of the calculation of these tests.

The test for \( \sigma = \sigma_0 \) is given by

\[
\chi^2 = \frac{(n-1)s^2}{\sigma_0^2}
\]

which is distributed as \( \chi^2 \) with \( n - 1 \) degrees of freedom.

The test for \( \sigma_x^2 = \sigma_y^2 \) is given by

\[
F = \frac{s_x^2}{s_y^2}
\]

which is distributed as \( F \) with \( n_x - 1 \) and \( n_y - 1 \) degrees of freedom.

Let \( X_{ij} \) be the \( j \)th observation of \( X \) for the \( i \)th group. Let \( Z_{ij} = |X_{ij} - \bar{X}_i| \), where \( \bar{X}_i \) is the mean of \( X \) in the \( i \)th group. Levene’s test statistic is

\[
W_0 = \frac{\sum_i n_i (Z_i - \bar{Z})^2 / (g - 1)}{\sum_i \sum_j (Z_{ij} - \bar{Z}_i)^2 / \sum_i (n_i - 1)}
\]

where \( n_i \) is the number of observations in group \( i \) and \( g \) is the number of groups. \( W_{50} \) is obtained by replacing \( \bar{X}_i \) with the \( i \)th group median of \( X_{ij} \), whereas \( W_{10} \) is obtained by replacing \( \bar{X}_i \) with the 10% trimmed mean for group \( i \).

**Description**

`search` searches a keyword database and the Internet for Stata materials related to your query. Capitalization of the words following `search` is irrelevant, as is the inclusion or exclusion of special characters such as commas and hyphens.

`set searchdefault` affects the default behavior of the `search` command. `all` is the default. `search`, `all` is the best way to search for information on a topic across all sources, including the system help, the FAQs at the Stata website, the *Stata Journal*, and all Stata-related Internet sources including community-contributed additions. From the results, you can click to go to a source or to install additions.

**Quick start**

Search local keyword database and materials available via Stata’s `net` command for all words (word1, word2, and word3)

```
search word1 word2 word3
```

As above, but match any word (word1, word2, or word3)

```
search word1 word2 word3, or
```

Search for *Stata Journal* articles about new commands like `regress`

```
search regress, sj
```

Search the manuals for entries about `tabulate` and related commands

```
search tabulate, manual
```

**Menu**

Help > Search...
Syntax

```
search word [word ...] [, search_options]
```

```
set searchdefault {all|local|net} [, permanently]
```

<table>
<thead>
<tr>
<th>search_options</th>
<th>Description</th>
</tr>
</thead>
<tbody>

</tr>
<tr>
<td>sj</td>
<td>search the entries in the Stata Journal and the STB</td>
</tr>
</tbody>
</table>

Options for search

all, the default (unless changed by `set searchdefault`), specifies that the search be performed across both the local keyword database and the net materials. The results of a search performed with `all` and no other options will be displayed in the Viewer window.

local specifies that the search be performed using only Stata’s keyword database. The results of a search performed with `local` and no other options will be displayed in the Viewer window.

net specifies that the search be performed across the materials available via Stata’s net command. Using `search word [word ...]`, net is equivalent to typing `net search word [word ...]` (without options); see [R] net search. The results of a search performed with `net` and no other options will be displayed in the Viewer window.

author specifies that the search be performed on the basis of the author’s name rather than keywords. A search with the `author` option is performed on the local keyword database only, and the results are displayed in the Results window.

entry specifies that the search be performed on the basis of entry IDs rather than keywords. A search with the `entry` option is performed on the local keyword database only, and the results are displayed in the Results window.

exact prevents matching on abbreviations. A search with the `exact` option is performed across both the local keyword database and the net materials, and the results are displayed in the Results window.

faq limits the search to the FAQs posted on the Stata website: [https://www.stata.com](https://www.stata.com). A search with the `faq` option is performed on the local keyword database only, and the results are displayed in the Results window.
historical adds to the search entries that are of historical interest only. By default, such entries are not listed. Past entries are classified as historical if they discuss a feature that later became an official part of Stata. Updates to historical entries will always be found, even if historical is not specified. A search with the historical option is performed on the local keyword database only, and the results are displayed in the Results window.

or specifies that an entry be listed if any of the words typed after search are associated with the entry. The default is to list the entry only if all the words specified are associated with the entry. A search with the or option is performed on the local keyword database only, and the results are displayed in the Results window.

manual limits the search to entries in the Stata Documentation; that is, the search is limited to the User’s Guide and all the reference manuals. A search with the manual option is performed on the local keyword database only, and the results are displayed in the Results window.

sj limits the search to entries in the Stata Journal and its predecessor, the Stata Technical Bulletin; see [R] sj. A search with the sj option is performed on the local keyword database only, and the results are displayed in the Results window.

Option for set searchdefault

permanently specifies that, in addition to making the change right now, the searchdefault setting be remembered and become the default setting when you invoke Stata.

Remarks and examples

Remarks are presented under the following headings:

- Introduction
- Internet searches
- Author searches
- Entry ID searches
- Return codes

Introduction

See [U] 4 Stata’s help and search facilities for a tutorial introduction to search. search is one of Stata’s most useful commands. To understand the advanced features of search, you need to know how it works.

search has a database—files—containing the titles, etc., of every entry in the Stata Documentation, undocumented help files, NetCourses, Stata Press books, FAQs posted on the Stata website, videos posted on the Stata YouTube channel, selected articles on StataCorp’s official blog, selected community-contributed FAQs and examples, and the articles in the Stata Journal and the Stata Technical Bulletin. In these files is a list of words, called keywords, associated with each entry.

When you type search xyz, search reads the database and compares the list of keywords with xyz. If it finds xyz in the list or a keyword that allows an abbreviation of xyz, it displays the entry.

When you type search xyz abc, search does the same thing but displays an entry only if it contains both keywords. The order does not matter, so you can search linear regression or search regression linear.
Obviously, how many entries `search` finds depends on how the search database was constructed. We have included a plethora of keywords under the theory that, for a given request, it is better to list too much rather than risk listing nothing at all. Still, you are in the position of guessing the keywords. Do you look up normality test, normality tests, or tests of normality? Well, normality test would be best, but all would work. In general, use the singular, and strike the unnecessary words. For guidelines for specifying keywords, see [U] 4.6 More on search.

`set searchdefault` allows you to specify where `search` searches. `set searchdefault all`, the default, indicates that both the keyword database and the Internet are to be searched. `set searchdefault local` restricts `search` to using only Stata’s keyword database. `set searchdefault net` restricts `search` to searching only the Internet.

**Internet searches**

`search` with the `net` option searches the Internet for community-contributed additions to Stata, including, but not limited to, community-contributed additions published in the *Stata Journal* (SJ) and the *Stata Technical Bulletin* (STB). `search` `keywords`, `net` performs the same search as the command `net search` (with no options); see [R] `net search`.

```plaintext
.search random effect, net

   Grotti, / Department of Political and Social Sciences / European
   University Institute / San Domenico di Fiesole, Italy / Giorgio Cutuli,
(output omitted)
(end of search)
```

**Author searches**

`search` ordinarily compares the words following `search` with the keywords for the entry. If you specify the `author` option, however, it compares the words with the author’s name. In the search database, we have filled in author names for all SJ and STB inserts.

For instance, in [R] `kdensity` in this manual you will discover that Isaías H. Salgado-Ugarte wrote the first version of Stata’s `kdensity` command and published it in the STB. Assume that you read his original insert and found the discussion useful. You might now wonder what else he has written in the SJ or STB. To find out, you type

```plaintext
.search Salgado-Ugarte, author
(output omitted)
```
Names like Salgado-Ugarte are confusing to many people. `search` does not require you to specify the entire name; what you type is compared with each “word” of the name and, if any part matches, the entry is listed. The hyphen is a special character, and you can omit it. Thus you can obtain the same list by looking up Salgado, Ugarte, or Salgado Ugarte without the hyphen.

Actually, to find all entries written by Salgado-Ugarte, you need to type

```
.search Salgado-Ugarte, author historical
(output omitted)
```

Prior inserts in the SJ or STB that provide a feature that later was superseded by a built-in feature of Stata are marked as historical in the search database and, by default, are not listed. The `historical` option ensures that all entries are listed.

**Entry ID searches**

If you specify the `entry` option, `search` compares what you have typed with the entry ID. The entry ID is not the title—it is the reference listed to the left of the title that tells you where to look. For instance, in

```
[R] regress ........................................ Linear regression
(help regress)
```

`[R] regress` is the entry ID. This is a reference, of course, to this manual. In

```
FAQ .............................. Analysis of multiple failure-time survival data
.................................................. M. Cleves and I. Canette
07/09 How do I analyze multiple failure-time data using Stata?
```

“FAQ” is the entry ID. In

```
SJ-7-1 st0118 .. A survey on survey stat.: What is and can be done in Stata
.................................................. F. Kreuter and R. Valliant
Q1/07 SJ7(1):1--21 ................................ (no commands)
```

“SJ-7-1” is the entry ID.

`search` with the `entry` option searches these entry IDs.

Thus you could generate a table of contents for the *User’s Guide* by typing

```
.search [U], entry
(output omitted)
```

You could generate a table of contents for *Stata Journal*, Volume 1, Issue 1, by typing

```
.search sj-1-1, entry
(output omitted)
```

To generate a table of contents for the 26th issue of the STB, you would type

```
.search STB-26, entry historical
(output omitted)
```

The `historical` option here is important. STB-26 was published in July 1995, and its inserts have been marked as historical.
Return codes

In addition to indexing the entries in the User's Guide and all the Reference manuals, search also can be used to search return codes.

To see information on return code 131, type

```
.search rc 131
```

```
[P] error ........................................ Return code 131
    not possible with test;
    You requested a test of a hypothesis that is nonlinear in the
    variables.  test tests only linear hypotheses.  Use testnl.
    (output omitted)
```

If you want a list of all Stata return codes, type

```
.search error, entry
```

(output omitted)

Acknowledgment

We thank Nicholas J. Cox of the Department of Geography at Durham University, UK, and coeditor of the Stata Journal and author of Speaking Stata Graphics for his contributions to the search command.

[U] 4 Stata's help and search facilities
serrbar — Graph standard error bar chart

Description

serrbar is typically used with a dataset containing means, standard deviations or standard errors, and an xvar. serrbar uses this data to create a standard error bar chart. The means are plotted against xvar, and error bars around the means have a width determined by the standard deviation or standard error. While it is most common to use serrbar with this type of data, serrbar may also be used to create a scatterplot with error bars for other types of data.

Quick start

Plot of y versus x with error bars representing y ± s

serrbar y s x

As above, but with error bars for y ± 2 × s

serrbar y s x, scale(2)

Menu

Statistics > Other > Quality control > Standard error bar chart
Syntax

```
serrbar mvar svar xvar [if] [in] [, options]
```

<table>
<thead>
<tr>

<tr>
<td>Y axis, X axis, Titles, Legend, Overall</td>
<td>Any options other than <code>by()</code> documented in [G-3] <code>twoway_options</code></td>
</tr>
</tbody>
</table>

Options

- **Main**
  - `scale(#)` controls the length of the bars. The upper and lower limits of the bars will be `mvar + scale() * svar` and `mvar - scale() * svar`. The default is `scale(1)`.

- **Error bars**
  - `rcap_options` affect the rendition of the plotted error bars (the capped spikes). See [G-2] `graph twoway rcap`.

- **Plotted points**
  - `mvopt(scatter_options)` affects the rendition of the plotted points (mvar versus xvar). See [G-2] `graph twoway scatter`.

- **Add plots**
  - `addplot(plot)` provides a way to add other plots to the generated graph; see [G-3] `addplot_option`.

- **Y axis, X axis, Titles, Legend, Overall**
  - `twoway_options` are any of the options documented in [G-3] `twoway_options`, excluding `by()`. These include options for titling the graph (see [G-3] `title_options`) and for saving the graph to disk (see [G-3] `saving_option`).
Remarks and examples

Example 1

In quality-control applications, the three most commonly used variables with this command are the process mean, process standard deviation, and time. For instance, we have data on the average weights and standard deviations from an assembly line in San Francisco for the period January 8 to January 16. Our data are

```
.use https://www.stata-press.com/data/r16/assembly
.list, sep(0) divider
```

<table>
<thead>
<tr>
<th>date</th>
<th>mean</th>
<th>std</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>108</td>
<td>192.22</td>
</tr>
<tr>
<td>2</td>
<td>109</td>
<td>192.64</td>
</tr>
<tr>
<td>3</td>
<td>110</td>
<td>192.37</td>
</tr>
<tr>
<td>4</td>
<td>113</td>
<td>194.76</td>
</tr>
<tr>
<td>5</td>
<td>114</td>
<td>192.69</td>
</tr>
<tr>
<td>6</td>
<td>115</td>
<td>195.02</td>
</tr>
<tr>
<td>7</td>
<td>116</td>
<td>193.40</td>
</tr>
</tbody>
</table>

We type `serrbar mean std date, scale(2)` but, after seeing the result, decide to make it fancier:

```
serrbar mean std date, scale(2) title("Observed Weight Variation")
> sub("San Francisco plant, 1/8 to 1/16") yline(195) yaxis(1 2)
> ylab(195, axis(2)) ytitle("", axis(2))
```

Acknowledgment

`serrbar` was written by Nicholas J. Cox of the Department of Geography at Durham University, UK, and coeditor of the *Stata Journal* and author of *Speaking Stata Graphics*.

[R] QC — Quality control charts
Description

This entry provides a reference to Stata’s set commands. For many entries, more thorough information is provided elsewhere; see the Reference field in each entry below for the location of this information.

To reset system parameters to factory defaults, see [R] set_defaults.

Syntax

```
set [ setcommand ...]
```

set typed without arguments is equivalent to query typed without arguments.

Remarks and examples

**set adosize**

Syntax: `set adosize # [, permanently]`
Default: 1,000
Description: sets the maximum amount of memory that automatically loaded do-files may consume. $10 \leq # \leq 10000$.
Reference: [P] sysdir

**set autotabgraphs** (Windows only)

Syntax: `set autotabgraphs {on | off} [, permanently]`
Default: off
Description: determines whether graphs are created as tabs within one window or as separate windows.

**set cformat**

Syntax: `set cformat [fmt] [, permanently]`
Description: specifies the output format of coefficients, standard errors, and confidence limits in coefficient tables. `fmt` is a numerical format; see [D] format.
Reference: [R] set cformat

**set checksum**

Syntax: `set checksum {on | off} [, permanently]`
Default: off
Description: determines whether files should be prevented from being downloaded from the Internet if checksums do not match.
Reference: [D] checksum
set clevel
Syntax: set clevel # [, permanently]
Default: 95
Description: sets the default credible level for credible intervals for all commands
that report credible intervals. \[10.00 \leq # \leq 99.99\], and # can have at
most two digits after the decimal point.
Reference: [BAYES] set clevel

set coeftabresults
Syntax: set coeftabresults {on|off}
Default: on
Description: determines whether coefficient table results are stored in \(r()\).
There is no permanently option because permanently is implied.

set conren (Unix console only)
Syntax 1: set conren
Syntax 2: set conren clear
Syntax 3: set conren [sf | bf | it]
\{result | [txt | text] | input | error | link | hilite\}
\{char [char ...]\}
Syntax 4: set conren {ulen | uloff} [char [char ...]]
Syntax 5: set conren reset [char [char ...]]
Description: can possibly make the output on your screen appear prettier.
set conren displays a list of the currently defined display codes.
set conren clear clears all codes.
set conren followed by a font type (bf, sf, or it) and display context (result,
error, link, or hilite) and then followed by a series of space-separated
characters sets the code for the specified font type and display context. If the font
type is omitted, the code is set to the same specified code for all three font types.
set conren ulon and set conren uloff set the codes for turning on and off
underlining.
set conren reset sets the code that will turn off all display and underlining codes.
Reference: [GSU] conren

set copycolor (Mac and Windows only)
Syntax: set copycolor \{automatic | asis | gs1 | gs2 | gs3\} [, permanently]
Default: automatic
Description: determines how colors are handled when graphs are copied to the Clipboard.
Reference: [G-2] set printcolor

set dockable (Windows only)
Syntax: set dockable {on | off} [, permanently]
Default: on
Description: determines whether to enable the use of dockable window characteristics,
including the ability to dock or tab a window into another window.
set dots
Syntax: set dots \{on | off\} [, permanently]
Default: on
Description: enables or disables commands that support the dots() option from reporting a dot each time statistics are computed from a sample or resample of the dataset.

set doublebuffer (Windows only)
Syntax: set doublebuffer \{on | off\} [, permanently]
Default: on
Description: enables or disables double buffering of the Results, Viewer, and Data Editor windows. Double buffering prevents the windows from flickering when redrawn or resized. Users who encounter performance problems such as the Results window outputting very slowly should disable double buffering.

set dp
Syntax: set dp \{comma | period\} [, permanently]
Default: period
Description: determines whether a period or a comma is to be used as the decimal point.
Reference: [D] format

set emptycells
Syntax: set emptycells \{keep | drop\} [, permanently]
Default: keep
Description: sets what to do with empty cells in interactions.
Reference: [R] set emptycells

set fastscroll (Unix and Windows only)
Syntax: set fastscroll \{on | off\} [, permanently]
Default: on
Description: sets the scrolling method for new output in the Results window. Setting fastscroll to on is faster but can be jumpy. Setting fastscroll to off is slower but smoother.

set floatwindows (Windows only)
Syntax: set floatwindows \{on | off\}
Default: off
Description: determines whether to enable floating window behavior for dialog boxes and dockable window. The term “float” in this context means that a window will always float over the main Stata window; these windows cannot be placed behind the main Stata window. There is no permanently option because permanently is implied.
set fredkey
Syntax: \texttt{set fredkey key [\textbackslash, permanently]}  
Description: sets the API key for importing data from the Federal Reserve Economic Data.  
Reference: [D] \texttt{import fred}

set fvbase
Syntax: \texttt{set fvbase \{on | off\}}  
Description: specifies whether to automatically determine the default base level for factor variables.

set fvlabel
Syntax: \texttt{set fvlabel \{on | off\} [\textbackslash, permanently]}  
Description: specifies whether to display factor-variable value labels in coefficient tables.  
Reference: [R] \texttt{set showbaselevels}

set fvtrack
Syntax: \texttt{set fvtrack \{term | factor\} [\textbackslash, permanently]}  
Description: allows you to control how Stata keeps track of factor levels when you use factor-variables notation.

set fvwrap
Syntax: \texttt{set fvwrap \# [\textbackslash, permanently]}  
Description: specifies that long value labels wrap \# lines in coefficient tables.  
Reference: [R] \texttt{set showbaselevels}

set fvwrapon
Syntax: \texttt{set fvwrapon \{word | width\} [\textbackslash, permanently]}  
Description: specifies whether value labels that wrap will break at word boundaries or break based on available space.  
Reference: [R] \texttt{set showbaselevels}

set graphics
Syntax: \texttt{set graphics \{on | off\}}  
Default: on; default is off for console Stata  
Description: determines whether graphs are displayed on your monitor.  
Reference: [G-2] \texttt{set graphics}

set haverdir
Syntax: \texttt{set haverdir "path" [\textbackslash, permanently]}  
Description: specifies the directory where the Haver databases are stored.  
Reference: [D] \texttt{import haver}

set httpproxy
Syntax: \texttt{set httpproxy \{on | off\} [\textbackslash, init]}  
Default: off  
Description: turns on/off the use of a proxy server. There is no permanently option because permanently is implied.  
Reference: [R] \texttt{netio}
set httpproxyauth
Syntax:    set httpproxyauth {on|off}
Default:   off
Description: determines whether authorization is required for the proxy server.
            There is no permanently option because permanently is implied.
Reference: [R] netio

set httpproxyhost
Syntax:    set httpproxyhost ""name"
Description: sets the name of a host to be used as a proxy server. There is no permanently option because permanently is implied.
Reference: [R] netio

set httpproxyport
Syntax:    set httpproxyport #
Default:   8080 if Stata cannot autodetect the proper setting for your computer.
Description: sets the port number for a proxy server. There is no permanently option because permanently is implied.
Reference: [R] netio

set httpproxypw
Syntax:    set httpproxypw ""password"
Description: sets the appropriate password. There is no permanently option because permanently is implied.
Reference: [R] netio

set httpproxyuser
Syntax:    set httpproxyuser ""name"
Description: sets the appropriate user ID. There is no permanently option because permanently is implied.
Reference: [R] netio

set include_bitmap (Mac only)
Syntax:    set include_bitmap {on|off} [ , permanently ]
Default:   on
Description: sets the output behavior when copying an image to the Clipboard.

set iterlog
Syntax:    set iterlog {on|off} [ , permanently ]
Description: specifies whether to display an iteration log.
Reference: [R] set iter
set java_heapmax
Syntax: set java_heapmax {default | \# \[m|g\]}
Description: sets the maximum amount of heap memory allocated for the Java Virtual Machine.
Reference: set java_heapmax is a synonym for java set heapmax; see [P] Java utilities

set java_home
Syntax: set java_home {default | "path_to_java_home_dir"}
Description: sets the path to the Java Runtime Environment.
Reference: set java_home is a synonym for java set home; see [P] Java utilities

set level
Syntax: set level \# [\, permanently]
Default: 95
Description: sets the default confidence level for confidence intervals for all commands that report confidence intervals. 10.00 ≤ \# ≤ 99.99, and \# can have at most two digits after the decimal point.
Reference: [R] level

set linegap
Syntax: set linegap \#
Default: 1
Description: sets the space between lines, in pixels, in the Results window. There is no permanently option because permanently is implied.

set linesize
Syntax: set linesize \#
Default: 1 less than the full width of the screen
Description: sets the line width, in characters, for both the screen and the log file.
Reference: [R] log

set locale_functions
Syntax: set locale_functions locale
Default: en_US
Description: sets the locale to be used by functions that take locale as an optional argument.
Reference: [P] set locale_functions

set locale_ui
Syntax: set locale_ui locale
Default: en_US
Description: sets the locale that Stata uses for the user interface.
Reference: [P] set locale_ui

set locksplitters (Windows only)
Syntax: set locksplitters \{on|off\} [\, permanently]
Default: off
Description: determines whether splitters should be locked so that docked windows cannot be resized.
set logtype
Syntax: set logtype {text|smcl} [, permanently]
Default: smcl
Description: sets the default log filetype.
Reference: [R] log

set lstretch
Syntax: set lstretch [on|off] [, permanently]
Default: on
Description: specifies whether to automatically widen the coefficient table up to the width of the Results window to accommodate longer variable names.

set matacache, set matafavor, set matalibs, set matalnum, set matamofirst,
set mataoptimize, and set matastrict; see [M-3] mata set.

set maxdb
Syntax: set maxdb # [, permanently]
Default: 50
Description: sets the maximum number of dialog boxes whose contents are remembered from one invocation to the next during a session. \(5 \leq # \leq 1000\)
Reference: [R] db

set maxiter
Syntax: set maxiter # [, permanently]
Default: 16000
Description: sets the default maximum number of iterations for estimation commands. \(0 \leq # \leq 16000\)
Reference: [R] set iter

set max_memory
Syntax: set max_memory # [b|k|m|g] [, permanently]
Default: . (all the memory the operating system will supply)
Description: specifies the maximum amount of memory Stata can use to store your data. \(2 \times \text{segmentsize} \leq # \leq .\)
Reference: [D] memory

set max_preservemem
Syntax: set max_preservemem # [b|k|m|g] [, permanently]
Default: 1g (1 gigabyte)
Description: controls the maximum amount of memory preserve will use to store preserved datasets in memory.
Reference: [P] preserve

set maxvar
Syntax: set maxvar # [, permanently]
Default: 5000 for Stata/MP and Stata/SE and 2048 for Stata/IC
Description: sets the maximum number of variables. This can be changed only in Stata/MP and Stata/SE. \(2048 \leq # \leq 32767\)
Reference: [D] memory
set min_memory
Syntax: set min_memory [#b | k | m | g] [, permanently]
Default: 0
Description: specifies an amount of memory Stata will not fall below. This setting affects efficiency, not the size of datasets you can analyze. $0 \leq # \leq \text{max}\_memory$
Reference: [D] memory

set more
Syntax: set more {on | off} [, permanently]
Default: off
Description: pauses when —more— is displayed, continuing only when the user presses a key.
Reference: [R] more

set niceness
Syntax: set niceness [#] [, permanently]
Default: 5
Description: affects how soon Stata gives back unused segments to the operating system. $0 \leq # \leq 10$
Reference: [D] memory

set notifyuser (Mac only)
Syntax: set notifyuser {on | off} [, permanently]
Default: on
Description: sets the default Notification Manager behavior in Stata.

set obs
Syntax: set obs #
Default: current number of observations
Description: changes the number of observations in the current dataset. # must be at least as large as the current number of observations. If there are variables in memory, the values of all new observations are set to missing.
Reference: [D] obs

set odbcdriver
Syntax: set odbcdriver {unicode | ansi} [, permanently]
Default: unicode
Description: determines whether Unicode or ANSI is your ODBC driver.
Reference: [D] odbc

set odbcmgr (Mac and Unix only)
Syntax: set odbcmgr {iodbc | unixodbc} [, permanently]
Default: iodbc
Description: determines whether iODBC or unixODBC is your ODBC driver manager.
Reference: [D] odbc
set output
Syntax: set output \{proc|inform|error\}
Default: proc
Description: specifies the output to be displayed. proc means display all output; inform suppresses procedure output but displays informative messages and error messages; error suppresses all output except error messages. set output is seldom used.
Reference: [P] quietly

set pagesize
Syntax: set pagesize #
Default: 2 less than the physical number of lines on the screen
Description: sets the number of lines between —more— messages.
Reference: [R] more

set pformat
Syntax: set pformat [fmt] [, permanently]
Description: specifies the output format of p-values in coefficient tables. fmt is a numerical format; see [D] format.
Reference: [R] set cformat

set pinnable (Windows only)
Syntax: set pinnable \{on|off\} [, permanently]
Default: on
Description: determines whether to enable the use of pinnable window characteristics for certain windows in Stata.

set playsnd (Mac only)
Syntax: set playsnd \{on|off\} [, permanently]
Default: on
Description: sets the sound behavior for the Notification Manager behavior in Stata.

set printcolor
Syntax: set printcolor \{automatic|asis|gs1|gs2|gs3\} [, permanently]
Default: automatic
Description: determines how colors are handled when graphs are printed.
Reference: [G-2] set printcolor

set processors
Syntax: set processors #
Description: sets the number of processors or cores that Stata/MP will use. The default is the number of processors available on the computer, or the number of processors allowed by Stata/MP’s license, whichever is less.

set python_exec
Syntax: set python_exec pyexecutable [, permanently]
Description: sets which version of Python to use.
Reference: set python_exec is a synonym for python set exec; see [P] python
set python_userpath
Syntax: set python_userpath path [path ...] [, permanently prepend]
Description: sets the user’s own module search paths in addition to the system search paths.
Reference: set python_userpath is a synonym for python set userpath; see [P] python

set reventries
Syntax: set reventries # [, permanently]
Default: 5000
Description: sets the number of scrollback lines available in the History window. $5 \leq # \leq 32000$.

set revkeyboard (Mac only)
Syntax: set revkeyboard {on|off} [, permanently]
Default: on
Description: sets the keyboard navigation behavior for the History window. on indicates that you can use the keyboard to navigate and enter items from the History window into the Command window. off indicates that all keyboard input be directed at the Command window; items can be entered from the History window only by using the mouse.

set rmsg
Syntax: set rmsg {on|off} [, permanently]
Default: off
Description: indicates whether a return message telling the execution time is to be displayed at the completion of each command.
Reference: [P] rmsg

set rng
Syntax: set rng {default|mt64|mt64s|kiss32}
Default: default
Description: determines which random-number generator Stata’s random-number functions and commands will use.
Reference: [R] set rng

set rngstate
Syntax: set rngstate statecode
Description: resets the state of the random-number generator to the value specified.
Reference: [R] set seed

set rngstream
Syntax: set rngstream #
Description: specifies the stream from which Stata’s stream random-number generator should draw random numbers.
Reference: [R] set rngstream
set scheme
Syntax: set scheme schemename [, permanently]
Default: s2color
Description: determines the overall look for graphs.
Reference: [G-2] set scheme

set scrollbufsize
Syntax: set scrollbufsize #
Default: 200000
Description: sets the scrollback buffer size, in bytes, for the Results window; may be set between 10,000 and 2,000,000.

set searchdefault
Syntax: set searchdefault {local|net|all} [, permanently]
Default: local
Description: sets the default behavior of the search command. set searchdefault local restricts search to use only Stata’s keyword database. set searchdefault net restricts search to searching only the Internet. set searchdefault all indicates that both the keyword database and the Internet are to be searched.
Reference: [R] search

set seed
Syntax: set seed #
Default: 123456789
Description: specifies initial value of the random-number seed used by the random-number functions, such as runiform() and rnormal().
Reference: [R] set seed

set segmentsize
Syntax: set segmentsize #b|k|m|g [, permanently]
Default: 32m for 64-bit machines
Description: Stata allocates memory for data in units of segmentsize. This setting changes the amount of memory in a single segment. $1m ≤ # ≤ 32g$ for 64-bit machines
Reference: [D] memory

set sformat
Syntax: set sformat [fmt] [, permanently]
Description: specifies the output format of test statistics in coefficient tables. fmt is a numerical format; see [D] format.
Reference: [R] set cformat

set showbaselevels
Syntax: set showbaselevels {on|off|all} [, permanently]
Description: specifies whether to display base levels of factor variables and their interactions in coefficient tables.
Reference: [R] set showbaselevels
set showemptycells
Syntax: set showemptycells \{on\ |off\} [ , permanently ]
Description: specifies whether to display empty cells in coefficient tables.
Reference: [R] set showbaselevels

set showomitted
Syntax: set showomitted \{on\ |off\} [ , permanently ]
Description: specifies whether to display omitted coefficients in coefficient tables.
Reference: [R] set showbaselevels

set smoothfonts (Mac only)
Syntax: set smoothfonts \{on\ |off\}
Default: on
Description: determines whether to use font smoothing (antialiased text) in the Results, Viewer,
and Data Editor windows.

set timeout1
Syntax: set timeout1 \#seconds [ , permanently ]
Default: 30
Description: sets the number of seconds Stata will wait for a remote host to respond to an initial
contact before giving up. In general, users should not modify this value unless
instructed to do so by Stata Technical Services.
Reference: [R] netio

set timeout2
Syntax: set timeout2 \#seconds [ , permanently ]
Default: 180
Description: sets the number of seconds Stata will keep trying to get information from a remote
host after initial contact before giving up. In general, users should not modify this value unless
instructed to do so by Stata Technical Services.
Reference: [R] netio

set trace
Syntax: set trace \{on\ |off\}
Default: off
Description: determines whether to trace the execution of programs for debugging.
Reference: [P] trace

set tracedepth
Syntax: set tracedepth #
Default: 32000 (equivalent to ∞)
Description: if trace is set on, traces execution of programs and nested programs up to
tracedepth. For example, if tracedepth is 2, the current program and any
subroutine called would be traced, but subroutines of subroutines would not
be traced.
Reference: [P] trace
set traceexpand
Syntax: set traceexpand {on | off} [, permanently]
Default: on
Description: if trace is set on, shows lines both before and after macro expansion. If traceexpand is set off, only the line before macro expansion is shown.
Reference: [P] trace

set tracehilite
Syntax: set tracehilite "pattern" [, word]
Default: ""
Description: highlights pattern in the trace output.
Reference: [P] trace

set traceindent
Syntax: set traceindent {on | off} [, permanently]
Default: on
Description: if trace is set on, indents displayed lines according to their nesting level. The lines of the main program are not indented. Two spaces of indentation are used for each level of nested subroutine.
Reference: [P] trace

set tracenumber
Syntax: set tracenumber {on | off} [, permanently]
Default: off
Description: if trace is set on, shows the nesting level numerically in front of the line. Lines of the main program are preceded by 01, lines of subroutines called by the main program are preceded by 02, etc.
Reference: [P] trace

set tracesep
Syntax: set tracesep {on | off} [, permanently]
Default: on
Description: if trace is set on, displays a horizontal separator line that displays the name of the subroutine whenever a subroutine is called or exits.
Reference: [P] trace

set type
Syntax: set type {float | double} [, permanently]
Default: float
Description: specifies the default storage type assigned to new variables.
Reference: [D] generate

set update_interval (Mac and Windows only)
Syntax: set update_interval #
Default: 7
Description: sets the number of days to elapse before performing the next automatic update query.
Reference: [R] update
set update_prompt (Mac and Windows only)
Syntax: set update_prompt \{on|off\}
Default: on
Description: determines whether a dialog is to be displayed before performing an automatic update query. There is no permanently option because permanently is implied.
Reference: [R] update

set update_query (Mac and Windows only)
Syntax: set update_query \{on|off\}
Default: on
Description: determines whether update query is to be automatically performed when Stata is launched. There is no permanently option because permanently is implied.
Reference: [R] update

set varabbrev
Syntax: set varabbrev \{on|off\} [, permanently]
Default: on
Description: indicates whether Stata should allow variable abbreviations.
Reference: [P] varabbrev

set varkeyboard (Mac only)
Syntax: set varkeyboard \{on|off\} [, permanently]
Default: on
Description: sets the keyboard navigation behavior for the Variables window. on indicates that you can use the keyboard to navigate and enter items from the Variables window into the Command window. off indicates that all keyboard input be directed at the Command window; items can be entered from the Variables window only by using the mouse.

Also see
[R] query — Display system parameters
[R] set_defaults — Reset system parameters to original Stata defaults
[M-3] mata set — Set and display Mata system parameters
[P] creturn — Return c-class values
set cformat — Format settings for coefficient tables

Description

set cformat specifies the output format of coefficients, standard errors, and confidence limits in coefficient tables.

set pformat specifies the output format of $p$-values in coefficient tables.

set sformat specifies the output format of test statistics in coefficient tables.

Syntax

set cformat [fmt] [, permanently]

set pformat [fmt] [, permanently]

set sformat [fmt] [, permanently]

where fmt is a numerical format.

Option

permanently specifies that, in addition to making the change right now, the setting be remembered and become the default setting when you invoke Stata.

Remarks and examples

The formatting of the numbers in the coefficient table can be controlled by using the set cformat, set pformat, and set sformat commands or by using the cformat(%)fmt), pformat(%)fmt), and sformat(%)fmt) options at the time of estimation or on replay of the estimation command. See [R] Estimation options.

The maximum format widths for set cformat, set pformat, and set sformat in coefficient tables are 9, 5, and 8, respectively.
Example 1

We use auto.dta to illustrate.

```stata
use https://www.stata-press.com/data/r16/auto
(1978 Automobile Data)
regress mpg weight displacement
```

```

Also see

[R] Estimation options — Estimation options
[R] query — Display system parameters
[R] set — Overview of system parameters
[U] 20.9 Formatting the coefficient table
set_defaults — Reset system parameters to original Stata defaults

Description

set_defaults resets settings made by set to the original default settings that were shipped with Stata.

set_defaults may not be used with java or python system-parameter categories.

Syntax

set_defaults { category | _all} [, permanently]

where category is one of memory | output | interface | graphics | efficiency | network | update | trace | mata | unicode | other

Option

permanently specifies that, in addition to making the change right now, the settings be remembered and become the default settings when you invoke Stata.

Remarks and examples

Example 1

To assist us in debugging a new command, we modified some of the trace settings. To return them to their original values, we type

. set defaults trace
-> set trace off
-> set tracedepth 32000
-> set traceexpand on
-> set tracesep on
-> set traceindent on
-> set tracenumber off
-> set tracehilite ""
(preferences reset)
Also see

[R] query — Display system parameters

[R] set — Overview of system parameters

[M-3] mata set — Set and display Mata system parameters
set emptycells — Set what to do with empty cells in interactions

Description

set emptycells allows you to control how Stata handles interaction terms with empty cells. Stata can keep empty cells or drop them. The default is to keep empty cells.

Syntax

```
set emptycells {keep|drop} [, permanently]
```

Option

permanently specifies that, in addition to making the change right now, the setting be remembered and become the default setting when you invoke Stata.

Remarks and examples

By default, Stata keeps empty cells so they can be reported in the coefficient table. For example, type

```
.use https://www.stata-press.com/data/r16/auto
.regress mpg rep78#foreign, baselevels
```

and you will see a regression of mpg on 10 indicator variables because rep78 takes on 5 values and foreign takes on 2 values in the auto dataset. Two of those cells will be reported as empty because the data contain no observations of foreign cars with a rep78 value of 1 or 2.

Many real datasets contain a large number of empty cells, and this could cause the “unable to allocate matrix” error message, r(915). In that case, type

```
.set emptycells drop
```

to get Stata to drop empty cells from the list of coefficients. If you commonly fit models with empty cells, you can permanently set Stata to drop empty cells by typing the following:

```
.set emptycells drop, permanently
```

Also see

[R] set — Overview of system parameters
set iter — Control iteration settings

Description

*set iterlog* and *set maxiter* control the display of the iteration log and the maximum number of iterations, respectively, for estimation commands that iterate and for the Mata optimization functions *moptimize()*, *optimize()*, and *solvenl()*.

*set iterlog* specifies whether to display the iteration log. The default setting is *on*, which displays the log. You can specify *set iterlog off* to suppress it. To change whether the iteration log is displayed for a particular estimation command, you need not reset *iterlog*; you can specify the *log* or *nolog* option with that command. If you do not specify *log* or *nolog*, the *iterlog* setting is used. To view the current setting of *iterlog*, type *display c(iterlog)*.

*set maxiter* specifies the default maximum number of iterations. The initial value is 16000, and *#* can be 0 to 16000. To change the maximum number of iterations performed by a particular estimation command, you need not reset *maxiter*; you can specify the *iterate(#)* option with that command. If you do not specify *iterate(#)*, the *maxiter* value is used. To view the current setting of *maxiter*, type *display c(maxiter)*.

Syntax

Set whether to display the iteration log

```
set iterlog {on | off} [, permanently]
```

Set default maximum iterations

```
set maxiter # [, permanently ]
```

Option

`permanently` specifies that, in addition to making the change right now, the setting be remembered and become the default setting when you invoke Stata.

Remarks and examples

The *iterlog* setting is particularly useful in combination with the *nolog* and *log* options; see example 1 below. Also see [R] *Maximize* for details about the options. The *iterlog* setting has no effect on commands that suppress the iteration log by default, for example, commands prefixed with *svy*. To display the log with those commands, you need to use the *log* option.

You will rarely need to modify the *maxiter* setting to change the maximum number of iterations used by Stata’s iterative commands. Instead, you may want to specify the *iterate()* option with these commands. For example, specifying *iterate(0)* is useful for viewing results evaluated at the initial value of the coefficient vector.
The `iter` and `maxiter` settings also control the default output displayed by the Mata optimization functions `moptimize()`, `optimize()`, and `solvenl()`.

### Example 1: Display and suppress the iteration log

Stata estimation commands that iterate usually display the iteration log by default:

```
. sysuse auto
   (1978 Automobile Data)
   . logit foreign mpg
```

```
Iteration 0:  log likelihood =  -45.03321
Iteration 1:  log likelihood = -39.380959
Iteration 2:  log likelihood = -39.288802
Iteration 3:  log likelihood = -39.28864
Iteration 4:  log likelihood = -39.28864

Logistic regression
   Number of obs   =        74
   LR chi2(1)      =     11.49
   Prob > chi2     =     0.0007
Log likelihood = -39.28864  Pseudo R2 = 0.1276

 foreign       Coef.   Std. Err.      z    P>|z|     [95% Conf. Interval]
------------- -------- -------- -------- -------- ------------------
     mpg    .1597621   .0525876    3.04    0.002      .0566922    .262832
   _cons  -4.378866   1.211295   -3.62    0.000    -6.752961   -2.004771
```

You can suppress the log by specifying the `nolog` option:

```
. logit foreign mpg, nolog
```

```
Logistic regression
   Number of obs   =        74
   LR chi2(1)      =     11.49
   Prob > chi2     =     0.0007
Log likelihood = -39.28864  Pseudo R2 = 0.1276

 foreign       Coef.   Std. Err.      z    P>|z|     [95% Conf. Interval]
------------- -------- -------- -------- -------- ------------------
     mpg    .1597621   .0525876    3.04    0.002      .0566922    .262832
   _cons  -4.378866   1.211295   -3.62    0.000    -6.752961   -2.004771
```

If you want to suppress the iteration log from all estimation commands every time they are run within the current Stata session, type

```
. set iterlog off
```

We can run `logit` again but now without the `nolog` option, and the iteration log will not be displayed:

```
. logit foreign mpg
```

```
Logistic regression
   Number of obs   =        74
   LR chi2(1)      =     11.49
   Prob > chi2     =     0.0007
Log likelihood = -39.28864  Pseudo R2 = 0.1276

 foreign       Coef.   Std. Err.      z    P>|z|     [95% Conf. Interval]
------------- -------- -------- -------- -------- ------------------
     mpg    .1597621   .0525876    3.04    0.002      .0566922    .262832
   _cons  -4.378866   1.211295   -3.62    0.000    -6.752961   -2.004771
```
Or we can run a different command, for example, `mlogit`, and the log will still be suppressed:

```bash
.mlogit rep78 mpg
```

Multinomial logistic regression

|                          | Coef.    | Std. Err. | z       | P>|z|     | [95% Conf. Interval] |

|                          | (base outcome) |                     |         |         |                     |
| 4                        |          |           |         |         |                     |
| mpg                      | 0.0958626| 0.063329  | 1.51    | 0.130   | -0.0282676 - 0.2199927 |
| _cons                    | -2.474187| 1.341131  | -1.84   | 0.065   | -5.102756 - 1.543813 |
| 5                        |          |           |         |         |                     |
| mpg                      | 0.2477469| 0.0764076 | 3.24    | 0.001   | 0.0979908 - 0.397503  |
| _cons                    | -6.653164| 1.841794  | -3.61   | 0.000   | -10.26301 -3.043314  |
With the `iterlog` setting off, we can display the iteration log for specific commands by specifying the `log` option:

```
. mlogit rep78 mpg, log
Iteration 0:  log likelihood = -93.692061
Iteration 1:  log likelihood = -86.581485
Iteration 2:  log likelihood = -85.767758
Iteration 3:  log likelihood = -85.752385
Iteration 4:  log likelihood = -85.752375
Iteration 5:  log likelihood = -85.752375
Multinomial logistic regression  Number of obs      =       69
LR chi2(4)         =    15.88
Prob > chi2        =    0.0032
Log likelihood = -85.752375  Pseudo R2          =    0.0847

rep78             Coef.   Std. Err.      z    P>|z|     [95% Conf. Interval]
-------------      --------      ------      ------     ��             --------
1      mpg          .0708122   .1471461     0.48    0.630     -.2175888    .3592132
       _cons        -4.137144   3.157077    -1.31    0.190    -10.32489     2.0506
2      mpg         -.0164251   .0926724    -0.18    0.859    -.1980597    .1652096
       _cons       -1.005118   1.822129    -0.55    0.581    -4.576426    2.56619
3      (base outcome)
4      mpg          .0958626   .0633329     1.51    0.130    -.0282676    .2199927
       _cons        -2.474187   1.341131    -1.84    0.065    -5.102756    .1843813
5      mpg         .2477469   .0764076     3.24    0.001     .0979908    .3975030
       _cons        -6.653164   1.841794    -3.61    0.000    -10.26301   -3.043314
```

You can switch back to displaying iteration logs by typing

```
. set iterlog on
```

The default setting will be restored automatically the next time you invoke Stata. If you want the setting to be remembered for future Stata sessions, specify the `permanently` option with `set iterlog`.

[M-5] solvenl() — Solve systems of nonlinear equations
set rng — Set which random-number generator (RNG) to use

Description

set rng determines which random-number generator (RNG) Stata’s random-number functions and commands will use.

Syntax

```
set rng {default | mt64 | mt64s | kiss32}
```

Remarks and examples

Remarks are presented under the following headings:

Introduction
Random-number generators in Stata

Introduction

By default, Stata uses the 64-bit Mersenne Twister (mt64) RNG. mt64s is a stream RNG based on the 64-bit Mersenne Twister. Earlier versions of Stata used the 32-bit KISS (keep it simple stupid) (kiss32) RNG.

With `set rng default` (the default), code running under version control will automatically use the appropriate RNG—mt64 in Stata 14 and later and kiss32 for earlier code.

The scope of `set rng` is the Stata session, do-file, or program in which rng is set.

Unless you want to simultaneously draw random numbers in separate instances of Stata, we recommend that you do not change Stata’s default behavior for its RNGs. See [R] set rngstream for an introduction to simultaneously drawing random numbers in separate instances of Stata.

See [FN] Random-number functions, [R] set seed, and [R] set rngstream for more information.

Random-number generators in Stata

The default RNG in Stata is the 64-bit Mersenne Twister. See Matsumoto and Nishimura (1998) for more details. The default RNG in Stata 13 and earlier versions was George Marsaglia’s 32-bit KISS generator (G. Marsaglia, 1994, pers. comm.). The KISS generator is still available under version control or via `set rng`. Multiple independent random-number streams (based on the 64-bit Mersenne Twister) are also supported for use in multiple simultaneous instances of Stata; see [R] set rngstream for more information on this. The abbreviations mt64, kiss32, and mt64s are used, respectively, to specify these three generators in Stata commands and functions.
So far, we have discussed two ways you can specify the RNG: with `set rng` and through version control. Another way to specify the RNG is with functions and system parameters explicitly named after the generators. In fact, all random-number functions have variants that are explicitly named after each generator, using the generator abbreviation as the suffix. For example, `runiform_mt64()`, `runiform_kiss32()`, and `runiform_mt64s()` are variants of `runiform()` for each generator. Similarly, we have `rnormal_mt64()`, `rnormal_kiss32()`, `rnormal_mt64s()`, etc.

The system parameters `seed` and `rngstate` also have variants explicitly named after each generator: `seed_mt64`, `seed_kiss32`, `seed_mt64s`, `rngstate_mt64`, `rngstate_kiss32`, and `rngstate_mt64s`.

For example, here is how you can use functions and parameters specific to `mt64` to set the seed, generate random numbers, preserve a state, generate more numbers, and restore the previously preserved state:

```
. set seed_mt64 482637
. generate u = runiform_mt64()
. local state = c(rngstate_mt64)
. generate l = rlogistic_mt64()
. set rngstate_mt64 'state'
```

Note that calling functions and setting parameters specific to, say, `kiss32`, will not change the current RNG, the seed of the current RNG, or the state of the current RNG—unless the current RNG is `kiss32`.

Title

**set rngstream** — Specify the stream for the stream random-number generator

<table>
<thead>
<tr>
<th>Description</th>
<th>Syntax</th>
<th>Remarks and examples</th>
</tr>
</thead>
<tbody>
<tr>
<td>References</td>
<td>Also see</td>
<td></td>
</tr>
</tbody>
</table>

Description

`set rngstream` specifies the subsequence, known as a stream, from which Stata’s stream random-number generator should draw random numbers. When performing a bootstrap estimation or a Monte Carlo simulation in parallel on multiple machines, you should set the same seed on all machines but set a different stream on each machine. This will ensure that random numbers drawn on different machines are independent. We strongly recommend that you set the seed and the stream only once in each Stata session.

Syntax

```
set rngstream #
```

# is any integer between 1 and 32,767.

Remarks and examples

Stata’s stream random-number generator, the stream 64-bit Mersenne Twister (mt64s), allows separate instances of Stata to simultaneously draw independent random numbers. This feature enables you to use `bootstrap` and to run Monte Carlo simulations in parallel on multiple machines.

What we call random numbers are elements in a sequence of deterministic numbers that appear to be random. A seed specifies a starting value in this sequence. In figure 1, each tick is an element in a random sequence and setting the seed to 12345 means that the tick identified by the arrow below is the first number drawn.

![Figure 1. Seed specifies first number in random sequence](#)

A stream random-number generator partitions a sequence of random numbers into nonoverlapping subsequences known as streams. The random numbers in each stream are independent of those in other streams because they come from distinct nonoverlapping subsets of the original sequence.
Figure 2 depicts a stream version of the generator depicted in figure 1. The stream version also starts at the place implied by seed 12345, but it additionally partitions the random numbers into 4 streams and a set of unused numbers.

![Figure 2. A stream version of figure 1 generator](image)

In contrast to nonstream random-number generators, setting the seed for a random-number generator controls not just where the sequence starts but also how the sequence is partitioned. Compare figure 2 with figure 3 for an illustration.

![Figure 3. Changing the seed changes the streams](image)

Seed 123456 specifies the first random number, and the streams of random numbers in figure 3 differ from those in figure 2.

The mt64s generator is a stream version of Stata’s default generator, the 64-bit Mersenne Twister implemented in mt64; see Matsumoto and Nishimura (1998) and Random-number generators in Stata in [R] set rng for more details. Our implementation of the method discussed in Haramoto et al. (2008) partitions the mt64 sequence into 32,767 streams, each containing $2^{128}$ random numbers. The remaining numbers are unused. The mt64s seed determines the starting point of every stream in the Mersenne Twister sequence.

Stream 1 of mt64s has the same starting point as the mt64 generator. That is, given the same seed, mt64s with rngstream set to 1 will generate the same random numbers as mt64.

The mt64s generator is designed to simultaneously draw independent random numbers on different machines. To draw from different streams that guarantee independence, use the same seed and change the stream. For example, to draw some uniform(0,1) random numbers from stream 10 of the mt64s generator under seed 123, type

```
. set rng mt64s
. set rngstream 10
. set seed 123
. generate u = runiform()
```

If we wanted to simultaneously draw some uniform(0,1) random numbers on another machine from stream 11 of the mt64s generator, we would type

```
. set rng mt64s
. set rngstream 11
. set seed 123
. generate u = runiform()
```

Again, each seed creates a different partition of the mt64 sequence into nonoverlapping subsets.

We strongly recommend that you set the stream and the seed once in each Stata session and draw numbers only from this stream.
c(rngstream) returns the current stream number. c(rngseed_mt64s) returns the last seed that was set for mt64s. See \[P\] creturn for more details. See \[R\] set seed for details about storing and restoring the current position in the random sequence.

As with the single-stream generators, use local state = c(rngstate) to store the current position in the current random stream; see \[R\] set seed for details. The mt64s state encodes the seed used in addition to the stream number, because the seed determines the position of every random number in every stream. Unlike the case of single-stream generators, restoring the state also restores the seed. For example, suppose you save an mt64s state with local state = c(rngstate) change the seed and the stream, and later restore that state with set rngstate ‘state’. The current mt64s seed is changed to the one encoded in state. In addition to changing the current stream to the one encoded in state, the current mt64s seed is changed to the one encoded in state. This behavior ensures any subsequent stream changes draw from nonoverlapping subsets.

set rngstream also sets the random-number generator to mt64s.

Example 1: Using stream random numbers to parallelize a bootstrap

We illustrate how to simultaneously perform 100 bootstrap replications on machine 1 and 100 bootstrap replications on machine 2. We focus on the mechanics of distributing the draws over machines using stream random numbers; see \[R\] bootstrap for an introduction to the bootstrap.

On machine 1, we type

```
.set rng mt64s
.set rngstream 1
.set seed 12345
. bootstrap, reps(100) saving(machine1, replace): regress mpg weight gear foreign
(running regress on estimation sample)
(note: file machine1.dta not found)
```

| Coef. | Std. Err. | z     | P>|z| | [95% Conf. Interval] |
|-------|-----------|-------|------|----------------------|
| mpg   |           |       |      |                      |
| weight| -0.006139 | 0.0005462 | -11.24 | 0.000 | -.0072095 to -.0050685 |
| gear_ratio| 1.457113  | 1.271301 | 1.15  | 0.252 | -1.03459 to 3.948817  |
| foreign| -2.221682 | 1.090115 | -2.04 | 0.042 | -4.358267 to -0.0850957 |
| _cons | 36.10135  | 4.720623 | 7.65  | 0.000 | 26.8491 to 45.3536    |

On machine 2, we type

```
.set rng mt64s
.set rngstream 2
.set seed 12345
... (bootstrap command)...
```

... (output similar to machine 1)...
On machine 2, we type

```
. clear all
. use https://www.stata-press.com/data/r16/auto
   (1978 Automobile Data)
. set rng mt64s
. set rngstream 2
. set seed 12345
. bootstrap, reps(100) saving(machine2, replace): regress mpg weight gear foreign
    (running regress on estimation sample)
    (note: file machine2.dta not found)

We used `regress` in this example, but the divide-and-conquer strategy reduces computation time for any command that works with `bootstrap`. In fact, problems that take longer produce more noticeable speed improvements. For computationally intensive problems, the two-machine time will be about one-half the one-machine time. Using distinct streams on many different machines can dramatically reduce the time required for computationally intensive problems.
Example 2: Using stream random numbers to parallelize a Monte Carlo simulation

We want to simultaneously perform 100 Monte Carlo replications on machine 3 and 100 Monte Carlo replications on machine 4. Again, we focus entirely on the mechanics of distributing the draws over machines. See Drukker (2015) for an introduction to Monte Carlo simulations using Stata.

As discussed in [R] simulate, the simulate command uses an ado-file that draws from the population of interest; it then computes and returns the estimates. Our program chi2sim draws from a $\chi^2$ distribution with one degree of freedom.

```
program define chi2sim, rclass
  version 16.0
  drop _all
  set obs 200
  tempvar z
  generate `z' = rchi2(1)
  summarize `z'
  return scalar mean = r(mean)
  return scalar Var = r(Var)
end
```

On machine 3, we type

```
. set rng mt64s
. set rngstream 3
. set seed 12345
. simulate mean=r(mean) var=r(Var), reps(500) saving(machine3, replace): chi2sim
```

```
Simulations (500)

</tr>
</tbody>
</table>

As in example 1, more machines enable further parallelization.

⚠️ Technical note

While `mt64s` has been made robust to switching between streams within a Stata session, convoluted combinations of `set rngstream #` and `set seed #` can lead to drawing the same random numbers, just as it can in the case of single-stream generators. We strongly recommend that you do not switch between streams within a session.

➤ Example 3: Position within a stream is stored

This example illustrates that the sequence picks up where it left off when the stream is switched, and it illustrates that `clear rngstream` resets all streams to their beginning positions. These features facilitate advanced programming techniques, and we recommend against using this feature in standard use.
. clear all
. set obs 10

After setting the `rngstream` to 5 and setting the seed, we put the first 5 draws from stream 5 into observations 1–5 of x, switch to `rngstream` 6, put the first 10 random draws from stream 6 into y, return to `rngstream` 5, and put the next 5 draws from stream 5 into observations 6–10 of x. Then we use `clear rngstream` to initialize each `rngstream` at its initial position for seed 12345 and put the first 10 draws from stream 5 into z.

That the random numbers in x match those in z illustrates that the sequence picks up where it left off when the stream is switched and the seed has not been changed.

set seed — Specify random-number seed and state

Description

set seed # specifies the initial value of the random-number seed used by the random-number functions, such as runiform() and rnormal().

set rngstate statecode resets the state of the random-number generator to the value specified, which is a state previously obtained from creturn value c(rngstate).

set seed # and set rngstate statecode apply to the current random-number generator. Every random-number generator in Stata has its own seed and state encoding.

Syntax

set seed #

set rngstate statecode

# is any number between 0 and $2^{31} - 1$ (or 2,147,483,647).
statecode is a random-number state previously obtained from creturn value c(rngstate).

Remarks and examples

Remarks are presented under the following headings:

Examples
Setting the seed
How to choose a seed
Do not set the seed too often
Preserving and restoring the random-number generator state

Examples

1. Specify initial value of random-number seed
   . set seed 339487731

2. Create variable u containing uniformly distributed pseudorandom numbers on the interval $(0, 1)$
   . generate u = runiform()

3. Create variable z containing normally distributed random numbers with mean 0 and standard deviation 1
   . generate z = rnormal()
4. Obtain state of pseudorandom-number generator and store it in a local macro named state
   
```
   . local state = c(rngstate)
   ```

5. Restore pseudorandom-number generator state to that previously stored in local macro named state
   
```
   . set rngstate `state'
   ```

### Setting the seed

Stata’s random-number generation functions, such as `runiform()` and `rnormal()`, do not really produce random numbers. These functions are deterministic algorithms that produce numbers that can pass for random. `runiform()` produces numbers that can pass for independent draws from a rectangular distribution over \((0, 1)\); `rnormal()` produces numbers that can pass for independent draws from \(N(0, 1)\). Stata’s random-number functions are formally called pseudorandom-number functions. The default pseudorandom-number generator introduced in Stata 14 is the 64-bit Mersenne Twister. See Matsumoto and Nishimura (1998) and Random-number generators in Stata in [R] `set rng` for more details.

The sequences the random-number functions produce are determined by the seed, which is just a number and which is set to 123456789 every time Stata is launched. This means that `runiform()` produces the same sequence each time you start Stata. The first time you use `runiform()` after Stata is launched, `runiform()` returns 0.348871704556195. The second time you use it, `runiform()` returns 0.266885709753138. The third time you use it, ...

To obtain different sequences, you must specify different seeds using the `set seed` command. You might specify the seed 472195:

```
   . set seed 472195
   ```

If you were now to use `runiform()`, the first call would return 0.713028143573182, the second call would return 0.920524469911484, and so on. Whenever you `set seed 472195`, `runiform()` will return those numbers the first two times you use it.

Thus you set the seed to obtain different pseudorandom sequences from the pseudorandom-number functions.

If you record the seed you set, pseudorandom results such as results from a simulation or imputed values from `mi impute` can be reproduced later. Whatever you do after setting the seed, if you set the seed to the same value and repeat what you did, you will obtain the same results.

### How to choose a seed

Your best choice for the seed is an element chosen randomly from the set \(\{0, 1, \ldots, 2^{31} - 1\}\) (where \(2^{31} - 1 = 2,147,483,647\)). We recommend that, but that is difficult to achieve because finding easy-to-access, truly random sources is difficult.

One person we know uses digits from the serial numbers from dollar bills he finds in his wallet. Of course, the numbers he obtains are not really random, but they are good enough, and they are probably a good deal more random than the seeds most people choose. Some people use dates and times, although we recommend against that because, over the day, it just gets later and later, and that is a pattern. Others try to make up a random number, figuring if they include enough digits, the result just has to be random. This is a variation on the five-second rule for dropped food, and we admit to using both of these rules.
It does not really matter how you set the seed, as long as there is no obvious pattern in the seeds that you set and as long as you do not set the seed too often during a session.

Nonetheless, here are two methods that we have seen used but you should not use:

1. The first time you set the seed, you set the number 1. The next time, you set 2, and then 3, and so on. Variations on this included setting 1001, 1002, 1003, \ldots, or setting 1001, 2001, 3001, and so on.

Do not follow any of these procedures. The seeds you set must not exhibit a pattern.

2. To set the seed, you obtain a pseudorandom number from \texttt{runiform()} and then use the digits from that to form the seed.

This is a bad idea because the pseudorandom-number generator can converge to a cycle. If you obtained the pseudorandom-number generator unrelated to those in Stata, this would work well, but then you would have to find a rule to set the first generator’s seed.

Choosing seeds that do not exhibit a pattern is of great importance. That the seeds satisfy the other properties of randomness is minor by comparison.

**Do not set the seed too often**

We cannot emphasize this enough: Do not set the seed too often.

To see why this is such a bad idea, consider the limiting case: You set the seed, draw one pseudorandom number, reset the seed, draw again, and so continue. The pseudorandom numbers you obtain will be nothing more than the seeds you run through a mathematical function. The results you obtain will not pass for random unless the seeds you choose pass for random. If you already had such numbers, why are you even bothering to use the pseudorandom-number generator?

The definition of too often is more than once per problem.

If you are running a simulation of 10,000 replications, set the seed at the start of the simulation and do not reset it until the 10,000th replication is finished. The pseudorandom-number generators provided by Stata have long periods. The longer you go between setting the seed, the more random-like are the numbers produced.

It is sometimes useful later to be able to reproduce in isolation any one of the replications, and so you might be tempted to set the seed to a known value for each of the replications. We negatively mentioned setting the seed to 1, 2, \ldots, and it is in exactly such situations that we have seen this done. The advantage, however, is that you could reproduce the fifth replication merely by setting the seed to 5 and then repeating whatever it is that is to be replicated. If this is your goal, you do not need to reset the seed. You can record the state of the random-number generator, save the state with your replication results, and then use the recorded states later to reproduce whichever of the replications that you wish. This will be discussed in \textit{Preserving and restoring the random-number generator state}.

There is another reason you might be tempted to set the seed more than once per problem. It sometimes happens that you run a simulation, let’s say for 5,000 replications, and then you decide you should have run it for 10,000 replications. Instead of running all 10,000 replications afresh, you decide to save time by running another 5,000 replications and then combining those results with your previous 5,000 results. That is okay. We at StataCorp do this kind of thing. If you do this, it is important that you set the seed especially well, particularly if you repeat this process to add yet another 5,000 replications. It is also important that in each run there be a large enough number of replications, which is say thousands of them.

Even so, do not do this: You want 500,000 replications. To obtain them, you run in batches of 1,000, setting the seed 500 times. Unless you have a truly random source for the seeds, it is unlikely
you can produce a patternless sequence of 500 seeds. The fact that you ran 1,000 replications in
between choosing the seeds does not mitigate the requirement that there be no pattern to the seeds
you set.

In all cases, the best solution is to set the seed only once and then use the method we suggest in
the next section.

Preserving and restoring the random-number generator state

In the previous section, we discussed the case in which you might be tempted to set the seed
more frequently than otherwise necessary, either to save time or to be able to rerun any one of the
replications. In such cases, there is an alternative to setting a new seed: recording the state of the
pseudorandom-number generator and then restoring the state later should the need arise.

The state of the default random-number generator in Stata, the 64-bit Mersenne Twister, is a string
of about 5,000 characters. The state can be displayed by typing `display c(rngstate)`. It is more
practical to save the state, say, in a local macro named `state`:

```
local state = c(rngstate)
```

The state can later be restored by typing

```
set rngstate `state`
```

The state string specifies an entry point into the sequence produced by the pseudorandom-number
generator. Let us explain.

The best way to use a pseudorandom-number generator would be to choose a seed once, draw
random numbers until you use up the generator, and then get a new generator and choose a new key.
Pseudorandom-number generators have a period, after which they repeat the original sequence. That
is what we mean by using up a generator. The period of the 64-bit Mersenne Twister, the default
pseudorandom-number generator in Stata, is $2^{19937} - 1$. This is roughly $10^{6000}$. It is difficult to
imagine that you could ever use up this generator.

The string reported by `c(rngstate)` is an encoded form of the information necessary for Stata
to reestablish exactly where it is located in the pseudorandom-number generator’s sequence.

We are not seriously suggesting you choose only one seed over your entire lifetime, but let’s look
at how you might do that. Sometime after birth, when you needed your first random number, you
would set your seed,

```
set seed 1073741823
```

On that day, you would draw, say, 10,000 pseudorandom numbers, perhaps to impute some missing
values. Being done for the day, you can save the state, and then later restore it.

When you type `set rngstate` followed by a saved state string, Stata reestablishes the previous
state. Thus the next time you draw a pseudorandom number, Stata will produce the 10,001st result
after setting seed 1073741823. Let’s assume that you draw 100,000 numbers this day. Done for the
day, you save the state string.

On the third day, after setting the state to the saved state string above, you will be in a position
to draw the 110,001st pseudorandom number.

In this way, you would eat your way through the $2^{19937} - 1$ random numbers, but you would be
unlikely ever to make it to the end.

We do not expect you to set the seed just once in your life, but using the state string makes it
easy to set the seed just once for a problem.
When we do simulations at StataCorp, we record \texttt{c(rngstate)} for each replication. Just like everybody else, we record results from replications as observations in datasets; we just happen to have an extra variable in the dataset, namely, a string variable named \texttt{state}. That string is filled in observation by observation from the then-current values of \texttt{c(rngstate)}, which is a function and so can be used in any context that a function can be used in Stata.

Anytime we want to reproduce a particular replication, we thus have the information we need to reset the pseudorandom-number generator, and having it in the dataset is convenient because we had to go there anyway to determine which replication we wanted to reproduce. If we want to add more replications later, we have a state string that we can use to continue from where we left off.

Title

**set showbaselevels** — Display settings for coefficient tables

Description

*set showbaselevels* specifies whether to display base levels of factor variables and their interactions in coefficient tables. *set showbaselevels on* specifies that base levels be reported for factor variables and for interactions whose bases cannot be inferred from their component factor variables. *set showbaselevels all* specifies that all base levels of factor variables and interactions be reported.

*set showemptycells* specifies whether to display empty cells in coefficient tables.

*set showomitted* specifies whether to display omitted coefficients in coefficient tables.

*set fvlabel* specifies whether to display factor-variable value labels in coefficient tables. *set fvlabel on*, the default, specifies that the labels be displayed. *set fvlabel off* specifies that the levels of factor variables rather than the labels be displayed.

*set fvwrap #* specifies that long value labels wrap # lines in the coefficient table. The default is *set fvwrap 1*, which means that long value labels will be abbreviated to fit on one line.

*set fvwrapon* specifies whether value labels that wrap will break at word boundaries or break based on available space. *set fvwrapon word*, the default, specifies that value labels break at word boundaries. *set fvwrapon width* specifies that value labels break based on available space.

Syntax

```
set showbaselevels {on|off|all} [, permanently]
set showemptycells {on|off} [, permanently]
set showomitted {on|off} [, permanently]
set fvlabel {on|off} [, permanently]
set fvwrap # [, permanently]
set fvwrapon {word|width} [, permanently]
```

Option

*permanently* specifies that, in addition to making the change right now, the setting be remembered and become the default setting when you invoke Stata.
Remarks and examples

Example 1

We illustrate the first three set commands using cholesterol2.dta.

```
. use https://www.stata-press.com/data/r16/cholesterol2
(Artificial cholesterol data, empty cells)
. generate x = race
. regress chol race##agegrp x
note: 2.race#2.agegrp identifies no observations in the sample
note: x omitted because of collinearity
```

**Description**

`signrank` tests the equality of matched pairs of observations by using the Wilcoxon matched-pairs signed-rank test (Wilcoxon 1945). The null hypothesis is that both distributions are the same.

`signtest` also tests the equality of matched pairs of observations (Arbuthnott [1710], but better explained by Snedecor and Cochran [1989]) by calculating the differences between `varname` and the expression. The null hypothesis is that the median of the differences is zero; no further assumptions are made about the distributions. This, in turn, is equivalent to the hypothesis that the true proportion of positive (negative) signs is one-half.

For equality tests on unmatched data, see [R] `ranksum`.

**Quick start**

Wilcoxon matched-pairs signed-rank test for `v1` and `v2`

```
signrank v1 = v2
```

Compute an exact $p$-value for the signed-rank test

```
signrank v1 = v2, exact
```

Conduct signed-rank test separately for groups defined by levels of `catvar`

```
by catvar: signrank v1 = v2
```

Test that the median of differences between matched pairs `v1` and `v2` is 0

```
signtest v1 = v2
```

**Menu**

`signrank`

Statistics > Nonparametric analysis > Tests of hypotheses > Wilcoxon matched-pairs signed-rank test

`signtest`

Statistics > Nonparametric analysis > Tests of hypotheses > Test equality of matched pairs
Syntax

Wilcoxon matched-pairs signed-rank test

```
signrank varname = exp [if] [in] [, exact]
```

Sign test of matched pairs

```
signtest varname = exp [if] [in]
```

by is allowed with signrank and signtest; see [D] by.

Option for signrank

```
exact
```

Main

```
exact specifies that the exact p-value be computed in addition to the approximate p-value. The exact p-value is based on the actual randomization distribution of the test statistic. The approximate p-value is based on a normal approximation to the randomization distribution. By default, the exact p-value is computed for sample sizes \( n \leq 200 \) because the normal approximation may not be precise in small samples. The exact computation can be suppressed by specifying noexact. For sample sizes larger than 200, you must specify exact to compute the exact p-value. The exact computation is available for sample sizes \( n \leq 2000 \).
```

Remarks and examples

Example 1: signrank

We are testing the effectiveness of a new fuel additive. We run an experiment with 12 cars. We first run each car without the fuel treatment and measure the mileage. We then add the fuel treatment and repeat the experiment. The results of the experiment are

<table>
<thead>
<tr>
<th>Without treatment</th>
<th>With treatment</th>
<th>Without treatment</th>
<th>With treatment</th>
</tr>
</thead>
<tbody>
<tr>
<td>20</td>
<td>24</td>
<td>18</td>
<td>17</td>
</tr>
<tr>
<td>23</td>
<td>25</td>
<td>24</td>
<td>28</td>
</tr>
<tr>
<td>21</td>
<td>21</td>
<td>20</td>
<td>24</td>
</tr>
<tr>
<td>25</td>
<td>22</td>
<td>24</td>
<td>27</td>
</tr>
<tr>
<td>18</td>
<td>23</td>
<td>23</td>
<td>21</td>
</tr>
<tr>
<td>17</td>
<td>18</td>
<td>19</td>
<td>23</td>
</tr>
</tbody>
</table>
We create two variables called mpg1 and mpg2, representing mileage without and with the treatment, respectively. We can test the null hypothesis that the treatment had no effect by typing

```
. use https://www.stata-press.com/data/r16/fuel
. signrank mpg1 = mpg2
```

<table>
<thead>
<tr>
<th>sign</th>
<th>obs</th>
<th>sum ranks</th>
<th>expected</th>
</tr>
</thead>
<tbody>
<tr>
<td>positive</td>
<td>3</td>
<td>13.5</td>
<td>38.5</td>
</tr>
<tr>

<td>63.5</td>
<td>38.5</td>
</tr>
<tr>
<td>zero</td>
<td>1</td>
<td>1</td>
<td>1</td>
</tr>
<tr>
<td>all</td>
<td>12</td>
<td>78</td>
<td>78</td>
</tr>
</tbody>
</table>

unadjusted variance 162.50
adjustment for ties -1.62
adjustment for zeros -0.25
adjusted variance 160.62
Ho: mpg1 = mpg2
    z = -1.973
    Prob > |z| = 0.0485
    Exact Prob = 0.0479

Despite the small sample size, the \( p \)-value computed using a normal approximation, 0.0485, is similar to the exact \( p \)-value, 0.0479. These results indicate that we can reject the null hypothesis at a significance level of 0.05.

Example 2: signtest

signtest tests that the median of the differences is zero, making no further assumptions, whereas signrank assumed that the distributions are equal as well. Using the data above, we type

```
. signtest mpg1 = mpg2
```

<table>
<thead>
<tr>
<th>sign</th>
<th>observed</th>
<th>expected</th>
</tr>
</thead>
<tbody>
<tr>
<td>positive</td>
<td>3</td>
<td>5.5</td>
</tr>
<tr>
<td>negative</td>
<td>8</td>
<td>5.5</td>
</tr>
<tr>
<td>zero</td>
<td>1</td>
<td>1</td>
</tr>
<tr>
<td>all</td>
<td>12</td>
<td>12</td>
</tr>
</tbody>
</table>

One-sided tests:
Ho: median of mpg1 - mpg2 = 0 vs.
Ha: median of mpg1 - mpg2 > 0
Pr(#positive >= 3) = \[\text{Binomial}(n = 11, x >= 3, p = 0.5) = 0.9673\]
Ho: median of mpg1 - mpg2 = 0 vs.
Ha: median of mpg1 - mpg2 < 0
Pr(#negative >= 8) = \[\text{Binomial}(n = 11, x >= 8, p = 0.5) = 0.1133\]

Two-sided test:
Ho: median of mpg1 - mpg2 = 0 vs.
Ha: median of mpg1 - mpg2 != 0
Pr(#positive >= 8 or #negative >= 8) = \[\text{min}(1, 2\text{Binomial}(n = 11, x >= 8, p = 0.5)) = 0.2266\]

The summary table indicates that there were three comparisons for which mpg1 exceeded mpg2, eight comparisons for which mpg2 exceeded mpg1, and one comparison for which they were the same.
The \( p \)-values displayed below the summary table are based on a binomial(\( n, p = 1/2 \)) distribution for the test statistic, which is the number of positive or negative signs. Zeros are ignored. The \( n \) for the test is the number of nonzero differences. Because no approximation is used, the \( p \)-values are “exact” \( p \)-values. The \( p \)-value for the one-sided test, where the alternative hypothesis is that the median of \( \text{mpg1} - \text{mpg2} \) is smaller than zero, is 0.1133. The \( p \)-value for the two-sided test, where the alternative hypothesis is simply that the median of the differences is different from zero, is \( 0.2266 = 2 \times 0.1133 \).

### Stored results

**signrank** stores the following in \( r() \):

- \( r(N) \) sample size
- \( r(N_{pos}) \) number of positive comparisons
- \( r(N_{neg}) \) number of negative comparisons
- \( r(N_{tie}) \) number of tied comparisons
- \( r(z) \) \( z \) statistic
- \( r(Var_a) \) adjusted variance
- \( r(sum_pos) \) sum of the positive ranks
- \( r(sum_neg) \) sum of the negative ranks
- \( r(p) \) two-sided \( p \)-value from normal approximation
- \( r(p_l) \) lower one-sided \( p \)-value from normal approximation
- \( r(p_u) \) upper one-sided \( p \)-value from normal approximation
- \( r(p_{exact}) \) two-sided exact \( p \)-value
- \( r(p_{l_exact}) \) lower one-sided exact \( p \)-value
- \( r(p_{u_exact}) \) upper one-sided exact \( p \)-value

**signtest** stores the following in \( r() \):

- \( r(N) \) sample size
- \( r(N_{pos}) \) number of positive comparisons
- \( r(N_{neg}) \) number of negative comparisons
- \( r(N_{tie}) \) number of tied comparisons
- \( r(p) \) two-sided \( p \)-value
- \( r(p_l) \) lower one-sided \( p \)-value
- \( r(p_u) \) upper one-sided \( p \)-value

### Methods and formulas

For a practical introduction to these techniques with an emphasis on examples rather than theory, see Bland (2015) or Sprent and Smeeton (2007). For a summary of these tests, see Snedecor and Cochran (1989).

Methods and formulas are presented under the following headings:

- **signrank**
- **signtest**
Both the sign test and Wilcoxon signed-rank tests test the null hypothesis that the distribution of a random variable $D = varname - exp$ has median zero. The sign test makes no additional assumptions, but the Wilcoxon signed-rank test makes the additional assumption that the distribution of $D$ is symmetric. If $D = X_1 - X_2$, where $X_1$ and $X_2$ have the same distribution, then it follows that the distribution of $D$ is symmetric about zero. Thus, the Wilcoxon signed-rank test is often described as a test of the hypothesis that two distributions are the same, that is, $X_1 \sim X_2$.

Let $d_j$ denote the difference for any matched pair of observations,

$$d_j = x_{1j} - x_{2j} = varname - exp$$

for $j = 1, 2, \ldots, n$.

Rank the absolute values of the differences, $|d_j|$, and assign any tied values the average rank. Consider the signs of $d_j$, and let

$$r_j = \text{sign}(d_j) \text{ rank}(|d_j|)$$

be the signed ranks. The test statistic is

$$T_{obs} = \sum_{j=1}^{n} r_j = (\text{sum of ranks for + signs}) - (\text{sum of ranks for - signs})$$

The distribution of the test statistic is based on Fisher’s principle of randomization (Fisher 1935). Fisher’s idea (stated in a modern way) was to look at a family of transformations of the observed data such that the a priori likelihood (under the null hypothesis) of the transformed data is the same as the likelihood of the observed data. The distribution of the test statistic is then produced by calculating its value for each of the transformed “randomization” datasets, assuming that each dataset is equally likely.

The null hypothesis is that the distribution of $d_j$ is symmetric about 0. Hence, the likelihood is unchanged if we flip signs on the $d_j$. The randomization distribution of our test statistic, $T$, is all of its values resulting from the $2^n$ possible sign changes for the $d_j$. Namely, the distribution is all the $2^n$ possible values of

$$T = \sum_{j=1}^{n} S_j r_j$$

where $r_j$ are the observed signed ranks (considered fixed) and $S_j$ is either +1 or −1. When the exact option is specified (or implied for $n \leq 200$), this distribution is computed using a recursive algorithm whose computational time is proportional to $n^3$. (See Fisher [1935] for the principle of randomization; Wilcoxon, Katti, and Wilcox [1970] for the computation with untied ranks; and Baker and Tilbury [1993] for the general recursive algorithm.)

$p$-values can also be computed using a normal approximation to the randomization distribution. For the randomization distribution, the mean and variance are given by

$$E(T) = 0 \quad \text{and} \quad \text{Var}_{adj}(T) = \sum_{j=1}^{n} r_j^2$$

The test statistic for the Wilcoxon signed-rank test is often expressed (equivalently) as the sum of the positive signed ranks, $T_+$, where
\[ E(T_+) = \frac{n(n + 1)}{4} \quad \text{and} \quad \text{Var}_{\text{adj}}(T_+) = \frac{1}{4} \sum_{j=1}^{n} r_j^2 \]

Zeros and ties do not affect the theory above, and the exact variance is still given by the above formula for \( \text{Var}_{\text{adj}}(T_+) \). When \( d_j = 0 \) is observed, \( r_j \) will always be zero in each of the randomization datasets, using \( \text{sign}(0) = 0 \). (This method of handling zeros is based on the theoretical arguments made by Pratt [1959].) When there are ties, averaged ranks are assigned for each group of ties and then treated the same as other ranks.

The “unadjusted variance” reported by \texttt{signrank} is the variance that the randomization distribution would have had if there had been no ties or zeros:

\[ \text{Var}_{\text{unadj}}(T_+) = \frac{1}{4} \sum_{j=1}^{n} j^2 = \frac{n(n + 1)(2n + 1)}{24} \]

The adjustment for zeros is the change in the variance when the ranks for the zeros are signed to make \( r_j = 0 \),

\[ \Delta \text{Var}_{\text{zero adj}}(T_+) = -\frac{1}{4} \sum_{j=1}^{n_0} j^2 = -\frac{n_0(n_0 + 1)(2n_0 + 1)}{24} \]

where \( n_0 \) is the number of zeros. The adjustment for ties is the change in the variance when the ranks (for nonzero observations) are replaced by averaged ranks:

\[ \Delta \text{Var}_{\text{ties adj}}(T_+) = \text{Var}_{\text{adj}}(T_+) - \text{Var}_{\text{unadj}}(T_+) - \Delta \text{Var}_{\text{zero adj}}(T_+) \]

A normal approximation is used to calculate

\[ z = \frac{T_+ - E(T_+)}{\sqrt{\text{Var}_{\text{adj}}(T_+)}} \]

\texttt{signtest}

The test statistic for the sign test is the number \( n_+ \) of differences

\[ d_j = x_{1j} - x_{2j} = \text{varname} - \text{exp} \]

greater than zero.

Again, the distribution of the test statistic is based on Fisher’s principle of randomization, which we described above for \texttt{signrank}. For the sign test, the “data” are simply the set of signs of the differences. Under the null hypothesis of the sign test, the probability that \( d_j \) is less than zero is equal to the probability that \( d_j \) is greater than zero. Thus, you can transform the observed signs by flipping any number of them, and the set of signs will have the same likelihood. The \( 2^n \) possible sign changes form the family of randomization datasets. If you have no zeros, this procedure leads to \( n_+ \sim \text{binomial}(n, p = 1/2) \).

But what if some differences are zero? If you do have zeros, changing their signs leaves them as zeros. So, if you observe \( n_0 \) zeros, each of the \( 2^n \) sign-change datasets will also have \( n_0 \) zeros. Hence, the values of \( n_+ \) calculated over the sign-change datasets range from 0 to \( n - n_0 \), and the “randomization” distribution of \( n_+ \) is \( \text{binomial}(n - n_0, p = 1/2) \).
The work of Arbuthnott (1710) and later eighteenth-century contributions is discussed by Hald (2003, chap. 17).

Frank Wilcoxon (1892–1965) was born in Ireland to American parents. After working in various occupations (including merchant seaman, oil-well pump attendant, and tree surgeon), he settled in chemistry, gaining degrees from Rutgers and Cornell and employment from various companies. Working mainly on the development of fungicides and insecticides, Wilcoxon became interested in statistics in 1925 and made several key contributions to nonparametric methods. After retiring from industry, he taught statistics at Florida State until his death.

simulate — Monte Carlo simulations

**Description**

simulate eases the programming task of performing Monte Carlo–type simulations. Typing

```
.ssimulate exp_list, reps(#): command
```

runs command for # replications and collects the results in exp_list.

*command* defines the command that performs one simulation. Most Stata commands and user-written programs can be used with simulate, as long as they follow standard Stata syntax; see [U] 11 Language syntax. The by prefix may not be part of command.

*exp_list* specifies the expression to be calculated from the execution of command. If no expressions are given, exp_list assumes a default, depending upon whether command changes results in e() or r(). If command changes results in e(), the default is _b. If command changes results in r() (but not e()), the default is all the scalars posted to r(). It is an error not to specify an expression in exp_list otherwise.

**Quick start**

*Simple program for use with simulate*

Define program myreg to generate data and fit a linear regression

```stata
program myreg, eclass
    drop _all
    set obs 25
    generate x = rnormal()
    generate y = 3*x + 1 + rnormal()
    regress y x
end
```

Perform simulation

Record coefficients and SEs from 1,000 simulated replications of program myreg

```
simulate _b _se, reps(1000): myreg
```

As above, and set random-number seed to 5,762 for reproducible results

```
simulate _b _se, reps(1000) seed(5762): myreg
```
### Syntax

Distinguish between [], which are to be typed, and [ ], which indicate optional arguments.

### Options

\text{reps}(\#) is required—it specifies the number of replications to be performed.

\text{nodots} and \text{dots}(\#) specify whether to display replication dots. By default, one dot character is displayed for each successful replication. A red ‘x’ is displayed if \text{command} returns an error or if any value in \text{exp\_list} is missing. You can also control whether dots are displayed using \text{set dots}; see [R] set.

\text{nodots} suppresses display of the replication dots.

\text{dots}(\#) displays dots every \# replications. \text{dots}(0) is a synonym for \text{nodots}.

\text{noisily} requests that any output from \text{command} be displayed. This option implies the \text{nodots} option.
trace causes a trace of the execution of command to be displayed. This option implies the noisily option.

saving(filename[, suboptions]) creates a Stata data file (.dta file) consisting of (for each statistic in exp_list) a variable containing the replicates.

double specifies that the results for each replication be saved as doubles, meaning 8-byte reals. By default, they are saved as floats, meaning 4-byte reals.

every(#) specifies that results be written to disk every #th replication. every() should be specified only in conjunction with saving() when command takes a long time for each replication. This will allow recovery of partial results should some other software crash your computer. See [P] postfile.

replace specifies that filename be overwritten if it exists.

nolegend suppresses display of the table legend. The table legend identifies the rows of the table with the expressions they represent.

verbose requests that the full table legend be displayed. By default, coefficients and standard errors are not displayed.

seed(#) sets the random-number seed. Specifying this option is equivalent to typing the following command before calling simulate:

   . set seed #

Remarks and examples

For an introduction to Monte Carlo methods, see Cameron and Trivedi (2010, chap. 4). White (2010) provides a command for analyzing results of simulation studies.

Example 1: Simulating basic summary statistics

We have a dataset containing means and variances of 100-observation samples from a lognormal distribution (as a first step in evaluating, say, the coverage of a 95%, t-based confidence interval). Then we perform the experiment 1,000 times.

The following command definition will generate 100 independent observations from a lognormal distribution and compute the summary statistics for this sample.

   program lnsim, rclass
   version 16.0
   drop _all
   set obs 100
   generate z = exp(rnormal())
   summarize z
   return scalar mean = r(mean)
   return scalar Var = r(Var)
   end

We can save 1,000 simulated means and variances from lnsim by typing

   . set seed 1234
   . simulate mean=r(mean) var=r(Var), reps(1000) nodots: lnsim

   command:  lnsim
   mean:  r(mean)
   var:  r(Var)
. describe *

<table>
<thead>
<tr>
<th>Variable name</th>
<th>Storage</th>
<th>Display</th>
<th>Value</th>
<th>Variable label</th>
</tr>
</thead>
<tbody>
<tr>
<td>mean</td>
<td>float</td>
<td>%9.0g</td>
<td>r(mean)</td>

</tr>
<tr>
<td>r(mean)</td>
<td>1.53425569280982</td>
</tr>
</tbody>
</table>

Example 2: Simulating a regression model

Consider a more complicated problem. Let’s experiment with fitting $y_j = a + bx_j + u_j$ when the true model has $a = 1$, $b = 2$, $u_j = z_j + cx_j$, and when $z_j$ is $N(0, 1)$. We will save the parameter estimates and standard errors and experiment with varying $c$. $x_j$ will be fixed across experiments but will originally be generated as $N(0, 1)$. We begin by interactively making the true data:

. drop _all
. set obs 100
number of observations (_N) was 0, now 100
. set seed 54321
. generate x = rnormal()
. generate true_y = 1+2*x
. save truth
file truth.dta saved

Our program is

```
program hetero1
    version 16.0
    args c
    use truth, clear
    generate y = true_y + (rnormal() + `c'*x)
    regress y x
end
```
Note the use of ‘c’ in our statement for generating y. c is a local macro generated from args c and thus refers to the first argument supplied to hetero1. If we want c = 3 for our experiment, we type

```
. simulate _b _se, reps(10000): hetero1 3
(output omitted)
```

Our program hetero1 could, however, be more efficient because it rereads the file truth once every replication. It would be better if we could read the data just once. In fact, if we read in the data right before running simulate, we really should not have to reread for each subsequent replication. A faster version reads

```
program hetero2
version 16.0
args c
capture drop y
generate y = true_y + (rnormal() + c*x)
regress y x
end
```

Requiring that the current dataset has the variables true_y and x may become inconvenient. Another improvement would be to require that the user supply variable names, such as in

```
program hetero3
version 16.0
args truey x c
capture drop y
generate y = truey + (rnormal() + c*x
regress y x
end
```

Thus we can type

```
. simulate _b _se, reps(10000): hetero3 true_y x 3
(output omitted)
```

### Example 3: Simulating a ratio of statistics

Now let’s consider the problem of simulating the ratio of two medians. Suppose that each sample of size \(n_i\) comes from a normal population with a mean \(\mu_i\) and standard deviation \(\sigma_i\), where \(i = 1, 2\). We write the program below and save it as a text file called myratio.ado (see [U] 17 Ado-files). Our program is an rclass command that requires six arguments as input, identified by the local macros \(n1\), \(mu1\), \(sigma1\), \(n2\), \(mu2\), and \(sigma2\), which correspond to \(n_1\), \(\mu_1\), \(\sigma_1\), \(n_2\), \(\mu_2\), and \(\sigma_2\), respectively. With these arguments, myratio will generate the data for the two samples, use summarize to compute the two medians and store the ratio of the medians in r(ratio).

```
program myratio, rclass
version 16.0
args n1 mu1 sigma1 n2 mu2 sigma2
// generate the data
drop _all
local N = n1+'n2'
set obs N
tempvar y
generate y = rnormal()
replace y = cond(_n<='n1',mu1+y*sigma1,mu2+y*sigma2)
// calculate the medians
tempname m1
summarize y if _n<='n1', detail
```

scalar 'm1' = r(p50)
summarize 'y' if _n>'n1', detail
// store the results
return scalar ratio = 'm1' / r(p50)
end

The result of running our simulation is

```
set seed 19192
simulate ratio=r(ratio), reps(1000) nodots: myratio 5 3 1 10 3 2
summarize
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>ratio</td>
<td>1,000</td>
<td>1.10875</td>
<td>.5219166</td>
<td>.3606606</td>
<td>9.857285</td>
</tr>
</tbody>
</table>

Technical note

Stata lets us do simulations of simulations and simulations of bootstraps. Stata’s bootstrap command (see [R] bootstrap) works much like simulate, except that it feeds the user-written program a bootstrap sample. Say that we want to evaluate the bootstrap estimator of the standard error of the median when applied to lognormally distributed data. We want to perform a simulation, resulting in a dataset of medians and bootstrap estimated standard errors.

As background, summarize (see [R] summarize) calculates summary statistics, leaving the mean in r(mean) and the standard deviation in r(sd). summarize with the detail option also calculates summary statistics, but more of them, and leaves the median in r(p50).

Thus our plan is to perform simulations by randomly drawing a dataset: we calculate the median of our random sample, we use bootstrap to obtain a dataset of medians calculated from bootstrap samples of our random sample, the standard deviation of those medians is our estimate of the standard error, and the summary statistics are stored in the results of summarize.

Our simulator is

```
program define bsse, rclass
version 16.0
drop _all
set obs 100
generate x = rnormal()
tempfile bsfile
bootstrap midp=r(p50), rep(100) saving('bsfile'): summarize x, detail
use 'bsfile', clear
summarize midp
return scalar mean = r(mean)
return scalar sd   = r(sd)
end
```
We can obtain final results, running our simulation 1,000 times, by typing

```
.set seed 48901
.simulate med=r(mean) bs_se=r(sd), reps(1000): bsse
    command:  bsse
    med: r(mean)
    bs_se: r(sd)
```

This is a case where the simulation dots (drawn by default, unless the `nodots` option is specified) will give us an idea of how long this simulation will take to finish as it runs.

The *Stata Journal* (SJ) is a quarterly journal containing articles about statistics, data analysis, teaching methods, and effective use of Stata’s language. The SJ publishes reviewed papers together with shorter notes and comments, regular columns, tips, book reviews, and other material of interest to researchers applying statistics in a variety of disciplines. You can read all about the *Stata Journal* at [https://www.stata-journal.com](https://www.stata-journal.com).

The *Stata Journal* is a printed and electronic journal with corresponding software. If you want the journal, you must subscribe, but the software is available for no charge from our website at [https://www.stata-journal.com](https://www.stata-journal.com). PDF copies of SJ articles that are older than three years are available for download for no charge at [https://www.stata-journal.com/archives.html](https://www.stata-journal.com/archives.html). More recent articles may be individually purchased.

The predecessor to the *Stata Journal* was the *Stata Technical Bulletin* (STB). The STB was also a printed and electronic journal with corresponding software. PDF copies of all STB journals are available for download for no charge at [https://www.stata-press.com/journals/stbj.html](https://www.stata-press.com/journals/stbj.html). The STB software is available for no charge from our website at [https://www.stata.com](https://www.stata.com).

Below are instructions for installing the *Stata Journal* and the *Stata Technical Bulletin* software from our website.

### Remarks and examples

Remarks are presented under the following headings:

- **Installing the Stata Journal software**
  - Obtaining from the Internet by pointing and clicking
  - Obtaining from the Internet via command mode

- **Installing the STB software**
  - Obtaining from the Internet by pointing and clicking
  - Obtaining from the Internet via command mode

### Installing the Stata Journal software

Each issue of the *Stata Journal* is labeled Volume #, Number #. Volume 1 refers to the first year of publication, Volume 2 to the second, and so on. Issues are numbered 1, 2, 3, and 4 within each year. The first issue of the *Journal* was published in the fourth quarter of 2001, and that issue is numbered Volume 1, Number 1. For installation purposes, we refer to this issue as *sj1-1*.

The articles, columns, notes, and comments that make up the *Stata Journal* are assigned a letter-and-number code, called an insert tag, such as st0001, an0034, or ds0011. The letters represent a category: st is the statistics category, an is the announcements category, etc. The numbers are assigned sequentially, so st0001 is the first article in the statistics category.

Sometimes inserts are subsequently updated, either to fix bugs or to add new features. A number such as st0001_1 indicates that this article, column, note, or comment is an update to the original st0001 article. Updates are complete; that is, installing st0001_1 provides all the features of the original article and more.
The *Stata Journal* software may be obtained by pointing and clicking or by using command mode. The sections below detail how to install an insert. In all cases, pretend that you wish to install insert st0274 from *sj12-4*.

**Obtaining from the Internet by pointing and clicking**

1. Select **Help > SJ and community-contributed commands**.
2. Click on *Stata Journal*.
3. Click on *sj12-4*.
4. Click on *st0274*.
5. Click on *(click here to install)*.

**Obtaining from the Internet via command mode**

Type the following:
```
. net from https://www.stata-journal.com/software
. net cd sj12-4
. net describe st0274
. net install st0274
```

The above could be shortened to
```
. net from https://www.stata-journal.com/software/sj12-4
. net describe st0274
. net install st0274
```

Alternatively, you could type
```
. net sj 12-4
. net describe st0274
. net install st0274
```

but going about it the long way is more entertaining, at least the first time.

**Installing the STB software**

Each issue of the STB is numbered. STB-1 refers to the first issue (published May 1991), STB-2 refers to the second (published July 1991), and so on.

An issue of the STB consists of inserts—articles—and these are assigned letter-and-number combinations, such as sg84, dm80, sbe26.1, etc. The letters represent a category; for example, sg is the general statistics category and dm the data management category. The numbers are assigned sequentially, so sbe39 is the 39th insert in the biostatistics and epidemiology series.

Insert sbe39, it turns out, provides a method of accounting for publication bias in meta-analysis; it adds a new command called *metatrim* to Stata. If you installed sbe39, you would have that command and its help file. Insert sbe39 was published in *STB-57* (September 2000). Obtaining *metatrim* simply requires going to STB-57 and getting sbe39.

Sometimes inserts were subsequently updated, either to fix bugs or to add new features. sbe39 was updated: the first update is sbe39.1 and the second is sbe39.2. You could install insert sbe39.2, and it would not matter whether you had previously installed sbe39.1. Updates are complete: installing sbe39.2 provides all the features of the original insert and more.
For computer naming purposes, insert sbe39.2 is referred to as sbe39_2. When referred to in normal text, however, the insert is still called sbe39.2 because that looks nicer.

Inserts are easily available from the Internet. Inserts may be obtained by pointing and clicking or by using command mode.

The sections below detail how to install an insert. In all cases, pretend that you wish to install insert sbe39.2 from STB-61.

**Obtaining from the Internet by pointing and clicking**

1. Select **Help > SJ and community-contributed commands**.
2. Click on **STB**.
3. Click on **stb61**.
4. Click on **sbe39_2**.
5. Click on *(click here to install)*.

**Obtaining from the Internet via command mode**

Type the following:

```
. net from https://www.stata.com
. net cd stb
. net cd stb61
. net describe sbe39_2
. net install sbe39_2
```

The above could be shortened to

```
. net from https://www.stata.com/stb/stb61
. net describe sbe39_2
. net install sbe39_2
```

but going about it the long way is more entertaining, at least the first time.

**sktest — Skewness and kurtosis test for normality**

**Description**
For each variable in `varlist`, `sktest` presents a test for normality based on skewness and another based on kurtosis and then combines the two tests into an overall test statistic. `sktest` requires a minimum of 8 observations to make its calculations. See [MV] `mvtest normality` for multivariate tests of normality.

**Quick start**
Test for normality of `v1` based on skewness and kurtosis

```
sktest v1
```

Separate tests for `v1` and `v2`

```
sktest v1 v2
```

With frequency weight `wvar`

```
sktest v1 v2 [fweight=wvar]
```

Suppress adjustment to the overall $\chi^2$ test

```
sktest v1 v2, noadjust
```

**Menu**
Statistics > Summaries, tables, and tests > Distributional plots and tests > Skewness and kurtosis normality test
### Syntax

```
sktest varlist [if] [in] [weight] [, noadjust]
```

aweight and fweight are allowed; see [U] 11.1.6 `weight`.

### Option

```
noadjust
```

noadjust suppresses the empirical adjustment made by Royston (1991c) to the overall \( \chi^2 \) and its significance level and presents the unaltered test as described by D’Agostino, Belanger, and D’Agostino (1990).

### Remarks and examples

Also see [R] `swilk` for the Shapiro–Wilk and Shapiro–Francia tests for normality. Those tests are, in general, preferred for nonaggregated data (Gould and Rogers 1991; Gould 1992; Royston 1991c). Moreover, a normal quantile plot should be used with any test for normality; see [R] `Diagnostic plots` for more information.

#### Example 1

Using our automobile dataset, we will test whether the variables `mpg` and `trunk` are normally distributed:

```
. use https://www.stata-press.com/data/r16/auto
(1978 Automobile Data)
. sktest mpg trunk
```

```
Skewness/Kurtosis tests for Normality

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Pr(Skewness)</th>
<th>Pr(Kurtosis)</th>
<th>adj chi2(2)</th>
<th>Prob&gt;chi2</th>
</tr>
</thead>
<tbody>
<tr>
<td>mpg</td>
<td>74</td>
<td>0.0015</td>
<td>0.0804</td>
<td>10.95</td>
<td>0.0042</td>
</tr>
<tr>
<td>trunk</td>
<td>74</td>
<td>0.9115</td>
<td>0.0445</td>
<td>4.19</td>
<td>0.1228</td>
</tr>
</tbody>
</table>
```

We can reject the hypothesis that `mpg` is normally distributed, but we cannot reject the hypothesis that `trunk` is normally distributed, at least at the 12% level. The kurtosis for `trunk` is 2.19, as can be verified by issuing the command

```
. summarize trunk, detail
```

(output omitted)

and the \( p \)-value of 0.0445 shown in the table above indicates that it is significantly different from the kurtosis of a normal distribution at the 5% significance level. However, on the basis of skewness alone, we cannot reject the hypothesis that `trunk` is normally distributed.
Technical note

sktest implements the test as described by D’Agostino, Belanger, and D’Agostino (1990) but with the adjustment made by Royston (1991c). In the above example, if we had specified the noadjust option, the $\chi^2$ values would have been 13.13 for mpg and 4.05 for trunk. With the adjustment, the $\chi^2$ value might show as ‘.’. This result should be interpreted as an absurdly large number; the data are most certainly not normal.

Stored results

sktest stores the following in r():

Scalars
- r(chi2) $\chi^2$
- r(P_skew) Pr(skewness)
- r(P_kurt) Pr(kurtosis)
- r(P_chi2) Prob > chi2

Matrices
- r(N) matrix of observations
- r(Utest) matrix of test results, one row per variable

Methods and formulas

sktest implements the test described by D’Agostino, Belanger, and D’Agostino (1990) with the empirical correction developed by Royston (1991c).

Let $g_1$ denote the coefficient of skewness and $b_2$ denote the coefficient of kurtosis as calculated by summarize, and let $n$ denote the sample size. If weights are specified, then $g_1$, $b_2$, and $n$ denote the weighted coefficients of skewness and kurtosis and weighted sample size, respectively. See [R] summarize for the formulas for skewness and kurtosis.

To perform the test of skewness, we compute

$$Y = g_1 \left\{ \frac{(n+1)(n+3)}{6(n-2)} \right\}^{1/2}$$

$$\beta_2(g_1) = \frac{3(n^2 + 27n - 70)(n+1)(n+3)}{(n-2)(n+5)(n+7)(n+9)}$$

$$W^2 = -1 + [2 \{ \beta_2(g_1) - 1 \}]^{1/2}$$

and

$$\alpha = \left\{ \frac{2}{W^2 - 1} \right\}^{1/2}$$

Then the distribution of the test statistic

$$Z_1 = \frac{1}{\sqrt{\ln W}} \ln \left[ Y/\alpha + \left\{ (Y/\alpha)^2 + 1 \right\}^{1/2} \right]$$

is approximately standard normal under the null hypothesis that the data are distributed normally.
To perform the test of kurtosis, we compute

\[ E(b_2) = \frac{3(n - 1)}{n + 1} \]

\[ \text{var}(b_2) = \frac{24n(n - 2)(n - 3)}{(n + 1)^2(n + 3)(n + 5)} \]

\[ X = \frac{b_2 - E(b_2)}{\sqrt{\text{var}(b_2)}} \]

\[ \sqrt{\beta_1(b_2)} = \frac{6(n^2 - 5n + 2)}{(n + 7)(n + 9)} \left\{ \frac{6(n + 3)(n + 5)}{n(n - 2)(n - 3)} \right\}^{1/2} \]

and

\[ A = 6 + \frac{8}{\sqrt{\beta_1(b_2)}} \left[ \frac{2}{\sqrt{\beta_1(b_2)}} + \left\{ 1 + \frac{4}{\beta_1(b_2)} \right\}^{1/2} \right] \]

Then the distribution of the test statistic

\[ Z_2 = \frac{1}{\sqrt{2/(9A)}} \left[ \left( 1 - \frac{2}{9A} \right) - \left\{ \frac{1 - 2/A}{1 + X\sqrt{2/(A - 4)}} \right\}^{1/3} \right] \]

is approximately standard normal under the null hypothesis that the data are distributed normally.

D’Agostino, Balanger, and D’Agostino Jr.’s omnibus test of normality uses the statistic

\[ K^2 = Z_1^2 + Z_2^2 \]

which has approximately a \( \chi^2 \) distribution with 2 degrees of freedom under the null of normality.

Royston (1991c) proposed the following adjustment to the test of normality, which \texttt{sktest} uses by default. Let \( \Phi(x) \) denote the cumulative standard normal distribution function for \( x \), and let \( \Phi^{-1}(p) \) denote the inverse cumulative standard normal function [that is, \( x = \Phi^{-1}\{\Phi(x)\} \)]. Define the following terms:

\[ Z_c = -\Phi^{-1}\left\{ \exp\left( -\frac{1}{2} K^2 \right) \right\} \]

\[ Z_t = 0.55n^{0.2} - 0.21 \]

\[ a_1 = (-5 + 3.46 \ln n) \exp(-1.37 \ln n) \]

\[ b_1 = 1 + (0.854 - 0.148 \ln n) \exp(-0.55 \ln n) \]

\[ a_2 = a_1 - \{2.13/(1 - 2.37 \ln n)\} Z_t \]

and

\[ b_2 = 2.13/(1 - 2.37 \ln n) + b_1 \]

If \( Z_c < -1 \) set \( Z = Z_c \); else if \( Z_c < Z_t \) set \( Z = a_1 + b_1 Z_c \); else set \( Z = a_2 + b_2 Z_c \). Define \( P = 1 - \Phi(Z) \). Then \( K^2 = -2 \ln P \) is approximately distributed \( \chi^2 \) with 2 degrees of freedom.

The relative merits of the skewness and kurtosis test versus the Shapiro–Wilk and Shapiro–Francia tests have been a subject of debate. The interested reader is directed to the articles in the \textit{Stata Technical Bulletin}. Our recommendation is to use the Shapiro–Francia test whenever possible, that is, whenever dealing with nonaggregated or ungrouped data (Gould and Rogers 1991; Gould 1992); see \texttt{R swilk}. If normality is rejected, use \texttt{sktest} to determine the source of the problem.
As both D’Agostino, Belanger, and D’Agostino (1990) and Royston (1991d) mention, researchers should also examine the normal quantile plot to determine normality rather than blindly relying on a few test statistics. See the `qnorm` command documented in [R] Diagnostic plots for more information on normal quantile plots.

`sktest` is similar in spirit to the Jarque–Bera (1987) test of normality. The Jarque–Bera test statistic is also calculated from the sample skewness and kurtosis, though it is based on asymptotic standard errors with no corrections for sample size. In effect, `sktest` offers two adjustments for sample size, that of Royston (1991c) and that of D’Agostino, Belanger, and D’Agostino (1990).

Acknowledgments

`sktest` has benefited greatly by the comments and work of Patrick Royston of the MRC Clinical Trials Unit, London, and coauthor of the Stata Press book *Flexible Parametric Survival Analysis Using Stata: Beyond the Cox Model*. At this point, the program should be viewed as due as much to Royston as to us, except, of course, for any errors. We are also indebted to Nicholas J. Cox of the Department of Geography at Durham University, UK, and coeditor of the *Stata Journal* and author of *Speaking Stata Graphics* for his helpful comments.

*indepvars* may contain factor variables; see [U] 11.4.3 Factor variables.

*bootstrap*, *by*, *fp*, *jackknife*, *rolling*, *statsby*, and *svy* are allowed; see [U] 11.10 Prefix commands.

Weights are not allowed with the *bootstrap* prefix; see [R] bootstrap.

*vce()* and weights are not allowed with the *svy* prefix; see [SVY] svy.

*fweights*, *iweights*, and *pweights* are allowed; see [U] 11.6 weight.

collinear and coeflegend do not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

Options

---

**Model**

*dimension(#)* specifies the dimension of the model, which is the number of equations required to describe the relationship between the dependent variable and the independent variables. The maximum dimension is \( \min(m - 1, p) \), where \( m \) is the number of categories of the dependent variable and \( p \) is the number of independent variables in the model. The stereotype model with maximum dimension is a reparameterization of the multinomial logistic model.

*baseoutcome(# | lbl)* specifies the outcome level whose scale parameters and intercept are constrained to be zero. The base outcome may be specified as a number or a label. By default, *slogit* assumes
that the outcome levels are ordered and uses the largest level of the dependent variable as the base outcome.

**constraints(numlist); see [R] Estimation options.**

By default, the linear equality constraints suggested by Anderson (1984), termed the corner constraints, are generated for you. You can add constraints to these as needed, or you can turn off the corner constraints by specifying nocorner. These constraints are in addition to the constraints placed on the $\phi$ parameters corresponding to baseoutcome(#).

nocorner specifies that slogit not generate the corner constraints. If you specify nocorner, you must specify at least dimension() $\times$ dimension() constraints for the model to be identified.

**vce(vcetype)** specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim, opg), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.

If specifying vce(bootstrap) or vce(jackknife), you must also specify baseoutcome().

**level(#), nocnsreport; see [R] Estimation options.**

**display_options:** noci, nopvalues, noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(#), fvwrapon(style), cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch; see [R] Estimation options.

**Maximization**

**maximize_options:** difficult, technique(algorithm_spec), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), itolerance(#), nrtolerance(#), nonrtolerance, and from(init_specs); see [R] Maximize. These options are seldom used.

Setting the optimization type to technique(bhhh) resets the default vcetype to vce(opg).

**initialize(constant|random|svd)** specifies how initial estimates are computed. The default, initialize(constant), is to set the scale parameters to the constant $\min(1/2, 1/d)$, where $d$ is the dimension specified in dimension().

initialize(random) requests that uniformly distributed random numbers between 0 and 1 be used as initial values for the scale parameters. If you specify this option, you should also use set seed to ensure that you can replicate your results; see [R] set seed.

initialize(svd) requests that a singular value decomposition (SVD) be performed on the matrix of regression estimates from mlogit to reduce its rank to the dimension specified in dimension(). slogit uses the reduced-rank components of the SVD as initial estimates for the scale and regression coefficients. For details, see Methods and formulas.

nonormalize specifies that the numeric variables not be normalized. Normalization of the numeric variables improves numerical stability but consumes more memory in generating temporary double-precision variables. Variables that are of type byte are not normalized, and if initial estimates are specified using the from() option, normalization of variables is not performed. See Methods and formulas for more information.
The following options are available with `slogit` but are not shown in the dialog box: `collinear`, `coeflegend`; see [R] Estimation options.

Remarks and examples

Remarks are presented under the following headings:

- Introduction
- One-dimensional model
- Higher-dimension models

Introduction

Like multinomial logistic and ordered logistic models, stereotype logistic models are used with categorical dependent variables. They are often used when subjects are requested to assess or judge something. In a multinomial logistic model, the categories cannot be ranked. By contrast, in an ordered logistic model, the categories follow a natural ranking scheme and are subject to the proportional-odds assumption. Stereotype logistic regression can be viewed as a compromise between these two models and is primarily used when you are unsure of the relevance of the ordering of the outcome.

A common case is when subjects are asked to assess or judge something. For example, consider a survey in which consumers are asked to rate the quality of a product on a scale from 1 to 5, with 1 indicating poor quality and 5 indicating excellent quality. If the categories are monotonically related to one underlying latent variable, the ordered logistic model is appropriate. However, suppose that consumers weigh two or three latent factors when assessing quality. The stereotype logistic model is preferred to the ordered logistic model in this case because it allows you to specify multiple equations to capture the effects of the latent variables. Unlike multinomial logit models, the number of equations you specify could be fewer than \( m - 1 \), where \( m \) is the number of categories of the dependent variable. Stereotype logistic models are also used when categories may be indistinguishable. Suppose that a consumer must choose among A, B, C, or D. Multinomial logistic modeling assumes that the four choices are distinct in the sense that a consumer choosing one of the goods can distinguish its characteristics from the others. If goods A and B are in fact similar, consumers may be randomly picking between the two. One alternative is to combine the two categories and fit a three-category multinomial logistic model. A more flexible alternative is to use a stereotype logistic model.

In the multinomial logistic model, you estimate \( m - 1 \) parameter vectors \( \tilde{\beta}_k, k = 1, \ldots, m - 1 \), where \( m \) is the number of categories of the dependent variable. The stereotype logistic model is a restriction on the multinomial model in the sense that there are \( d \) parameter vectors, where \( d \) is between one and \( \min(m - 1, p) \), and \( p \) is the number of regressors. The relationship between the stereotype model’s coefficients \( \beta_j, j = 1, \ldots, d \), and the multinomial model’s coefficients is \( \tilde{\beta}_k = -\sum_{j=1}^{d} \phi_{jk} \beta_j \). The \( \phi \)s are scale parameters to be estimated along with the \( \beta \)s.

Given a row vector of covariates \( x \), let \( \eta_k = \theta_k - \sum_{j=1}^{d} \phi_{jk} x \beta_j \). The probability of observing outcome \( k \) is

\[
\Pr(Y_i = k) = \begin{cases} 
\frac{\exp(\eta_k)}{1 + \sum_{l=1}^{m-1} \exp(\eta_l)} & k < m \\
\frac{1}{1 + \sum_{l=1}^{m-1} \exp(\eta_l)} & k = m 
\end{cases}
\]
This model includes a set of $\theta$ parameters so that each equation has an unrestricted constant term. If $d = m - 1$, the stereotype model is just a reparameterization of the multinomial logistic model. To identify the $\phi$s and the $\beta$s, you must place at least $d^2$ restrictions on the parameters. By default, `slogit` uses the “corner constraints” $\phi_{jj} = 1$ and $\phi_{jk} = 0$ for $j \neq k$, $k \leq d$, and $j \leq d$.

For a discussion of the stereotype logistic model, see Lunt (2005).

### One-dimensional model

#### Example 1

We have 2 years of repair rating data on the make, price, mileage rating, and gear ratio of 104 foreign and 44 domestic automobiles (with 13 missing values on repair rating). We wish to fit a stereotype logistic model to discriminate between the levels of repair rating using mileage, price, gear ratio, and origin of the manufacturer. Here is an overview of our data:

```
. use https://www.stata-press.com/data/r16/auto2yr
(Automobile Models)
. tabulate repair

<table>
<thead>
<tr>
<th>Repair rating</th>
<th>Freq.</th>
<th>Percent</th>
<th>Cum.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Poor</td>
<td>5</td>
<td>3.70</td>
<td>3.70</td>
</tr>
<tr>
<td>Fair</td>
<td>19</td>
<td>14.07</td>
<td>17.78</td>
</tr>
<tr>
<td>Average</td>
<td>57</td>
<td>42.22</td>
<td>60.00</td>
</tr>
<tr>
<td>Good</td>
<td>38</td>
<td>28.15</td>
<td>88.15</td>
</tr>
<tr>
<td>Excellent</td>
<td>16</td>
<td>11.85</td>
<td>100.00</td>
</tr>
<tr>
<td>Total</td>
<td>135</td>
<td>100.00</td>
<td></td>
</tr>
</tbody>
</table>
```

The variable `repair` can take five values, 1, ..., 5, which represent the subjective rating of the car model’s repair record as Poor, Fair, Average, Good, and Excellent.

We wish to fit the one-dimensional stereotype logistic model

$$\eta_k = \theta_k - \phi_k (\beta_1 \text{foreign} + \beta_2 \text{mpg} + \beta_3 \text{price} + \beta_4 \text{gratio})$$

for $k < 5$ and $\eta_5 = 0$. To fit this model, we type
The coefficient associated with the first scale parameter, $\phi_{11}$, is 1, and its standard error and other statistics are missing. This is the corner constraint applied to the one-dimensional model; in the header, this constraint is listed as $[\text{phi1}_1]_{\text{cons}} = 1$. Also, the $\phi$ and $\theta$ parameters that are associated with the base outcome are identified. Keep in mind, though, that there are no coefficient estimates for $[\text{phi1}_5]_{\text{cons}}$ or $[\text{theta5}]_{\text{cons}}$ in the e(merge) matrix $e(b)$. The Wald statistic is for a test of the joint significance of the regression coefficients on foreign, mpg, price, and gratio.

The one-dimensional stereotype model restricts the multinomial logistic regression coefficients $\tilde{\beta}_k$, $k = 1, \ldots, m-1$ to be parallel; that is, $\tilde{\beta}_k = -\phi_k \beta$. As Lunt (2001) discusses, in the one-dimensional stereotype model, one linear combination $x_i \beta$ best discriminates the outcomes of the dependent variable, and the scale parameters $\phi_k$ measure the distance between the outcome levels and the linear predictor. If $\phi_1 \geq \phi_2 \geq \cdots \geq \phi_{m-1} \geq \phi_m \equiv 0$, the model suggests that the subjective assessment of the dependent variable is indeed ordered. Here the maximum likelihood estimates of the $\phi$’s are not monotonic, as would be assumed in an ordered logit model.

We test that $\phi_1 = \phi_2$ by typing

```
.test [phi1_2]_cons = [phi1_1]_cons
(1) - [phi1_1]_cons + [phi1_2]_cons = 0
```

```
chi2( 1) = 0.55
Prob > chi2 = 0.4576
```
Because the two parameters are not statistically different, we decide to add a constraint to force $\phi_1 = \phi_2$:

```
constraint define 1 [phi1_2]_cons = [phi1_1]_cons
.slogit repair foreign mpg price gratio, constraint(1) nolog
```

Stereotype logistic regression

<table>
<thead>
<tr>
<th>Number of obs</th>
<th>Wald chi2(4)</th>
<th>Log likelihood</th>
<th>Prob &gt; chi2</th>
</tr>
</thead>
<tbody>
<tr>
<td>135</td>

<td>-159.65769</td>
<td>0.0003</td>
</tr>
</tbody>
</table>

(1) $[\phi1_1]_\text{cons} = 1$
(2) $- [\phi1_1]_\text{cons} + [\phi1_2]_\text{cons} = 0$

| repair | Coef.  | Std. Err. | z     | P>|z|   | [95% Conf. Interval] |
|--------|--------|-----------|-------|-------|----------------------|
| foreign| 7.166515 | 1.690177  | 4.24  | 0.000 | 3.853829 - 10.4792   |
| mpg    | 0.2340043| 0.0807042 | 2.90  | 0.004 | 0.0758271 - 0.3921816 |
| price  | -0.000041| 0.001618  | -0.25 | 0.800 | -.0003581 - 0.000276  |
| gratio | -5.218107| 1.798717  | -2.90 | 0.004 | -8.743528 - 1.692686  |

/phi1_1  1 (constrained)
/phi2_2  1 (constrained)
/phi3_3  0.9751096 0.1286563 7.58 0.000 0.7229478 1.227271
/phi4_4  0.7209343 0.1220353 5.91 0.000 0.4817494 0.9601191
/phi5_5  0 (base outcome)

/theta1 -8.293452 4.645182 -1.79 0.074 -17.39784 8.109368
/theta2 -6.958451 4.629292 -1.50 0.133 -16.0317 2.114795
/theta3 -5.620232 4.953981 -1.13 0.257 -15.32986 4.099392
/theta4 -3.745624 3.809189 -0.98 0.325 -11.2115 3.720249
/theta5  0 (base outcome)

(repair=Excellent is the base outcome)

The $\phi$ estimates are now monotonically decreasing and the standard errors of the $\phi$’s are small relative to the size of the estimates, so we conclude that, with the exception of outcomes Poor and Fair, the groups are distinguishable for the one-dimensional model and that the quality assessment can be ordered.

---

**Higher-dimension models**

The stereotype logistic model is not limited to ordered categorical dependent variables; you can use it on nominal data to reduce the dimension of the regressions. Recall that a multinomial model fit to a categorical dependent variable with $m$ levels will have $m-1$ sets of regression coefficients. However, a model with fewer dimensions may fit the data equally well, suggesting that some of the categories are indistinguishable.

**Example 2**

As discussed in [R] mlogit, we have data on the type of health insurance available to 616 psychologically depressed subjects in the United States (Tarlov et al. 1989; Wells et al. 1989). Patients may have either an indemnity (fee-for-service) plan or a prepaid plan, such as an HMO, or may be uninsured. Demographic variables include age, gender, race, and site.

First, we fit the saturated, two-dimensional model that is equivalent to a multinomial logistic model. We choose the base outcome to be 1 (indemnity insurance) because that is the default for mlogit.
. use https://www.stata-press.com/data/r16/sysdsn1  
(Health insurance data)

   site 2     0.1130359   0.2101903   0.54  0.591  -0.2989296   0.5250013
   site 3    -0.5879879   0.2279351  -2.58  0.010  -1.034733  -0.1412433
   _cons     0.2697127   0.3284422   0.82  0.412  -0.3740222   0.9134476
Uninsure
   age       -0.0077961   0.0114418  -0.68  0.496  -0.0302217   0.0146294
   male      0.4518496   0.3674867   1.23  0.219  -0.268411    1.17211
   nonwhite  0.2170589   0.4256361   0.51  0.610  -0.6171725   1.05129
   site 2    -1.211563   0.4705127  -2.57  0.010  -2.133751  -0.2893747
   site 3    -0.2078123   0.3662926  -0.57  0.570  -0.9257327   0.510108
   _cons    -1.286943   0.5923219  -2.17  0.030  -2.447872  -0.1260134
\end{verbatim}

Apart from having opposite signs, the coefficients from the stereotype logistic model are identical to those from the multinomial logit model. Recall the definition of $\eta_k$ given in the Remarks and examples, particularly the minus sign in front of the summation. One other difference in the output is that the constant estimates labeled /theta in the \texttt{slogit} output are the constants labeled \_cons in the \texttt{mlogit} output.

Next we examine the one-dimensional model.
. s logit insure age male nonwhite i.site, dim(1) base(1) nolog

(insure=Indemnity is the base outcome)

We have reduced a two-dimensional multinomial model to one dimension, reducing the number of estimated parameters by four and decreasing the model likelihood by ≈ 5.4.

slogit does not report a model likelihood-ratio test. The test of \(d = 1\) (a one-dimensional model) versus \(d = 0\) (the null model) does not have an asymptotic \(\chi^2\) distribution because the unconstrained \(\phi\) parameters (/phi1_3 in this example) cannot be identified if \(\beta = 0\). More generally, this problem precludes testing any hierarchical model of dimension \(d\) versus \(d - 1\). Of course, the likelihood-ratio test of a full-dimension model versus \(d = 0\) is valid because the full model is just multinomial logistic, and all the \(\phi\) parameters are fixed at 0 or 1.

Technical note

The stereotype model is a special case of the reduced-rank vector generalized linear model discussed by Yee and Hastie (2003). If we define \(\eta_{ik} = \theta_k - \sum_{j=1}^{d} \phi_{jk} x_i \beta_j\), for \(k = 1, \ldots, m - 1\), we can write the expression in matrix notation as

\[
\eta_i = \theta + \Phi (x_i \beta)'
\]

where \(\Phi\) is a \((m - 1) \times d\) matrix containing the \(\phi_{jk}\) parameters and \(\beta\) is a \(p \times d\) matrix with columns containing the \(\beta_j\) parameters, \(j = 1, \ldots, d\). The factorization \(\Phi \beta' = \Phi M M^{-1} \beta'\) for any nonsingular \(d \times d\) matrix \(M\). To avoid this identifiability problem, we choose \(M = \Phi_1^{-1}\), where

\[
\Phi = \begin{pmatrix}
\Phi_1 \\
\Phi_2
\end{pmatrix}
\]

and \(\Phi_1\) is \(d \times d\) of rank \(d\) so that

\[
\Phi M = \begin{pmatrix} I_d \\
\Phi_2 \Phi_1^{-1}
\end{pmatrix}
\]

and \(I_d\) is a \(d \times d\) identity matrix. Thus the corner constraints used by s logit are \(\phi_{jj} \equiv 1\) and \(\phi_{jk} \equiv 0\) for \(j \neq k\) and \(k, j \leq d\).
Stocked results

`slogit` stores the following in `e()`:

Scalars
- `e(N)` number of observations
- `e(k)` number of parameters
- `e(k_indvars)` number of independent variables
- `e(k_out)` number of outcomes
- `e(k_eq)` number of equations in `e(b)`
- `e(k_eq_model)` number of equations in overall model test
- `e(df_m)` Wald test degrees of freedom
- `e(df_0)` null model degrees of freedom
- `e(k_dim)` model dimension
- `e(i_base)` base outcome index
- `e(ll)` log likelihood
- `e(ll_0)` null model log likelihood
- `e(N_clust)` number of clusters
- `e(chi2)` $\chi^2$
- `e(p)` $p$-value for model test
- `e(ic)` number of iterations
- `e(rank)` rank of `e(V)`
- `e(rc)` return code
- `e(converged)` 1 if converged, 0 otherwise

Macros
- `e(cmd)` `slogit`
- `e(cmdline)` command as typed
- `e(depvar)` name of dependent variable
- `e(indvars)` independent variables
- `e(wtype)` weight type
- `e(wexp)` weight expression
- `e(title)` title in estimation output
- `e(clustvar)` name of cluster variable
- `e(out##)` outcome labels, $# = 1,..., e(k_out)$
- `e(chi2type)` Wald; type of model $\chi^2$ test
- `e(vce)` `vcetype` specified in `vce()`
- `e(vcetype)` title used to label Std. Err.
- `e(opt)` type of optimization
- `e(which)` `max` or `min`; whether optimizer is to perform maximization or minimization
- `e(ml_method)` type of `ml` method
- `e(user)` name of likelihood-evaluator program
- `e(technique)` maximization technique
- `e(properties)` `b V`
- `e(predict)` program used to implement `predict`
- `e(marginsnotok)` predictions disallowed by `margins`
- `e(marginsdefault)` default `predict()` specification for `margins`
- `e(footnote)` program used to implement the footnote display
- `e(asbalanced)` factor variables `fvset` as `asbalanced`
- `e(asobserved)` factor variables `fvset` as `asobserved`

Matrices
- `e(b)` coefficient vector
- `e(outcomes)` outcome values
- `e(Cns)` constraints matrix
- `e(lllog)` iteration log (up to 20 iterations)
- `e(gradient)` gradient vector
- `e(V)` variance–covariance matrix of the estimators
- `e(V_modelbased)` model-based variance

Functions
- `e(sample)` marks estimation sample
Methods and formulas

slogit obtains the maximum likelihood estimates for the stereotype logistic model by using ml; see [R] ml. Each set of regression estimates, one set of $\beta_j$’s for each dimension, constitutes one ml model equation. The $d \times (m - 1)$ $\phi$s and the $(m - 1)$ $\theta$s are ml ancillary parameters.

Without loss of generality, let the base outcome level be the $m$th level of the dependent variable. Define the row vector $\phi_k = (\phi_{1k}, \ldots, \phi_{dk})$ for $k = 1, \ldots, m - 1$, and define the $p \times d$ matrix $B = (\beta_1, \ldots, \beta_d)$. For observation $i$, the log odds of outcome level $k$ relative to level $m$, $k = 1, \ldots, m - 1$ is

$$\ln \left\{ \frac{Pr(Y_i = k)}{Pr(Y_i = m)} \right\} = \eta_{ik} = \theta_k - \phi_k (x_i B)'$$

$$= \theta_k - \phi_k \nu_i'$$

The row vector $\nu_i$ can be interpreted as a latent variable reducing the $p$-dimensional vector of covariates to a more interpretable $d < p$ dimension.

The probability of the $i$th observation having outcome level $k$ is then

$$Pr(Y_i = k) = p_{ik} = \begin{cases} \frac{e^{\eta_{ik}}}{1 + \sum_{j=1}^{m-1} e^{\eta_{ij}}}, & \text{if } k < m \\ \frac{1}{1 + \sum_{j=1}^{m-1} e^{\eta_{ij}}}, & \text{if } k = m \end{cases}$$

from which the log-likelihood function is computed as

$$L = \sum_{i=1}^{n} w_i \sum_{k=1}^{m} I_k(y_i) \ln(p_{ik})$$

(1)

Here $w_i$ is the weight for observation $i$ and

$$I_k(y_i) = \begin{cases} 1, & \text{if observation } y_i \text{ has outcome } k \\ 0, & \text{otherwise} \end{cases}$$

Numeric variables are normalized for numerical stability during optimization where a new double-precision variable $\tilde{x}_j$ is created from variable $x_j$, $j = 1, \ldots, p$, such that $\tilde{x}_j = (x_j - \bar{x}_j)/s_j$. This feature is turned off if you specify nonormalize, or if you use the from() option for initial estimates. Normalization is not performed on byte variables, including the indicator variables generated by [R] xi. The linear equality constraints for regression parameters, if specified, must be scaled also. Assume that a constraint is applied to the regression parameter associated with variable $j$ and dimension $i$, $\beta_{ji}$, and the corresponding element of the constraint matrix (see [P] makecns) is divided by $s_j$.

After convergence, the parameter estimates for variable $j$ and dimension $i$—$\tilde{\beta}_{ji}$, say—are transformed back to their original scale, $\beta_{ji} = \tilde{\beta}_{ji}/s_j$. For the intercepts, you compute

$$\theta_k = \tilde{\theta}_k + \sum_{i=1}^{d} \phi_{ik} \sum_{j=1}^{p} \frac{\tilde{\beta}_{ji} \bar{x}_j}{s_j}$$
Initial values are computed using estimates obtained using \texttt{mlogit} to fit a multinomial logistic model. Let the \( p \times (m - 1) \) matrix \( \mathbf{\tilde{B}} \) contain the multinomial logistic regression parameters less the \( m - 1 \) intercepts. Each \( \phi \) is initialized with constant values \( \min(1/2, 1/d) \), the \texttt{initialize(constant)} option (the default), or, with uniform random numbers, the \texttt{initialize(random)} option. Constraints are then applied to the starting values so that the structure of the \((m - 1) \times d\) matrix \( \Phi \) is

\[
\Phi = \begin{pmatrix}
\phi_1 \\
\phi_2 \\
\vdots \\
\phi_{m-1}
\end{pmatrix} = \begin{pmatrix}
\mathbf{I}_d \Phi
\end{pmatrix}
\]

where \( \mathbf{I}_d \) is a \( d \times d \) identity matrix. Assume that only the corner constraints are used, but any constraints you place on the scale parameters are also applied to the initial scale estimates, so the structure of \( \Phi \) will change accordingly. The \( \phi \) parameters are invariant to the scale of the covariates, so initial estimates in \([0, 1]\) are reasonable. The constraints guarantee that the rank of \( \Phi \) is at least \( d \), so the initial estimates for the stereotype regression parameters are obtained from \( \mathbf{B} = \mathbf{\tilde{B}} \Phi (\Phi' \Phi)^{-1} \).

One other approach for initial estimates is provided: \texttt{initialize(svd)}. It starts with the \texttt{mlogit} estimates and computes \( \mathbf{\tilde{B}}' = \mathbf{U} \mathbf{D} \mathbf{V}' \), where \( \mathbf{U}_{m-1 \times p} \) and \( \mathbf{V}_{p \times p} \) are orthonormal matrices and \( \mathbf{D}_{p \times p} \) is a diagonal matrix containing the singular values of \( \mathbf{\tilde{B}} \). The estimates for \( \mathbf{\Phi} \) and \( \mathbf{B} \) are the first \( d \) columns of \( \mathbf{U} \) and \( \mathbf{VD} \), respectively (Yee and Hastie 2003).

The score for regression coefficients is

\[
u_i(\beta_j) = \left( \frac{\partial L_{ik}}{\partial \beta_j} \right) = x_i \left( \sum_{l=1}^{m-1} \phi_{jl}p_{il} - \phi_{jk} \right)
\]

the score for the scale parameters is

\[
u_i(\phi_{jl}) = \left( \frac{\partial L_{ik}}{\partial \phi_{jl}} \right) = \begin{cases} 
  x_i \beta_j (p_{ik} - 1), & \text{if } l = k \\
  x_i \beta_j p_{il}, & \text{if } l \neq k
\end{cases}
\]

for \( l = 1, \ldots, m - 1 \); and the score for the intercepts is

\[
u_i(\theta_l) = \left( \frac{\partial L_{ik}}{\partial \theta_l} \right) = \begin{cases} 
  1 - p_{ik}, & \text{if } l = k \\
  -p_{il}, & \text{if } l \neq k
\end{cases}
\]

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using \texttt{vce(robust)} and \texttt{vce(cluster clustvar)}, respectively. See [P] \_robust, particularly \texttt{Maximum likelihood estimators} and \texttt{Methods and formulas}.

\texttt{slogit} also supports estimation with survey data. For details on VCEs with survey data, see [SVY] \texttt{Variance estimation}.

predict

Description for predict

predict creates a new variable containing predictions such as probabilities, indexes for the \( k \)th outcome, and standard errors.

Menu for predict

Statistics > Postestimation

Syntax for predict

\[
\text{predict [type] \{stub* | newvar | newvarlist\} [if] [in] [outcome(outcome)]}
\]

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>pr</td>
<td>probability of one of or all the dependent variable outcomes; the default</td>
</tr>
<tr>
<td>xb</td>
<td>index for the ( k )th outcome</td>
</tr>
<tr>
<td>stdp</td>
<td>standard error of the index for the ( k )th outcome</td>
</tr>
<tr>
<td>scores</td>
<td>equation-level scores</td>
</tr>
</tbody>
</table>

You specify one or \( k \) new variables with pr, where \( k \) is the number of outcomes. If you specify one new variable and you do not specify outcome(), then outcome(#1) is assumed.

You specify one new variable with xb and stdp. If you do not specify outcome(), then outcome(#1) is assumed.

These statistics are available both in and out of sample; type predict ... if e(sample) ... if wanted only for the estimation sample.

Options for predict

pr, the default, computes the predicted probabilities for all outcomes or for a specific outcome. To compute probabilities for all outcomes, you specify \( k \) new variables, where \( k \) is the number of categories of the dependent variable. Alternatively, you can specify stub*; in which case, pr will store predicted probabilities in variables stub1, stub2, ..., stubk. To compute the probability for a specific outcome, you specify one new variable and, optionally, the outcome value in option outcome(); if you omit outcome(), the first outcome value, outcome(#1), is assumed.

Say that you fit a model by typing estimation_cmd y x1 x2, and \( y \) takes on four values. Then, you could type predict p1 p2 p3 p4 to obtain all four predicted probabilities; alternatively, you could type predict p* to generate the four predicted probabilities. To compute specific probabilities one at a time, you can type predict p1, outcome(#1) (or simply predict p1), predict p2, outcome(#2), and so on. See option outcome() for other ways to refer to outcome values.

xb calculates the index, \( \theta_k = \sum_{j=1}^d \phi_{jk}x_i\beta_j \), for outcome level \( k \neq e(i_{\text{base}}) \) and dimension \( d = e(k_{\text{dim}}) \). It returns a vector of zeros if \( k = e(i_{\text{base}}) \). A synonym for xb is index. If outcome() is not specified, outcome(#1) is assumed.

stdp calculates the standard error of the index. A synonym for stdp is seindex. If outcome() is not specified, outcome(#1) is assumed.
outcome(outcome) specifies for which outcome the predicted probabilities are to be calculated. outcome() should contain either one value of the dependent variable or one of #1, #2, ... , with #1 meaning the first category of the dependent variable, #2 meaning the second category, etc. outcome() is not allowed with scores.

scores calculates the equation-level score variables. For models with d dimensions and m levels, d + (d + 1)(m − 1) new variables are created. Assume j = 1, ..., d and k = 1, ..., m in the following.

The first d new variables will contain \( \frac{\partial \ln L}{\partial (x\beta_j)} \).

The next d(m − 1) new variables will contain \( \frac{\partial \ln L}{\partial \phi_{jk}} \).

The last m − 1 new variables will contain \( \frac{\partial \ln L}{\partial \theta_k} \).

margins

Description for margins
margins estimates margins of response for probabilities and indexes for the kth outcome.

Menu for margins
Statistics > Postestimation

Syntax for margins

\[
margins [marginlist] [ , options ]
\]

\[
margins [marginlist] , \text{predict(statistic ...)} [\text{predict(statistic ...)} ...] [options]
\]

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>default</td>
<td>probabilities for each outcome</td>
</tr>
<tr>
<td>pr</td>
<td>probability of one of or all the dependent variable outcomes</td>
</tr>
<tr>
<td>xb</td>
<td>index for the kth outcome</td>
</tr>
<tr>
<td>stdp</td>
<td>not allowed with margins</td>
</tr>
</tbody>
</table>

pr and xb default to the first outcome.

Statistics not allowed with margins are functions of stochastic quantities other than e(b).

For the full syntax, see [R] margins.

Remarks and examples

Once you have fit a stereotype logistic model, you can obtain the predicted probabilities by using the predict command for both the estimation sample and other samples; see [U] 20 Estimation and postestimation commands and [R] predict.
predict without arguments (or with the `pr` option) calculates the predicted probability of each outcome of the dependent variable. You must therefore give a new variable name for each of the outcomes. To compute the estimated probability of one outcome, you use the `outcome(outcome)` option where `outcome` is the level encoding the outcome. If the dependent variable’s levels are labeled, the outcomes can also be identified by the label values (see [D] label).

The `xb` option in conjunction with `outcome(outcome)` specifies that the index be computed for the outcome encoded by level `outcome`. Its approximate standard error is computed if the `stdp` option is specified. Only one of the `pr`, `xb`, or `stdp` options can be specified with a call to `predict`.

### Example 1

In example 2 of [R] slogit, we fit the one-dimensional stereotype model, where the `depvar` is `insure` with levels $k = 1$ for outcome Indemnity, $k = 2$ for Prepaid, and $k = 3$ for Uninsure. The base outcome for the model is Indemnity, so for $k \neq 1$ the vector of indices for the $k$th level is

$$\eta_k = \theta_k - \phi_k (\beta_1 \text{age} + \beta_2 \text{male} + \beta_3 \text{nonwhite} + \beta_4 2.\text{site} + \beta_5 3.\text{site})$$

We estimate the group probabilities by calling `predict` after `slogit`.

```
use https://www.stata-press.com/data/r16/sysdsn1
(Health insurance data)
.slogit insure age male nonwhite i.site, dim(1) base(1) nolog
(output omitted)
.predict pIndemnity pPrepaid pUninsure, p
.list pIndemnity pPrepaid pUninsure insure in 1/10
```

<table>

<td>0.0880531</td>
<td>Prepaid</td>
</tr>
</tbody>
</table>

Observations 5 and 8 are not used to fit the model because `insure` is missing at these points, but `predict` estimates the probabilities for these observations since none of the independent variables is missing. You can use `if e(sample)` in the call to `predict` to use only those observations that are used to fit the model.

### Methods and formulas

#### predict

Let level $b$ be the base outcome that is used to fit the stereotype logistic regression model of dimension $d$. The index for observation $i$ and level $k \neq b$ is $\eta_{ik} = \theta_k - \sum_{j=1}^{d} \phi_{jik} x_i \beta_j$. This is the log odds of outcome encoded as level $k$ relative to that of $b$ so that we define $\eta_{ib} \equiv 0$. The outcome probabilities for this model are defined as $\Pr(Y_i = k) = e^{\eta_{ik}} / \sum_{j=1}^{m} e^{\eta_{ij}}$. Unlike in `mlogit`, `ologit`, and `oprobit`, the index is no longer a linear function of the parameters. The standard error of index $\eta_{ik}$ is thus computed using the delta method (see also [R] `predictnl`).
The equation-level score for regression coefficients is

$$\frac{\partial \ln L_{ik}}{\partial x_i \beta_j} = \left( \sum_{l=1}^{m-1} \phi_{jl} p_{il} - \phi_{jk} \right)$$

the equation-level score for the scale parameters is

$$\frac{\partial \ln L_{ik}}{\partial \phi_{jl}} = \begin{cases} x_i \beta_j (p_{ik} - 1), & \text{if } l = k \\ x_i \beta_j p_{il}, & \text{if } l \neq k \end{cases}$$

for \( l = 1, \ldots, m - 1 \); and the equation-level score for the intercepts is

$$\frac{\partial \ln L_{ik}}{\partial \theta_l} = \begin{cases} 1 - p_{ik}, & \text{if } l = k \\ -p_{il}, & \text{if } l \neq k \end{cases}$$

[U] 20 Estimation and postestimation commands
**smooth** — Robust nonlinear smoother

**Description**

`smooth` applies the specified resistant, nonlinear smoother to `varname` and stores the smoothed series in `newvar`.

**Quick start**

Running median smoother of span 3 for `v`, placing smoothed values in the new variable `newv`

`smooth 3 v, generate(newv)`

As above, but with a compound smoother of running medians, first of span 3, then span 5

`smooth 35 v, generate(newv)`

As above, but repeating the span-5 running median until convergence

`smooth 3S5R v, generate(newv)`

As above, splitting any repeated values after the span-3 running median

`smooth 3S5R,twice v, generate(newv)`

As above, but apply the compound smoother to the resulting rough

`smooth 3S5R,twice v, generate(newv)`

**Menu**

Statistics > Nonparametric analysis > Robust nonlinear smoother
Syntax

\texttt{smooth smoother[, twice] varname [if] [in], generate(newvar)}

where \texttt{smoother} is specified as \texttt{Sm[Sm[...]]} and \texttt{Sm} is one of

\{1|2|3|4|5|6|7|8|9}\}[R]

3[R]S[S|R][S|R]...

E

H

Letters may be specified in lowercase if preferred. Examples of \texttt{smoother[,twice]} include

3RSSH 3RSSH,twice 4253H 4253H,twice 43RSR2H,twice
3rssh 3rssh,twice 4253h 4253h,twice 43rsr2h,twice

Option

\texttt{generate(newvar)} is required; it specifies the name of the new variable that will contain the smoothed values.

Remarks and examples

Smoothing is an exploratory data-analysis technique for making the general shape of a series apparent. In this approach (Tukey 1977), the observed data series is assumed to be the sum of an underlying process that evolves smoothly (the smooth) and of an unsystematic noise component (the rough); that is,

\texttt{data} = \texttt{smooth} + \texttt{rough}

Smoothed values \( z_t \) are obtained by taking medians (or some other location estimate) of each point in the original data \( y_t \) and a few of the points around it. The number of points used is called the span of the smoother. Thus a span-3 smoother produces \( z_t \) by taking the median of \( y_{t-1}, y_t, \) and \( y_{t+1} \). \texttt{smooth} provides running median smoothers of spans 1 to 9—indicated by the digit that specifies their span. Median smoothers are resistant to isolated outliers, so they provide robustness to spikes in the data. Because the median is also a nonlinear operator, such smoothers are known as robust (or resistant) nonlinear smoothers.

\texttt{smooth} also provides the Hanning linear, nonrobust smoother, indicated by the letter \texttt{H}. Hanning is a span-3 smoother with binomial weights. Repeated applications of \texttt{H—HH}, \texttt{HHH}, etc.—provide binomial smoothers of span 5, 7, etc. See Cox (1997, 2004) for a graphical application of this fact.

Because one smoother usually cannot adequately separate the smooth from the rough, compound smoothers—multiple smoothers applied in sequence—are used. The smoother 35H, for instance, then smooths the data with a span-3 median smoother, smooths the result with a span-5 median smoother, and finally smooths that result with the Hanning smoother. \texttt{smooth} allows you to specify any number of smoothers in any sequence.

Three refinements can be combined with the running median and Hanning smoothers. First, the endpoints of a smooth can be given special treatment. This is specified by the \texttt{E} operator. Second, smoothing by \texttt{3}, the span-3 running median, tends to produce flat-topped hills and valleys. The splitting operator, \texttt{S}, “splits” these repeated values, applies the endpoint operator to them, and then “rejoins” the series. Finally, it is sometimes useful to repeat an odd-span median smoother or the splitting operator until the smooth no longer changes. Following a digit or an \texttt{S} with an \texttt{R} specifies this type of repetition.
Even the best smoother may fail to separate the smooth from the rough adequately. To guard against losing any systematic components of the data series, after smoothing, the smoother can be reapplied to the resulting rough, and any recovered signal can be added back to the original smooth. The `twice` operator specifies this procedure. More generally, an arbitrary smoother can be applied to the rough (using a second `smooth` command), and the recovered signal can be added back to the smooth. This more general procedure is called reroughing (Tukey 1977).

The details of each of the smoothers and operators are explained in `Methods and formulas` below.

Example 1

`smooth` is designed to recover the general features of a series that has been contaminated with noise. To demonstrate this, we construct a series, add noise to it, and then `smooth` the noisy version to recover an estimate of the original data. First, we construct and display the data:

```
. drop _all
. set obs 10
. set seed 123456789
. generate time = _n
. label variable time "Time"
. generate x = _n^3 - 10*_n^2 + 5*_n
. label variable x "Signal"
. generate z = x + 50*rnormal()
. label variable z "Observed series"
. scatter x z time, c(l .) m(i o) ytitle(""
```

![Graph showing a noisy series and the recovered smooth signal](image.png)
Now we smooth the noisy series, $z$, assumed to be the only data we would observe:

```
. smooth 4253eh,twice z, gen(sz)
. label variable sz "Smoothed series"
. scatter x z time, c(l . l) m(i o i) ytitle("") || scatter sz time,
    > c(l . l) m(i o i) ytitle("") clpattern(dash_dot)
```

Example 2

Salgado-Ugarte and Curts-García (1993) provide data on the frequencies of observed fish lengths. In this example, the series to be smoothed—the frequencies—is ordered by fish length rather than by time.

```
. use https://www.stata-press.com/data/r16/fishdata, clear
. smooth 4253eh,twice freq, gen(sfreq)
. scatter sfreq freq length, c(l .) m(i o)
    > title("Smoothed frequencies of fish lengths") ytitle("") xlabel(#4)
```
Technical note

smooth allows missing values at the beginning and end of the series, but missing values in the middle are not allowed. Leading and trailing missing values are ignored. If you wish to ignore missing values in the middle of the series, you must drop the missing observations before using smooth. Doing so, of course, would violate smooth’s assumption that observations are equally spaced—each observation represents a year, a quarter, or a month (or a 1-year birth-rate category). In practice, smooth produces good results as long as the spaces between adjacent observations do not vary too much.

Smoothing is usually applied to time series, but any variable with a natural order can be smoothed. For example, a smoother might be applied to the birth rate recorded by the age of the mothers (birth rate for 17-year-olds, birth rate for 18-year-olds, and so on).

Methods and formulas

Methods and formulas are presented under the following headings:

- Running median smoothers of odd span
- Running median smoothers of even span
- Repeat operator
- Endpoint rule
- Splitting operator
- Hanning smoother
- Twicing

Running median smoothers of odd span

The smoother 3 defines

\[
 z_t = \text{median}(y_{t-1}, y_t, y_{t+1})
\]

The smoother 5 defines

\[
 z_t = \text{median}(y_{t-2}, y_{t-1}, y_t, y_{t+1}, y_{t+2})
\]

and so on. The smoother 1 defines \( z_t = \text{median}(y_t) \), so it does nothing.

Endpoints are handled by using smoothers of shorter, odd span. Thus for 3,

\[
 z_1 = y_1 \\
 z_2 = \text{median}(y_1, y_2, y_3) \\
 \vdots \\
 z_{N-1} = \text{median}(y_{N-2}, y_{N-1}, y_N) \\
 Z_N = y_N
\]
For 5,
\[
\begin{align*}
    z_1 &= y_1 \\
    z_2 &= \text{median}(y_1, y_2, y_3) \\
    z_3 &= \text{median}(y_1, y_2, y_3, y_4, y_5) \\
    z_4 &= \text{median}(y_2, y_3, y_4, y_5, y_6) \\
    &\vdots \\
    z_{N-2} &= \text{median}(y_{N-4}, y_{N-3}, y_{N-2}, y_{N-1}, y_N) \\
    z_{N-1} &= \text{median}(y_{N-2}, y_{N-1}, y_N) \\
    Z_N &= y_N
\end{align*}
\]
and so on.

**Running median smoothers of even span**

Define the median() function as returning the linearly interpolated value when given an even number of arguments. Thus the smoother 2 defines
\[
z_{t+0.5} = \frac{(y_t + y_{t+1})}{2}
\]
The smoother 4 defines \(z_{t+0.5}\) as the linearly interpolated median of \((y_{t-1}, y_t, y_{t+1}, y_{t+2})\), and so on. Endpoints are always handled using smoothers of shorter, even span. Thus for 4,
\[
\begin{align*}
    z_{0.5} &= y_1 \\
    z_{1.5} &= \text{median}(y_1, y_2) = \frac{(y_1 + y_2)}{2} \\
    z_{2.5} &= \text{median}(y_1, y_2, y_3, y_4) \\
    &\vdots \\
    z_{N-2.5} &= \text{median}(y_{N-4}, y_{N-3}, y_{N-2}, y_N) \\
    z_{N-1.5} &= \text{median}(y_{N-2}, y_{N-1}) \\
    z_{N-0.5} &= \text{median}(y_{N-1}, y_N) \\
    z_{N+0.5} &= y_N
\end{align*}
\]
As defined above, an even-span smoother increases the length of the series by 1 observation. However, the series can be recentered on the original observation numbers, and the “extra” observation can be eliminated by smoothing the series again with another even-span smoother. For instance, the smooth of 4 illustrated above could be followed by a smooth of 2 to obtain
smooth keeps track of the number of even smoothers applied to the data and expands and shrinks the length of the series accordingly. To ensure that the final smooth has the same number of observations as varname, smooth requires you to specify an even number of even-span smoothers. However, the pairs of even-span smoothers need not be contiguous; for instance, 4253 and 4523 are both allowed.

Repeat operator

R indicates that a smoother is to be repeated until convergence, that is, until repeated applications of the smoother produce the same series. Thus 3 applies the smoother of running medians of span 3. 33 applies the smoother twice. 3R produces the result of repeating 3 an infinite number of times. R should be used only with odd-span smoothers because even-span smoothers are not guaranteed to converge.

The smoother 453R2 applies a span-4 smoother, followed by a span-5 smoother, followed by repeated applications of a span-3 smoother, followed by a span-2 smoother.

Endpoint rule

The endpoint rule E modifies the values \( z_1 \) and \( z_N \) according to the following formulas:

\[
\begin{align*}
  z_1 &= \text{median}(3z_2 - 2z_3, z_1, z_2) \\
  z_N &= \text{median}(3z_{N-2} - 2z_{N-1}, z_N, z_{N-1})
\end{align*}
\]

When the endpoint rule is not applied, endpoints are typically “copied in”; that is, \( z_1 = y_1 \) and \( z_N = y_N \).

Splitting operator

The smoothers 3 and 3R can produce flat-topped hills and valleys. The split operator attempts to eliminate such hills and valleys by splitting the sequence, applying the endpoint rule E, rejoining the series, and then resmoothing by 3R.

The S operator may be applied only after 3, 3R, or S.

We recommend that the S operator be repeated once (SS) or until no further changes take place (SR).
Hanning smoother

H is the Hanning linear smoother:

\[ z_t = (y_{t-1} + 2y_t + y_{t+1})/4 \]

Endpoints are copied in: \( z_1 = y_1 \) and \( z_N = y_N \). H should be applied only after all nonlinear smoothers.

Twicing

A smoother divides the data into a smooth and a rough:

\[ \text{data} = \text{smooth} + \text{rough} \]

If the smoothing is successful, the rough should exhibit no pattern. Twicing refers to applying the smoother to the observed, calculating the rough, and then applying the smoother to the rough. The resulting "smoothed rough" is then added back to the smooth from the first step.

Acknowledgments

smooth was originally written by William Gould (1992)—at which time it was named nlsm—and was inspired by Salgado-Ugarte and Curts-García (1992). Salgado-Ugarte and Curts-García (1993) subsequently reported anomalies in nlsm’s treatment of even-span median smoothers. smooth corrects these problems and incorporates other improvements but otherwise is essentially the same as originally published.

**spearman** — Spearman’s and Kendall’s correlations

**Description**

`spearman` displays Spearman’s rank correlation coefficients for all pairs of variables in `varlist` or, if `varlist` is not specified, for all the variables in the dataset.

`ktau` displays Kendall’s rank correlation coefficients between the variables in `varlist` or, if `varlist` is not specified, for all the variables in the dataset. `ktau` is intended for use on small- and moderate-sized datasets; it requires considerable computation time for larger datasets.

**Quick start**

Spearman’s rank correlation coefficients for all pairs of `v1`, `v2`, and `v3`

```
spearman v1 v2 v3
```

Same as above

```
spearman v1 v2 v3, stats(rho)
```

Also display significance levels

```
spearman v1 v2 v3, stats(rho p)
```

As above, but perform Bonferroni’s adjustment to `p`-values

```
spearman v1 v2 v3, stats(rho p) bonferroni
```

Kendall’s rank correlation coefficients, scores, and std. err. of the scores for pairs of `v1`, `v2`, and `v3`

```
ktau v1 v2 v3, stats(taua taub score se)
```

As above, but use pairwise instead of casewise deletion

```
ktau v1 v2 v3, stats(taua taub score se) pw
```

**Menu**

`spearman`

Statistics > Nonparametric analysis > Tests of hypotheses > Spearman’s rank correlation

`ktau`

Statistics > Nonparametric analysis > Tests of hypotheses > Kendall’s rank correlation
## Syntax

### Spearman’s rank correlation coefficients

```
spearman [varlist] [if] [in] [, spearman_options]
```

### Kendall’s rank correlation coefficients

```
ktau [varlist] [if] [in] [, ktau_options]
```

`by` is allowed with `spearman` and `ktau`; see `[D] by.`

where the elements of `spearman_list` may be

- `rho` correlation coefficient
- `obs` number of observations
- `p` significance level

and the elements of `ktau_list` may be

- `taua` correlation coefficient $\tau_a$
- `taub` correlation coefficient $\tau_b$
- `score` score
- `se` standard error of score
- `obs` number of observations
- `p` significance level
Options for spearman

\texttt{stats(spearman\_list)} specifies the statistics to be displayed in the matrix of output. \texttt{stats(rho)} is the default. Up to three statistics may be specified; \texttt{stats(rho obs p)} would display the correlation coefficient, number of observations, and significance level. If \texttt{varlist} contains only two variables, all statistics are shown in tabular form, and \texttt{stats()}, \texttt{print()}, and \texttt{star()} have no effect unless the \texttt{matrix} option is specified.

\texttt{print(\#)} specifies the significance level of correlation coefficients to be printed. Correlation coefficients with larger significance levels are left blank in the matrix. Typing \texttt{spearman, print(.10)} would list only those correlation coefficients that are significant at the 10\% level or lower.

\texttt{star(\#)} specifies the significance level of correlation coefficients to be marked with a star. Typing \texttt{spearman, star(.05)} would “star” all correlation coefficients significant at the 5\% level or lower.

\texttt{bonferroni} makes the Bonferroni adjustment to calculated significance levels. This adjustment affects printed significance levels and the \texttt{print()} and \texttt{star()} options. Thus \texttt{spearman, print(.05)} \texttt{bonferroni} prints coefficients with Bonferroni-adjusted significance levels of 0.05 or less.

\texttt{sidak} makes the Štěpán Šidák adjustment to calculated significance levels. This adjustment affects printed significance levels and the \texttt{print()} and \texttt{star()} options. Thus \texttt{spearman, print(.05) sidak} prints coefficients with Štěpán-Šidák-adjusted significance levels of 0.05 or less.

\texttt{pw} specifies that correlations be calculated using pairwise deletion of observations with missing values. By default, \texttt{spearman} uses casewise deletion, where observations are ignored if any of the variables in \texttt{varlist} are missing.

\texttt{matrix} forces \texttt{spearman} to display the statistics as a matrix, even if \texttt{varlist} contains only two variables. \texttt{matrix} is implied if more than two variables are specified.

Options for ktau

\texttt{stats(ktau\_list)} specifies the statistics to be displayed in the matrix of output. \texttt{stats(taua)} is the default. Up to six statistics may be specified; \texttt{stats(taua taub score se obs p)} would display the correlation coefficients $\tau_a$, $\tau_b$, score, standard error of score, number of observations, and significance level. If \texttt{varlist} contains only two variables, all statistics are shown in tabular form and \texttt{stats()}, \texttt{print()}, and \texttt{star()} have no effect unless the \texttt{matrix} option is specified.

\texttt{print(\#)} specifies the significance level of correlation coefficients to be printed. Correlation coefficients with larger significance levels are left blank in the matrix. Typing \texttt{ktau, print(.10)} would list only those correlation coefficients that are significant at the 10\% level or lower.

\texttt{star(\#)} specifies the significance level of correlation coefficients to be marked with a star. Typing \texttt{ktau, star(.05)} would “star” all correlation coefficients significant at the 5\% level or lower.

\texttt{bonferroni} makes the Bonferroni adjustment to calculated significance levels. This adjustment affects printed significance levels and the \texttt{print()} and \texttt{star()} options. Thus \texttt{ktau, print(.05)} \texttt{bonferroni} prints coefficients with Bonferroni-adjusted significance levels of 0.05 or less.

\texttt{sidak} makes the Štěpán Šidák adjustment to calculated significance levels. This adjustment affects printed significance levels and the \texttt{print()} and \texttt{star()} options. Thus \texttt{ktau, print(.05) sidak} prints coefficients with Štěpán-Šidák-adjusted significance levels of 0.05 or less.
pw specifies that correlations be calculated using pairwise deletion of observations with missing values. By default, ktau uses casewise deletion, where observations are ignored if any of the variables in varlist are missing.

matrix forces ktau to display the statistics as a matrix, even if varlist contains only two variables. matrix is implied if more than two variables are specified.

Remarks and examples

Example 1

We wish to calculate the correlation coefficients among marriage rate (mrgrate), divorce rate (divorce_rate), and median age (medage) in state data. We can calculate the standard Pearson correlation coefficients and significance by typing

```
use https://www.stata-press.com/data/r16/states2
(pstate data)
pwcorr mrgrate divorce_rate medage, sig
```

```
<table>
<thead>
<tr>
<th></th>
<th>mrgrate</th>
<th>divorce_rate</th>
<th>medage</th>
</tr>
</thead>
<tbody>
<tr>
<td>mrgrate</td>
<td>1.0000</td>
<td></td>
<td></td>
</tr>
<tr>
<td>divorce_rate</td>
<td>0.7895</td>
<td>1.0000</td>
<td></td>
</tr>
<tr>
<td></td>
<td>0.0000</td>
<td></td>
<td></td>
</tr>
<tr>
<td>medage</td>
<td>0.0011</td>
<td>-0.1526</td>
<td>1.0000</td>
</tr>
<tr>
<td></td>
<td>0.9941</td>
<td>0.2900</td>
<td></td>
</tr>
</tbody>
</table>
```

We can calculate Spearman’s rank correlation coefficients by typing

```
spearman mrgrate divorce_rate medage, stats(rho p)
(obs=50)
```

```
Key

<table>
<thead>
<tr>
<th></th>
<th>mrgrate</th>
<th>divorce_rate</th>
<th>medage</th>
</tr>
</thead>
<tbody>
<tr>
<td>mrgrate</td>
<td>1.0000</td>
<td></td>
<td></td>
</tr>
<tr>
<td>divorce_rate</td>
<td>0.6933</td>
<td>1.0000</td>
<td></td>
</tr>
<tr>
<td></td>
<td>0.0000</td>
<td></td>
<td></td>
</tr>
<tr>
<td>medage</td>
<td>-0.4869</td>
<td>-0.2455</td>
<td>1.0000</td>
</tr>
<tr>
<td></td>
<td>0.0003</td>
<td>0.0857</td>
<td></td>
</tr>
</tbody>
</table>
```

The large difference in the results is caused by one observation. Nevada’s marriage rate is almost 10 times higher than the state with the next-highest marriage rate. An important feature of the Spearman rank correlation coefficient is its reduced sensitivity to extreme values compared with the Pearson correlation coefficient.
We can calculate Kendall’s rank correlations by typing

```
. ktau mrgrate divorce_rate medage, stats(taua taub p)
(obs=50)
```

<table>
<thead>
<tr>
<th>Key</th>
<th>mrgrate</th>
<th>divorce_rate</th>
<th>medage</th>
</tr>
</thead>
<tbody>
<tr>
<td>tau_a</td>
<td>0.9829</td>
<td>1.0000</td>
<td>0.5110</td>
</tr>
<tr>
<td>tau_b</td>
<td>1.0000</td>
<td>0.9804</td>
<td>0.9845</td>
</tr>
<tr>
<td>Sig. level</td>
<td></td>
<td></td>
<td>0.0004</td>
</tr>
</tbody>
</table>

There are tied values for variables `mrgrate`, `divorce_rate`, and `medage`, so tied ranks are used. As a result, \( \tau_a < 1 \) on the diagonal (see Methods and formulas for the definition of \( \tau_a \)).

**Technical note**

According to Conover (1999, 323), “Spearman’s \( \rho \) tends to be larger than Kendall’s \( \tau \) in absolute value. However, as a test of significance, there is no strong reason to prefer one over the other because both will produce nearly identical results in most cases.”

**Example 2**

We illustrate `spearman` and `ktau` with the auto data, which contains some missing values.

```
. use https://www.stata-press.com/data/r16/auto
   (1978 Automobile Data)
. spearman mpg rep78
```

```
Number of obs = 69
Spearman’s rho = 0.3098
Test of Ho: mpg and rep78 are independent
   Prob > |t| = 0.0096
```

Because we specified two variables, `spearman` displayed the sample size, correlation, and \( p \)-value in tabular form. To obtain just the correlation coefficient displayed in matrix form, we type
The `pw` option instructs `spearman` and `ktau` to use all nonmissing observations between a pair of variables when calculating their correlation coefficient. In the output below, some correlations are based on 74 observations, whereas others are based on 69 because 5 observations contain a missing value for `rep78`.

```
. spearman mpg price rep78, pw stats(rho obs p) star(0.01)

Key

<table>
<thead>
<tr>
<th>rho</th>
<th>Number of obs</th>
<th>Sig. level</th>
</tr>
</thead>
</table>

<table>
<thead>
<tr>
<th></th>
<th>mpg</th>
<th>price</th>
<th>rep78</th>
</tr>
</thead>
<tbody>
<tr>
<td>mpg</td>
<td>1.0000</td>
<td></td>
<td></td>
</tr>
<tr>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>price</td>
<td>-0.5419*</td>
<td>1.0000</td>
<td></td>
</tr>
<tr>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>rep78</td>
<td>0.3098*</td>
<td>0.1028</td>
<td>1.0000</td>
</tr>
<tr>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>
```

The output shows the following:

- The correlation between `mpg` and `rep78` is 0.3098, based on 69 observations, with a p-value of 0.0096.
- The correlation between `mpg` and `price` is -0.5419, based on 74 observations, with a p-value of 0.0000.
- The correlation between `price` and `rep78` is 0.1028, based on 74 observations, with a p-value of 0.4008.
Finally, the bonferroni and sidak options provide adjusted significance levels:

```
.ktau mpg price rep78, stats(taua taub score se p) bonferroni
(obs=69)
```

Charles Edward Spearman (1863–1945) was a British psychologist who made contributions to correlation, factor analysis, test reliability, and psychometrics. After several years’ military service, he obtained a PhD in experimental psychology at Leipzig and became a professor at University College London, where he sustained a long program of work on the interpretation of intelligence tests. Ironically, the rank correlation version bearing his name is not the formula he advocated.

Maurice George Kendall (1907–1983) was a British statistician who contributed to rank correlation, time series, multivariate analysis, among other topics, and wrote many statistical texts. Most notably, perhaps, his advanced survey of the theory of statistics went through several editions, later ones with Alan Stuart; the baton has since passed to others. Kendall was employed in turn as a government and business statistician, as a professor at the London School of Economics, as a consultant, and as director of the World Fertility Survey. He was knighted in 1974.
stored results

spearman stores the following in r():

Scalars
- r(N) number of observations (last variable pair)
- r(rho) \( \rho \) (last variable pair)
- r(p) two-sided \( p \)-value (last variable pair)

Matrices
- r(Nobs) number of observations
- r(Rho) \( \rho \)
- r(P) two-sided \( p \)-value

ktau stores the following in r():

Scalars
- r(N) number of observations (last variable pair)
- r(tau_a) \( \tau_a \) (last variable pair)
- r(tau_b) \( \tau_b \) (last variable pair)
- r(score) Kendall’s score (last variable pair)
- r(se_score) standard error of score (last variable pair)
- r(p) two-sided \( p \)-value (last variable pair)

Matrices
- r(Nobs) number of observations
- r(Tau_a) \( \tau_a \)
- r(Tau_b) \( \tau_b \)
- r(Score) Kendall’s score
- r(Se_Score) standard error of score
- r(P) two-sided \( p \)-value

Methods and formulas

Spearman’s (1904) rank correlation is calculated as Pearson’s correlation computed on the ranks and average ranks (Conover 1999, 314–315). Ranks are as calculated by egen; see [D] egen. The significance is calculated using the approximation

\[
p = 2 \times \text{ttail}(n - 2, |\hat{\rho}| \sqrt{n - 2} / \sqrt{1 - \hat{\rho}^2})
\]

For any two pairs of ranks \((x_i, y_i)\) and \((x_j, y_j)\) of one variable pair \((\text{varname}_1, \text{varname}_2)\), \(1 \leq i, j \leq n\), where \(n\) is the number of observations, define them as concordant if

\[(x_i - x_j)(y_i - y_j) > 0\]

and discordant if this product is less than zero.

Kendall’s (1938; also see Kendall and Gibbons [1990] or Bland [2015], 187–188) score \(S\) is defined as \(C - D\), where \(C\) (\(D\)) is the number of concordant (discordant) pairs. Let \(N = n(n - 1)/2\) be the total number of pairs, so \(\tau_a\) is given by

\[\tau_a = S/N\]

and \(\tau_b\) is given by

\[\tau_b = \frac{S}{\sqrt{N - U} \sqrt{N - V}}\]
where

\[
U = \sum_{i=1}^{N_1} u_i(u_i - 1)/2
\]

\[
V = \sum_{j=1}^{N_2} v_j(v_j - 1)/2
\]

and where \(N_1\) is the number of sets of tied \(x\) values, \(u_i\) is the number of tied \(x\) values in the \(i\)th set, \(N_2\) is the number of sets of tied \(y\) values, and \(v_j\) is the number of tied \(y\) values in the \(j\)th set. Under the null hypothesis of independence between \(\text{varname}_1\) and \(\text{varname}_2\), the variance of \(S\) is exactly (Kendall and Gibbons 1990, 66)

\[
\text{Var}(S) = \frac{1}{18} \left\{ n(n-1)(2n+5) - \sum_{i=1}^{N_1} u_i(u_i - 1)(2u_i + 5) - \sum_{j=1}^{N_2} v_j(v_j - 1)(2v_j + 5) \right\}
\]

\[
+ \frac{1}{9n(n-1)(n-2)} \left\{ \sum_{i=1}^{N_1} u_i(u_i - 1)(u_i - 2) \right\} \left\{ \sum_{j=1}^{N_2} v_j(v_j - 1)(v_j - 2) \right\}
\]

\[
+ \frac{1}{2n(n-1)} \left\{ \sum_{i=1}^{N_1} u_i(u_i - 1) \right\} \left\{ \sum_{j=1}^{N_2} v_j(v_j - 1) \right\}
\]

Using a normal approximation with a continuity correction,

\[
z = \frac{|S| - 1}{\sqrt{\text{Var}(S)}}
\]

For the hypothesis of independence, the statistics \(S\), \(\tau_a\), and \(\tau_b\) produce equivalent tests and give the same significance.

For Kendall’s \(\tau\), the normal approximation is surprisingly accurate for sample sizes as small as 8, at least for calculating \(p\)-values under the null hypothesis for continuous variables. (See Kendall and Gibbons [1990, chap. 4], who also present some tables for calculating exact \(p\)-values for \(n < 10\).) For Spearman’s \(\rho\), the normal approximation requires larger samples to be valid.

Let \(v\) be the number of variables specified so that \(k = v(v - 1)/2\) correlation coefficients are to be estimated. If \text{bonferroni} is specified, the adjusted significance level is \(p' = \min(1, kp)\). If \text{sidak} is specified, \(p' = \min\{1, 1 - (1 - p)^n\}\). See \textit{Methods and formulas} in [R] \texttt{oneway} for a more complete description of the logic behind these adjustments.

Early work on rank correlation is surveyed by Kruskal (1958).

**Acknowledgment**

The original version of \texttt{ktau} was written by Sean Becketti, a past editor of the \textit{Stata Technical Bulletin} and author of the Stata Press book \textit{Introduction to Time Series Using Stata}.

Description

spikeplot produces a frequency plot for a variable in which the frequencies are depicted as vertical lines from zero. The frequency may be a count, a fraction, or the square root of the count (Tukey’s rootogram, circa 1965). The vertical lines may also originate from a baseline other than zero at the user’s option.

Quick start

Spike plot of \( v1 \)
spikeplot \( v1 \)

As above, but apply frequency weights \( wvar \)
spikeplot \( v1 \) \[ fweight = wvar \]

Plot proportions of the total number of observations instead of frequencies
spikeplot \( v1 \), fraction

Tukey’s rootogram of \( v2 \)
spikeplot \( v2 \), root

Menu

Graphics > Distributional graphs > Spike plot and rootogram
Syntax

```
spikeplot varname [if] [in] [weight] [, options]
```

<table>
<thead>
<tr>
<th>options</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Main</strong></td>
<td></td>
</tr>
<tr>
<td><code>round(#)</code></td>
<td>round <code>varname</code> to nearest multiple of # (bin width)</td>

<td></td>
</tr>
<tr>
<td><code>addplot(plot)</code></td>
<td>add other plots to generated graph</td>
</tr>
<tr>
<td><code>twoway_options</code></td>
<td>any options documented in [G-3] <code>twoway_options</code></td>
</tr>
</tbody>
</table>

Fweights, aweights, and iweights are allowed; see [U] 11.1.6 `weight`.

Options

- `round(#)` rounds the values of `varname` to the nearest multiple of #. This action effectively specifies the bin width.
- `fraction` specifies that the vertical scale be the proportion of total values (percentage) rather than the count.
- `root` specifies that the vertical scale show square roots. This option may not be specified if `fraction` is specified.

- `spike_options` affect the rendition of the plotted spikes; see [G-2] `graph twoway spike`.

- `addplot(plot)` provides a way to add other plots to the generated graph. See [G-3] `addplot_option`.

- `twoway_options` are any of the options documented in [G-3] `twoway_options`. These include options for titling the graph (see [G-3] `title_options`), options for saving the graph to disk (see [G-3] `saving_option`), and the `by()` option (see [G-3] `by_option`).
Remarks and examples

Example 1

Cox and Brady (1997a) present an illustrative example using the age structure of the population of Ghana from the 1960 census (rounded to the nearest 1,000). The dataset has ages from 0 (less than 1 year) to 90. To view the distribution of ages, we would like to use each integer from 0 to 90 as the bins for the dataset.

```
. use https://www.stata-press.com/data/r16/ghanaage
. spikeplot age [fw=pop], ytitle("Population in 1000s") xlab(0(10)90) > xmtick(5(10)85)
```

The resulting graph shows a “heaping” of ages at the multiples of 5. Also, ages ending in even numbers are more frequent than ages ending in odd numbers (except for 5). This preference for reporting ages is well known in demography and other social sciences.

Note also that we used the `ytitle()` option to override the default title of “Frequency” and that we used the `xlab()` and `xmtick()` options with `numlists` to further customize the resulting graph. See [U] 11.1.8 `numlist` for details on specifying `numlists`.

Example 2

The rootogram is a plot of the square-root transformation of the frequency counts. The square root of a normal distribution is a multiple of another normal distribution.

```
. clear
. set seed 1234567
. set obs 5000
  number of observations (_N) was 0, now 5000
. generate normal = rnormal()
. label variable normal "Gaussian(0,1) random numbers"
```
Interpreting a histogram in terms of normality is thus similar to interpreting the rootogram for normality.

This example also shows how the \texttt{round()} option is used to bin the values for a spike plot of a continuous variable.
Example 3

`spikeplot` can also be used to produce time-series plots. `varname` should be the time variable, and weights should be specified as the values for those times. To get a plot of daily rainfalls, we type

```
. spikeplot day [w=rain] if rain, ytitle("Daily rainfall in mm")
```

The `base()` option of `graph twoway spike` may be used to set a different baseline, such as when we want to show variations relative to an average or to some other measure of level.

Acknowledgments

The original version of `spikeplot` was written by Nicholas J. Cox of the Department of Geography at Durham University, UK, and coeditor of the *Stata Journal* and author of *Speaking Stata Graphics* and by Anthony R. Brady founder of Sealed Envelope, London (1997a, 1997b).

[R] `histogram` — Histograms for continuous and categorical variables
ssc — Install and uninstall packages from SSC

**Description**

ssc works with packages (and files) from the Statistical Software Components (SSC) archive, which is often called the Boston College Archive and is provided by http://repec.org.

The SSC has become the premier Stata download site for community-contributed software on the web. ssc provides a convenient interface to the resources available there. For example, on Statalist (see https://www.statalist.org/), users will often write

The program can be found by typing **ssc install newprogramname**. Typing that would load everything associated with **newprogramname**, including the help files.

If you are searching for what is available, type **ssc new** and **ssc hot**, and see [R] **search**. **search** searches the SSC and other places, too. **search** provides a GUI interface from which programs can be installed, including the programs at the SSC archive.

You can uninstall particular packages by using **ssc uninstall**. For the packages that you keep, see [R] **ado update** for an automated way of keeping those packages up to date.

**Command overview**

**ssc new** summarizes the packages made available or updated recently. Output is presented in the Stata Viewer, and from there you may click to find out more about individual packages or to install them.

**ssc hot** lists the most popular packages—popular based on a moving average of the number of downloads in the past three months. By default, 10 packages are listed.

**ssc describe pkgname** describes, but does not install, the specified package. Use **search** to find packages; see [R] **search**. If you know the package name but do not know the exact spelling, type **ssc describe** followed by one letter, a–z or _ (underscore), to list all the packages starting with that letter.

**ssc install pkgname** installs the specified package. You do not have to describe a package before installing it. (You may also install a package by using **net install**; see [R] **net**.)

**ssc uninstall pkgname** removes the previously installed package from your computer. It does not matter how the package was installed. (**ssc uninstall** is a synonym for **ado uninstall**, so either may be used to installed any package.)

**ssc type filename** types a specific file stored at SSC. **ssc cat** is a synonym for **ssc type**, which may appeal to those familiar with Unix.

**ssc copy filename** copies a specific file stored at SSC to your computer. By default, the file is copied to the current directory, but you can use options to change this. **ssc copy** is a rarely used alternative to **ssc install ... all**. **ssc cp** is a synonym for **ssc copy**.

Options

Options are presented under the following headings:

  Options for use with ssc new
  Options for use with ssc hot
  Option for use with ssc describe
  Options for use with ssc install
  Option for use with ssc type
  Options for use with ssc copy

Options for use with ssc new

saving(filename[, replace]) specifies that the “what’s new” summary be saved in filename. If filename is specified without a suffix, filename.smcl is assumed. If saving() is not specified, saving(ssc_results.smcl) is assumed.

type specifies that the “what’s new” results be displayed in the Results window rather than in the Viewer.
Options for use with ssc hot

n(#) specifies the number of packages to list; n(10) is the default. Specify n(.) to list all packages in order of popularity.

author(name) lists the 10 most popular packages by the specified author. If n(#) is also specified, the top # packages are listed.

Option for use with ssc describe

saving(filename[, replace]) specifies that, in addition to the description’s being displayed on your screen, it be saved in the specified file.

If filename is specified without an extension, .smcl will be assumed, and the file will be saved as a SMCL file.

If filename is specified with an extension, no default extension is added. If the extension is .log, the file will be stored as a text file.

If replace is specified, filename is replaced if it already exists.

Options for use with ssc install

all specifies that any ancillary files associated with the package be downloaded to your current directory, in addition to the program and help files being installed. Ancillary files are files that do not end in .ado or .sthlp and typically contain datasets or examples of the use of the new command.

You can find out which files are associated with the package by typing ssc describe pkgname before or after installing. If you install without using the all option and then want the ancillary files, you can ssc install again.

replace specifies that any files being downloaded that already exist on your computer be replaced by the downloaded files. If replace is not specified and any files already exist, none of the files from the package is downloaded or installed.

It is better not to specify the replace option and wait to see if there is a problem. If there is a problem, it is usually better to uninstall the old package by using ssc uninstall or ado uninstall (which are, in fact, the same command).

Option for use with ssc type

asis affects how files with the suffixes .smcl and .sthlp are displayed. The default is to interpret SMCL directives the file might contain. asis specifies that the file be displayed in raw, uninterpreted form.

Options for use with ssc copy

plus specifies that the file be copied to the PLUS directory, the directory where community-contributed additions are installed. Typing sysdir will display the identity of the PLUS directory on your computer; see [P] sysdir.

personal specifies that the file be copied to your PERSONAL directory as reported by sysdir; see [P] sysdir.

If neither plus nor personal is specified, the default is to copy the file to the current directory.
replace specifies that, if the file already exists on your computer, the new file replace it.

public specifies that the new file be made readable by everyone; otherwise, the file will be created according to the default permission you have set with your operating system.

binary specifies that the file being copied is a binary file and that it is to be copied as is. The default is to assume that the file is a text file and change the end-of-line characters to those appropriate for your computer/operating system.

**Remarks and examples**

Users can add new features to Stata, and some users choose to make new features that they have written available to others via the web. The files that comprise a new feature are called a package, and a package usually consists of one or more ado-files and help files. The `net` command (see `[R] net`) makes it reasonably easy to install and uninstall packages regardless of where they are on the web. One site, the SSC, has become particularly popular as a repository for additions to Stata. Command `ssc` is an easier to use version of `net` designed especially for the SSC.

Many packages are available at the SSC. Packages have names, such as oaxaca, estout, or egenmore. At SSC, capitalization is not significant, so Oaxaca, ESTOUT, and EGENmore are ways of writing the same package names.

When you type

```
.ssc install oaxaca
```

the files associated with the package are downloaded and installed on your computer. Package names usually correspond to the names of the command being added to Stata, so one would expect that installing the package oaxaca will add command oaxaca to Stata on your computer, and expect that typing help oaxaca will provide the documentation. That is the situation here, but that is not always so. Before or after installing a package, type `ssc describe pkgname` to obtain the details.

### Example 1

`ssc new` summarizes the packages most recently made available or updated. Output is presented in the Viewer, from which you may click on a package name to find out more or install it. For example,

```
.ssc new
(contacting http://repec.org)
(output omitted)
CVCRAND
  module for efficient design and analysis of Cluster Randomized Trials
  > Authors: John A. Gallis Fan Li Hengshi Yu Elizabeth L. Turner
  > Req: Stata version 14
  > Revised: 2019-05-12
MULTIDOT
  module for multiple panel dot charts and similar
  > Authors: Nicholas J. Cox Req: Stata version 10
  > Revised: 2019-05-18
REG2DOCX
  module to report regression results to formatted table in DOCX file.
  > Authors: Chuntao Li Yuan Xue Req: Stata version 15
  > Revised: 2019-05-04
(output omitted)
```

End of recent additions and updates
ssc hot provides a list of the most popular packages at SSC.

(Click on package name for description)

`ssc describe` `pkgname` describes, but does not install, the specified package. You must already know the name of the package. See [R] search for assistance in searching for packages. Sometimes you know the package name, but you do not know the exact spelling. Then you can type `ssc describe` followed by one letter, a–z or _, to list all the packages starting with that letter; even so, using search is better.

```
.ssc describe bidensity
```

package `bidensity` from http://fmwww.bc.edu/repec/bocode/b

**TITLE**

'BIDENSITY': module to produce and graph bivariate density estimates

**DESCRIPTION/AUTHOR(S)**

`bidensity` produces bivariate kernel density estimates and graphs the result using a twoway contourline plot, optionally overlaying a scatterplot. The default kernel is Epanechnikov; all the kernels provided by `-kdensity-` are also available. Compared to Baum’s `-kdens2-` (SSC), which was recently enhanced to produce contourline plots, `-bidensity-` computes the bivariate kernel densities much more efficiently through use of Mata, and provides a choice of kernel estimators. The estimated densities can be saved in a Stata dataset or accessed as Mata matrices.

KW: density estimation
KW: bivariate density
KW: contourline plots
Requires: Stata version 12.1 and `moremata` from SSC (q.v.)
Distribution-Date: 20130119
Author: John Luke Gallup, Portland State University
Support: email jlgallup@pdx.edu
Author: Christopher F Baum, Boston College
Support: email baum@bc.edu

**INSTALLATION FILES**

`bidensity.ado`
`bidensity.sthlp`

(type `net install bidensity`)
The default setting for the saving() option is for the output to be saved with the .smcl extension. You could also save the file with a log extension, and in this case, the file would be stored as a text file.

```
.ssc describe b, saving(b.index)
(output omitted)
.ssc describe bidensity, saving(bidensity.log)
(output omitted)
```

**ssc** install pkpname installs the specified package. You do not have to describe a package before installing it. There are ways of installing packages other than **ssc** install, such as **net**; see [R] **net**. It does not matter how a package is installed. For instance, a package can be installed using **net** and still be uninstalled using **ssc**.

```
.ssc install bidensity
checking bidensity consistency and verifying not already installed...
installing into C:\ado\plus\...
installation complete.
```

**ssc** uninstall pkpname removes the specified, previously installed package from your computer. You can uninstall immediately after installation or at any time in the future. (Technical note: **ssc** uninstall is a synonym for **ado** uninstall, so it can uninstall any installed package, not just packages obtained from the **ssc**.)

```
.ssc uninstall bidensity
package bidensity from http://fmwww.bc.edu/repec/bocode/b
'BIDENSITY': module to produce and graph bivariate density estimates
(package uninstalled)
```

**ssc** type filename types a specific file stored at the **ssc**. Although not shown in the syntax diagram, **ssc** cat is a synonym for **ssc** type, which may appeal to those familiar with Unix. To view only the bidensity help file for the bidensity package, you would type

```
.ssc type bidensity.sthlp
```

```
help for bidensity
```

Bivariate kernel density estimation

```
bidity varnameY varnameX [if exp] [in range] [, n(#) 
kernell(kernelname) xwidth(#) ywidth(#) saving(name) replace 
nograph scatter[(scatter_options)] contourline_options 
mname(name)
```

(output omitted)

**ssc** copy filename copies a specific file stored at the **ssc** to your computer. By default, the file is copied to the current directory, but you can use options to change this. **ssc** copy is a rarely used alternative to **ssc** install ... , all. **ssc** cp is a synonym for **ssc** copy.

```
.ssc copy bidensity.ado
(file bidensity.ado copied to current directory)
```

For more details on the **ssc** archive and for information on how to submit your own programs to the **ssc**, see http://repec.org/bocode/s/sscssubmit.html.
Acknowledgments

ssc is based on archutil by Nicholas J. Cox of the Department of Geography at Durham University, UK, and coeditor of the Stata Journal and author of Speaking Stata Graphics and by Christopher F. Baum of the Department of Economics at Boston College and author of the Stata Press books An Introduction to Modern Econometrics Using Stata and An Introduction to Stata Programming. The reworking of the original was done with their blessing and their participation.

Baum maintains the Stata-related files stored at the SSC archive. We thank him for this contribution to the Stata community.

</tbody>
</table>

by is allowed; see [D] by.

Options

- **Main**
  - `prune` prevents printing any stems that have no leaves.
  - `round(#)` rounds the data to this value and displays the plot in these units. If `round()` is not specified, noninteger data will be rounded automatically.
  - `truncate(#)` truncates the data to this value and displays the plot in these units.
  - `digits(#)` sets the number of digits per leaf. The default is 1.
  - `lines(#)` sets the number of stems per every data interval of $10^{\text{digits}}$. The value of `lines()` must divide $10^{\text{digits}}$; that is, if `digits(1)` is specified, then `lines()` must divide 10. If `digits(2)` is specified, then `lines()` must divide 100, etc. Only one of `lines()` or `width()` may be specified. If neither is specified, an appropriate value will be set automatically.
  - `width(#)` sets the width of a stem. `lines()` is equal to $10^{\text{digits}}/\text{width}$, and this option is merely an alternative way of setting `lines()`. The value of `width()` must divide $10^{\text{digits}}$. Only one of `width()` or `lines()` may be specified. If neither is specified, an appropriate value will be set automatically.

Note: If `lines()` or `width()` is not specified, `digits()` may be decreased in some circumstances to make a better-looking plot. If `lines()` or `width()` is set, the user-specified value of `digits()` will not be altered.

Remarks and examples

- **Example 1**

  Stem-and-leaf displays are a compact way to present considerable information about a batch of data. For instance, using our automobile data (described in [U] 1.2.2 Example datasets):
The stem-and-leaf display provides a way to list our data. The expression to the left of the vertical bar is called the stem; the digits to the right are called the leaves. All the stems that begin with the same digit and the corresponding leaves, written beside each other, reconstruct an observation of the data. Thus, if we look at the four stems that begin with the digit 1 and their corresponding leaves, we see that we have two cars rated at 12 mpg, 6 cars at 14, 2 at 15, and so on. The car with the highest mileage rating in our data is rated at 41 mpg.

The above plot is a five-line plot with lines() equal to 5 (five lines per interval of 10) and width() equal to 2 (two leaves per stem).

Instead, we could specify lines(2):

```
. stem mpg, lines(2)
```

```
<table>
<thead>
<tr>
<th>Stem-and-leaf plot for mpg (Mileage (mpg))</th>
</tr>
</thead>
<tbody>
<tr>
<td>1*</td>
</tr>
<tr>
<td>1. 5566667778888888899999999999999999999</td>
</tr>
<tr>
<td>2* 00011111122223334444444444444444444444</td>
</tr>
<tr>
<td>3* 0014</td>
</tr>
<tr>
<td>4* 1</td>
</tr>
</tbody>
</table>
```

```
. stem mpg, width(5)
```

stem mpg, width(5) would produce the same plot as above.
The stem-and-leaf display provides a crude histogram of our data, one not so pretty as that produced
by histogram (see \[R\] histogram), but one that is nonetheless informative.

---

**Example 2**

The miles per gallon rating fits easily into a stem-and-leaf display because, in our data, it has two
digits. However, stem does not require two digits.

```
. stem price, lines(1) digits(3)
```

```
Stem-and-leaf plot for price (Price)

3*** 291,299,667,748,798,799,829,895,955,984,995
4*** 010,060,082,099,172,181,187,195,296,389,424,425,453,482,499, ... (26)
5*** 079,104,172,189,222,379,397,705,719,788,798,799,886,899
6*** 165,229,295,303,342,486,850
7*** 140,827
8*** 129,814
9*** 690,735
10*** 371,372
11*** 385,497,995
12*** 990
13*** 466,594
14*** 500
15*** 906
```

The (26) at the right of the second stem shows that there were 26 leaves on this stem—too many
to display on one line.

We can make a more compact stem-and-leaf plot by rounding. To display stem in units of 100, we
could type

```
. stem price, round(100)
```

```
Stem-and-leaf plot for price (Price)

price rounded to nearest multiple of 100
plot in units of 100

3* 33778889
4* 00001112223444555555667777899
5* 112224477888899
6* 2233359
7* 18
8* 18
9* 77
10* 44
11* 45
12* 0
13* 056
14* 5
15* 9
```

price, in our data, has four or five digits. stem presented the display in terms of units of 100, so a
car that cost $3,291 was treated for display purposes as $3,300.
Technical note

Stem-and-leaf diagrams have been used in Japanese railway timetables, as shown in Tufte (1990, 46–47).

Stored results

```
stem stores the following in r():

Scalars
  r(width)   width of a stem
  r(digits)  number of digits per leaf; default is 1

Macros
  r(round)   number specified in round()
  r(truncate) number specified in truncate()
```

Description

**stepwise** performs stepwise estimation. Typing

```
  . stepwise, pr(#) : command
```

performs backward-selection estimation for *command*. The stepwise selection method is determined by the following option combinations:

<table>
<thead>
<tr>
<th>Options</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>pr(#)</code></td>
<td>backward selection</td>
</tr>
<tr>
<td><code>pr(#)</code> hierarchical</td>
<td>backward hierarchical selection</td>
</tr>
<tr>
<td><code>pr(#)</code> <code>pe(#)</code></td>
<td>backward stepwise</td>
</tr>
<tr>
<td><code>pe(#)</code></td>
<td>forward selection</td>
</tr>
<tr>
<td><code>pe(#)</code> hierarchical</td>
<td>forward hierarchical selection</td>
</tr>
<tr>
<td><code>pr(#)</code> <code>pe(#)</code> forward</td>
<td>forward stepwise</td>
</tr>
</tbody>
</table>

*command* defines the estimation command to be executed. The following Stata commands are supported by *stepwise*:

```
  betareg, clogit, cloglog, glm, intreg, logistic, logit, nbreg, ologit, oprobit, poisson, probit, qreg, regress, scobit, stcox, stcrreg, stintreg, streg, tobit
```

*stepwise* expects *command* to have the following form:

```
  command_name [ depvar ] term [ term ... ] [ if ] [ in ] [ weight ] [, command_options]
```

where *term* is either *varname* or *(varlist)* (a *varlist* in parentheses indicates that this group of variables is to be included or excluded together). *depvar* is not present when *command_name* is *stcox*, *stcrreg*, *stintreg*, or *streg*; otherwise, *depvar* is assumed to be present. For *intreg*, *depvar* is actually two dependent variable names (*depvar*$_1$ and *depvar*$_2$).

`sw` is a synonym for *stepwise*.

For model selection and estimation using lasso, see the *Stata Lasso Reference Manual*. 
Quick start

Backward selection, removing terms with $p \geq 0.2$

```bash
stepwise, pr(.2): regress y x1 x2 x3 x4
```

As above, but force x1 to be included in model

```bash
stepwise, pr(.2) lockterm1: regress y x1 x2 x3 x4
```

Add d1, d2, and d3, and consider as a group for inclusion in model

```bash
stepwise, pr(.2): regress y x1 x2 x3 x4 (d1 d2 d3)
```

Force d1, d2, and d3 to be included in model

```bash
stepwise, pr(.2) lockterm1: regress y (d1 d2 d3) x1 x2 x3 x4
```

Forward selection, adding terms with $p < 0.1$

```bash
stepwise, pe(.1): regress y x1 x2 x3 x4
```

Backward stepwise selection, removing terms with $p \geq 0.2$ and adding those with $p < 0.1$

```bash
stepwise, pr(.2) pe(.1): regress y x1 x2 x3 x4
```

Forward stepwise selection, adding terms with $p < 0.1$ and removing those with $p \geq 0.2$

```bash
stepwise, pr(.2) pe(.1) forward: regress y x1 x2 x3 x4
```

Backward hierarchical selection

```bash
stepwise, pr(.2) hierarchical: regress y x1 x2 x3 x4
```

Forward hierarchical selection

```bash
stepwise, pe(.1) hierarchical: regress y x1 x2 x3 x4
```

Note: In the above examples, `regress` could be replaced with any estimation command allowing the `stepwise` prefix.

* At least one of `pr(#)` or `pe(#)` must be specified.

by and `xi` are allowed; see [U] 11.1.10 Prefix commands.

Weights are allowed if `command` allows them; see [U] 11.1.6 weight.

All postestimation commands behave as they would after `command` without the `stepwise` prefix; see the postestimation manual entry for `command`.

Options

### Model

- `pr(#)`: specifies the significance level for removal from the model; terms with $p \geq \text{pr}()$ are eligible for removal.
- `pe(#)`: specifies the significance level for addition to the model; terms with $p < \text{pe}()$ are eligible for addition.

### Model 2

- `forward`: specifies the forward-stepwise method and may be specified only when both `pr()` and `pe()` are also specified. Specifying both `pr()` and `pe()` without `forward` results in backward-stepwise selection. Specifying only `pr()` results in backward selection, and specifying only `pe()` results in forward selection.
- `lockterm1`: specifies that the first term be included in the model and not be subjected to the selection criteria.
- `lr`: specifies that the test of term significance be the likelihood-ratio test. The default is the less computationally expensive Wald test; that is, the test is based on the estimated variance–covariance matrix of the estimators.

### Reporting

`display_options`: `noci`, `nopvalues`, `cformat(%fmt)`, `pformat(%fmt)`, `sformat(%fmt)`, and `nolstretch`; see [R] Estimation options.

Programming for stepwise

Introduction

Typing

. stepwise, pr(.10): regress y1 x1 x2 d1 d2 d3 x4 x5

performs a backward-selection search for the regression model y1 on x1, x2, d1, d2, d3, x4, and x5. In this search, each explanatory variable is said to be a term. Typing

. stepwise, pr(.10): regress y1 x1 x2 (d1 d2 d3) (x4 x5)

performs a similar backward-selection search, but the variables d1, d2, and d3 are treated as one term, as are x4 and x5. That is, d1, d2, and d3 may or may not appear in the final model, but they appear or do not appear together.

Example 1

Using the automobile dataset, we fit a backward-selection model of mpg:

```
use https://www.stata-press.com/data/r16/auto
. generate weight2 = weight^2
. stepwise, pr(.2): regress mpg weight weight2 displ gear turn headroom foreign price

begin with full model
p = 0.7116 >= 0.2000 removing headroom
p = 0.6138 >= 0.2000 removing displacement
p = 0.3278 >= 0.2000 removing price

Source | SS df MS Number of obs = 74
---------+--------------------------------------------------
Model | 1736.31455 5 347.262911 Prob > F = 0.0000
Residual | 707.144906 68 10.3991898 R-squared = 0.7106
Total | 2443.45946 73 33.4720474 Adj R-squared = 0.6893

mpg | Coef. Std. Err. t P>|t| [95% Conf. Interval]
---------+--------------------------------------------------
weight | -.0158002 .0039169 -4.03 0.000 -.0236162 -.0079842
weight2 | 1.77e-06 6.20e-07 2.86 0.006 5.37e-07 3.01e-06
foreign | -3.615107 1.260844 -2.87 0.006 -6.131082 -1.099131
gear_ratio | 2.011674 1.468831 1.37 0.175 -.9193321 4.94268
turn | -.3087038 .1763099 -1.75 0.084 -.6605248 .0431172
_cons | 59.02133 9.3903 6.29 0.000 40.28327 77.75938
```

This estimation treated each variable as its own term and thus considered each one separately. The engine displacement and gear ratio should really be considered together:

>
. stepwise, pr(.2): regress mpg weight weight2 (displ gear) turn headroom > foreign price
begin with full model

p = 0.7116 >= 0.2000 removing headroom
p = 0.3944 >= 0.2000 removing displacement gear_ratio
p = 0.2798 >= 0.2000 removing price

### Search logic for a step

Before discussing the complete search logic, consider the logic for a step—the first step—in detail. The other steps follow the same logic. If you type

```
. stepwise, pr(.20): regress y1 x1 x2 (d1 d2 d3) (x4 x5)
```

the logic is

1. Fit the model $y$ on $x1$ $x2$ $d1$ $d2$ $d3$ $x4$ $x5$.
2. Consider dropping $x1$.
3. Consider dropping $x2$.
4. Consider dropping $d1$ $d2$ $d3$.
5. Consider dropping $x4$ $x5$.
6. Find the term above that is least significant. If its significance level is $\geq 0.20$, remove that term.

If you type

```
. stepwise, pr(.20) hierarchical: regress y1 x1 x2 (d1 d2 d3) (x4 x5)
```

the logic would be different because the `hierarchical` option states that the terms are ordered. The initial logic would become

1. Fit the model $y$ on $x1$ $x2$ $d1$ $d2$ $d3$ $x4$ $x5$.
2. Consider dropping $x4$ $x5$—the last term.
3. If the significance of this last term is $\geq 0.20$, remove the term.

The process would then stop or continue. It would stop if $x4$ $x5$ were not dropped, and otherwise, `stepwise` would continue to consider the significance of the next-to-last term, $d1$ $d2$ $d3$. 
Specifying `pe()` rather than `pr()` switches to forward estimation. If you type

```
    . stepwise, pe(.20): regress y1 x1 x2 (d1 d2 d3) (x4 x5)
```

`stepwise` performs forward-selection search. The logic for the first step is

1. Fit a model of $y$ on nothing (meaning a constant).
2. Consider adding $x_1$.
3. Consider adding $x_2$.
4. Consider adding $d_1$ $d_2$ $d_3$.
5. Consider adding $x_4$ $x_5$.
6. Find the term above that is most significant. If its significance level is $< 0.20$, add that term.

As with backward estimation, if you specify `hierarchical`,

```
    . stepwise, pe(.20) hierarchical: regress y1 x1 x2 (d1 d2 d3) (x4 x5)
```

the search for the most significant term is restricted to the next term:

1. Fit a model of $y$ on nothing (meaning a constant).
2. Consider adding $x_1$—the first term.
3. If the significance is $< 0.20$, add the term.

If $x_1$ were added, `stepwise` would next consider $x_2$; otherwise, the search process would stop.

`stepwise` can also use a stepwise selection logic that alternates between adding and removing terms. The full logic for all the possibilities is given below.
### Full search logic

<table>
<thead>
<tr>
<th>Option</th>
<th>Logic</th>
</tr>
</thead>
<tbody>
<tr>
<td>pr() (backward selection)</td>
<td>Fit the full model on all explanatory variables. While the least-significant term is “insignificant”, remove it and reestimate.</td>
</tr>
<tr>
<td>pr() hierarchical (backward hierarchical selection)</td>
<td>Fit full model on all explanatory variables. While the last term is “insignificant”, remove it and reestimate.</td>
</tr>
</tbody>
</table>
| pr() pe() (backward stepwise) | Fit full model on all explanatory variables. If the least-significant term is “insignificant”, remove it and reestimate; otherwise, stop.  
Do that again: if the least-significant term is “insignificant”, remove it and reestimate; otherwise, stop. 
Repeatedly,  
if the most-significant excluded term is “significant”, add it and reestimate;  
if the least-significant included term is “insignificant”, remove it and reestimate;  
until neither is possible. |
| pe() (forward selection) | Fit “empty” model. While the most-significant excluded term is “significant”, add it and reestimate.                                     |
| pe() hierarchical (forward hierarchical selection) | Fit “empty” model. While the next term is “significant”, add it and reestimate.                                                        |
| pr() pe() forward (forward stepwise) | Fit “empty” model. If the most-significant excluded term is “significant”, add it and reestimate; otherwise, stop.  
Do that again: if the most-significant excluded term is “significant”, add it and reestimate; otherwise, stop. 
Repeatedly,  
if the least-significant included term is “insignificant”, remove it and reestimate;  
if the most-significant excluded term is “significant”, add it and reestimate;  
until neither is possible. |
Examples

The following two statements are equivalent; both include solely single-variable terms:

```
stepwise, pr(.2): regress price mpg weight displ
stepwise, pr(.2): regress price (mpg) (weight) (displ)
```

The following two statements are equivalent; the last term in each is r1, ..., r4:

```
stepwise, pr(.2) hierarchical: regress price mpg weight displ (r1-r4)
stepwise, pr(.2) hierarchical: regress price (mpg) (weight) (displ) (r1-r4)
```

To group variables weight and displ into one term, type

```
stepwise, pr(.2) hierarchical: regress price mpg (weight displ) (r1-r4)
```

`stepwise` can be used with commands other than `regress`; for instance,

```
stepwise, pr(.2): logit outcome (sex weight) treated1 treated2
stepwise, pr(.2): logistic outcome (sex weight) treated1 treated2
```

Either statement would fit the same model because `logistic` and `logit` both perform logistic regression; they differ only in how they report results; see [R] logit and [R] logistic.

We use the `lockterm1` option to force the first term to be included in the model. To keep treated1 and treated2 in the model no matter what, we type

```
stepwise, pr(.2) lockterm1: logistic outcome (treated1 treated2) ...
```

After `stepwise` estimation, we can type `stepwise` without arguments to redisplay results,

```
stepwise
(output from logistic appears)
```

or type the underlying estimation command:

```
logistic
(output from logistic appears)
```

At estimation time, we can specify options unique to the command being stepped:

```
stepwise, pr(.2): logit outcome (sex weight) treated1 treated2, or
```

or is logit’s option to report odds ratios rather than coefficients; see [R] logit.

Estimation sample considerations

Whether you use backward or forward estimation, `stepwise` forms an estimation sample by taking observations with nonmissing values of all the variables specified (except for depvar1 and depvar2 for `intreg`). The estimation sample is held constant throughout the stepping. Thus if you type

```
stepwise, pr(.2) hierarchical: regress amount sk edul sval
```

and variable `sval` is missing in half the data, that half of the data will not be used in the reported model, even if `sval` is not included in the final model.

The function `e(sample)` identifies the sample that was used. `e(sample)` contains 1 for observations used and 0 otherwise. For instance, if you type

```
stepwise, pr(.2) pe(.10): logistic outcome x1 x2 (x3 x4) (x5 x6 x7)
```
and the final model is outcome on \( x_1, x_5, x_6, \) and \( x_7 \), you could re-create the final regression by typing

```
.logistic outcome x1 x5 x6 x7 if e(sample)
```

You could obtain summary statistics within the estimation sample of the independent variables by typing

```
.summarize x1 x5 x6 x7 if e(sample)
```

If you fit another model, \( e(sample) \) will automatically be redefined. Typing

```
.stepwise, lock pr(.2): logistic outcome (x1 x2) (x3 x4) (x5 x6 x7)
```

would automatically drop \( e(sample) \) and re-create it.

**Messages**

**note: _______ dropped because of collinearity**

Each term is checked for collinearity, and variables within the term are dropped if collinearity is found. For instance, say that you type

```
.stepwise, pr(.2): regress y x1 x2 (r1-r4) (x3 x4)
```

and assume that variables \( r_1 \) through \( r_4 \) are mutually exclusive and exhaustive dummy variables—perhaps \( r_1, \ldots, r_4 \) indicate in which of four regions the subject resides. One of the \( r_1, \ldots, r_4 \) variables will be automatically dropped to identify the model.

This message should cause you no concern.

**Error message: between-term collinearity, variable _______**

After removing any within-term collinearity, if \texttt{stepwise} still finds collinearity between terms, it refuses to continue. For instance, assume that you type

```
.stepwise, pr(.2): regress y1 x1 x2 (d1-d8) (r1-r4)
```

Assume that \( r_1, \ldots, r_4 \) identify in which of four regions the subject resides, and that \( d_1, \ldots, d_8 \) identify the same sort of information, but more finely. \( r_1 \), say, amounts to \( d_1 \) and \( d_2 \); \( r_2 \) to \( d_3, d_4, \) and \( d_5 \); \( r_3 \) to \( d_6 \) and \( d_7 \); and \( r_4 \) to \( d_8 \). You can estimate the \( d^* \) variables or the \( r^* \) variables, but not both.

It is your responsibility to specify noncollinear terms.

**note: _______ dropped because of estimability**

**note: _______ obs. dropped because of estimability**

You probably received this message in fitting a logistic or probit model. Regardless of estimation strategy, \texttt{stepwise} checks that the full model can be fit. The indicated variable had a 0 or infinite standard error.

For logistic, logit, and probit, this message is typically caused by one-way causation. Assume that you type

```
.stepwise, pr(.2): logistic outcome (x1 x2 x3) d1
```
and assume that variable \( d_1 \) is an indicator (dummy) variable. Further assume that whenever \( d_1 = 1 \), outcome = 1 in the data. Then the coefficient on \( d_1 \) is infinite. One (conservative) solution to this problem is to drop the \( d_1 \) variable and the \( d_1 = 1 \) observations. The underlying estimation commands \textit{probit}, \textit{logit}, and \textit{logistic} report the details of the difficulty and solution; \textit{stepwise} simply accumulates such problems and reports the above summary messages. Thus if you see this message, you could type

```stata
    . logistic outcome x1 x2 x3 d1
```

to see the details. Although you should think carefully about such situations, Stata’s solution of dropping the offending variables and observations is, in general, appropriate.

### Programming for \textit{stepwise}

\textit{stepwise} requires that \textit{command\_name} follow standard Stata syntax and allow the \textit{if} qualifier; see \texttt{[U] 11 Language syntax}. Furthermore, \textit{command\_name} must have \texttt{sw} or \texttt{swml} as a program property; see \texttt{[P] program properties}. If \textit{command\_name} has \texttt{swml} as a property, \textit{command\_name} must store the log-likelihood value in \texttt{e(ll)} and model degrees of freedom in \texttt{e(df\_m)}.

### Stored results

\textit{stepwise} stores whatever is stored by the underlying estimation command. Also, \textit{stepwise} stores \texttt{stepwise} in \texttt{e(stepwise)}.

### Methods and formulas

Some statisticians do not recommend stepwise procedures; see Sribney (1998) for a summary.

[LASSO] Lasso intro — Introduction to lasso
Description

Results of calculations are stored by many Stata commands so that they can be easily accessed and substituted into later commands.

- `return list` lists results stored in `r()`.
- `ereturn list` lists results stored in `e()`.
- `sreturn list` lists results stored in `s()`.

This entry discusses using stored results. Programmers wishing to store results should see [P] return and [P] ereturn.

Syntax

List results from general commands, stored in `r()`

```
return list [, all]
```

List results from estimation commands, stored in `e()`

```
ereturn list [, all]
```

List results from parsing commands, stored in `s()`

```
sreturn list
```

Option

`all` is for use with `return list` and `ereturn list`. `all` specifies that hidden and historical stored results be listed along with the usual stored results. This option is seldom used. See Using hidden and historical stored results and Programming hidden and historical stored results under Remarks and examples of [P] return for more information. These sections are written in terms of `return list`, but everything said there applies equally to `ereturn list`.

`all` is not allowed with `sreturn list` because `s()` does not allow hidden or historical results.

Remarks and examples

Stata commands are classified as being

- `r-class` general commands that store results in `r()`
- `e-class` estimation commands that store results in `e()`
- `s-class` parsing commands that store results in `s()`
- `n-class` commands that do not store in `r()`, `e()`, or `s()`
There is also a c-class, c(), containing the values of system parameters and settings, along with certain constants, such as the value of pi; see [P] creturn. A program, however, cannot be c-class.

You can look at the Stored results section of the manual entry of a command to determine whether it is r-, e-, s-, or n-class, but it is easy enough to guess.

Commands producing statistical results are either r-class or e-class. They are e-class if they present estimation results and r-class otherwise. s-class is a class used by programmers and is primarily used in subprograms performing parsing. n-class commands explicitly state where the result is to go. For instance, generate and replace are n-class because their syntax is generate varname = ... and replace varname = ....

After executing a command, you can type return list, ereturn list, or sreturn list to see what has been stored.

Example 1

. use https://www.stata-press.com/data/r16/auto4
   (1978 Automobile Data)
. describe
Contains data from https://www.stata-press.com/data/r16/auto4.dta
   obs: 74 1978 Automobile Data
   vars: 6 6 Apr 2018 00:20
storage display value
variable name type format label variable label
   price  int %8.0gc Price
   weight  int %8.0gc Weight (lbs.)
   mpg  int %8.0g Mileage (mpg)
   make  str18 %-18s Make and Model
   length  int %8.0g Length (in.)
   rep78  int %8.0g Repair Record 1978
Sorted by:
. return list
scalars:
   r(changed) = 0
   r(width) = 28
   r(k) = 6
   r(N) = 74
macros:
   r(datalabel) : "1978 Automobile Data"

To view all stored results, including those that are historical or hidden, specify the all option.

. return list, all
scalars:
   r(changed) = 0
   r(width) = 28
   r(k) = 6
   r(N) = 74
macros:
   r(datalabel) : "1978 Automobile Data"

Historical; used before Stata 12, may exist only under version control

scalars:
   r(widthmax) = 1048576
   r(k_max) = 5000
   r(N_max) = 2147483619
 Stored results — Stored results 2575

$r(widthmax)$, $r(k\_max)$, and $r(N\_max)$ are historical stored results. They are no longer relevant because Stata dynamically adjusts memory beginning with Stata 12.

Technical note

In the above example, we stated that $r(widthmax)$ and $r(N\_max)$ are no longer relevant. In fact, they are not useful. Stata no longer has a fixed memory size, so the methods used to calculate $r(widthmax)$ and $r(N\_max)$ are no longer appropriate.

Example 2

You can use stored results in expressions.

```
. summarize mpg
Variable | Obs  | Mean  | Std. Dev. | Min | Max
---------|------|-------|-----------|-----|-----
    mpg   |  74  | 21.2973 | 5.785503 | 12  | 41  
. return list
scalars:
   r(N) = 74
   r(sum_w) = 74
   r(mean) = 21.2972972972973
   r(Var) = 33.47204738985561
   r(sd) = 5.785503209735141
   r(min) = 12
   r(max) = 41
   r(sum) = 1576
. generate double mpgstd = (mpg-r(mean))/r(sd)
. summarize mpgstd
Variable | Obs  | Mean  | Std. Dev. | Min  | Max  
---------|------|-------|-----------|------|-----
    mpgstd|  74  | -1.64e-16 | 1         | -1.606999 | 3.40553 
```

Be careful to use results stored in $r()$ soon because they will be replaced the next time you execute another r-class command. For instance, although $r(mean)$ was 21.3 (approximately) after `summarize mpg`, it is $-1.64e-16$ now because you just ran `summarize` with `mpgstd`.
Example 3

e-class is really no different from r-class, except for where results are stored and that, when an estimation command stores results, it tends to store a lot of them:

```
. regress mpg weight length
(output omitted)
. ereturn list

scalars:
  e(N) = 74
  e(df_m) = 2
  e(df_r) = 71
  e(F) = 69.34050004300227
  e(r2) = .6613903979336323
  e(rmse) = 3.413681741382589
  e(mss) = 1616.08062422659
  e(rss) = 827.378852328695
  e(r2_a) = .6518520992838754
  e(ll) = -194.3267619410807
  e(ll_0) = -234.3943376482347
  e(rank) = 3

macros:
  e(cmdline) : "regress mpg weight length"
  e(title) : "Linear regression"
  e(marginsok) : "XB default"
  e(vce) : "ols"
  e(depvar) : "mpg"
  e(cmd) : "regress"
  e(properties) : "b V"
  e(predict) : "regres_p"
  e(model) : "ols"
  e(estat_cmd) : "regress_estat"

matrices:
  e(b) : 1 x 3
  e(V) : 3 x 3

functions:
  e(sample)
```

These e-class results will stick around until you run another estimation command. Typing `return list` and `ereturn list` is the easy way to find out what a command stores.

Both r- and e-class results come in four flavors: scalars, macros, matrices, and functions. (s-class results come in only one flavor—macros—and as earlier noted, s-class is used solely by programmers, so ignore it.)

Scalars are just that—numbers by any other name. You can subsequently refer to `r(mean)` or `e(rmse)` in numeric expressions and obtain the result to full precision.

Macros are strings. For instance, `e(depvar)` contains “mpg”. You can refer to it, too, in subsequent expressions, but really that would be of most use to programmers, who will refer to it using constructs like `'e(depvar)'`. In any case, macros are macros, and you obtain their contents just as you would a local macro, by enclosing their name in single quotes. The name here is the full name, so `'e(depvar)'` is mpg.

Matrices are matrices, and all estimation commands store `e(b)` and `e(V)` containing the coefficient vector and variance–covariance matrix of the estimates (VCE).
Functions are stored by e-class commands only, and the only function existing is \( e(\text{sample}) \). \( e(\text{sample}) \) evaluates to 1 (meaning true) if the observation was used in the previous estimation and to 0 (meaning false) otherwise.

### Technical note

Say that some command set \( r(\text{scalar}) \) and \( r(\text{macro}) \), the first being stored as a scalar and the second as a macro. In theory, in subsequent use you are supposed to refer to \( r(\text{scalar}) \) and \( 'r(\text{macro})' \). In fact, however, you can refer to either one with or without quotes, so you could refer to \( 'r(\text{scalar})' \) and \( r(\text{macro}) \). Programmers sometimes do this.

When you refer to \( r(\text{scalar}) \), you are referring to the full double-precision stored result. Think of \( r(\text{scalar}) \) without quotes as a function returning the value of the stored result \( \text{scalar} \). When you refer to \( r(\text{scalar}) \) in quotes, Stata understands \( 'r(\text{scalar})' \) to mean “substitute the printed result of evaluating \( r(\text{scalar}) \)”. Pretend that \( r(\text{scalar}) \) equals the number 23. Then \( 'r(\text{scalar})' \) is 23, the character 2 followed by 3.

Referring to \( r(\text{scalar}) \) in quotes is sometimes useful. Say that you want to use the immediate command \( \text{cii} \) with \( r(\text{scalar}) \). The immediate command \( \text{cii} \) requires its arguments to be numbers—numeric literals in programmer’s jargon—and it will not take an expression. Thus you could not type \( '\text{cii }r(\text{scalar})...' \). You could, however, type \( '\text{cii }'r(\text{scalar})'...' \) because \( 'r(\text{scalar})' \) is just a numeric literal.

For \( r(\text{macro}) \), you are supposed to refer to it in quotes: \( 'r(\text{macro})' \). If, however, you omit the quotes in an expression context, Stata evaluates the macro and then pretends that it is the result of function-returning-string. There are side effects of this, the most important being that the result is trimmed to 80 characters.

Referring to \( r(\text{macro}) \) without quotes is never a good idea; the feature was included merely for completeness.

You can even refer to \( r(\text{matrix}) \) in quotes (assume that \( r(\text{matrix}) \) is a matrix). \( 'r(\text{matrix})' \) does not result in the matrix being substituted; it returns the word \( \text{matrix} \). Programmers sometimes find that useful.

[U] 18.8 Accessing results calculated by other programs

[U] 18.9 Accessing results calculated by estimation commands
**suest — Seemingly unrelated estimation**

**Description**

`suest` is a postestimation command; see [U] 20 Estimation and postestimation commands.

`suest` combines the estimation results—parameter estimates and associated (co)variance matrices—stored under `namelist` into one parameter vector and simultaneous (co)variance matrix of the sandwich/robust type. This (co)variance matrix is appropriate even if the estimates were obtained on the same or on overlapping data.

Typical applications of `suest` are tests for intramodel and cross-model hypotheses using `test` or `testnl`, for example, a generalized Hausman specification test. `lincom` and `nlcom` may be used after `suest` to estimate linear combinations and nonlinear functions of coefficients. `suest` may also be used to adjust a standard VCE for clustering or survey design effects.

Different estimators are allowed, for example, a `regress` model and a `probit` model; the only requirement is that `predict` produce equation-level scores with the `score` option after an estimation command. The models may be estimated on different samples, due either to explicit `if` or in selection or to missing values. If weights are applied, the same weights (type and values) should be applied to all models in `namelist`. The estimators should be estimated without `vce(robust)` or `vce(cluster clustvar)` options. `suest` returns the robust VCE, allows the `vce(cluster clustvar)` option, and automatically works with results from the `svy` prefix command (only for `vce(linearized)`). See example 8 in [SVY] svy postestimation for an example using `suest` with `svy: ologit`.

Because `suest` posts its results like a proper estimation command, its results can be stored via `estimates store`. Moreover, like other estimation commands, `suest` typed without arguments replays the results.

**Quick start**

Combined results for stored estimates `m1` and `m2`

```
suest m1 m2
```

As above, but report exponentiated coefficients and label them “Odds Ratio”

```
suest m1 m2, eform(Odds Ratio)
```

With cluster–robust standard errors adjusting for clustering by levels of `cvar`

```
suest m1 m2, vce(cluster cvar)
```

Use `svyset` data after specifying command prefix `svy`: to estimate `m1` and `m2`

```
suest m1 m2
```
Menu

Statistics  >  Postestimation

Syntax

suest namelist [, options]

where namelist is a list of one or more names under which estimation results were stored via estimates store; see [R] estimates store. Wildcards may be used. * and _all refer to all stored results. A period (.) may be used to refer to the last estimation results, even if they have not (yet) been stored.

options       Description

SE/Robust

svy           survey data estimation
vce(vcetype)  vcetype may be robust or cluster clustvar

Reporting

level(#)      set confidence level; default is level(95)
dir           display a table describing the models
eform(string) report exponentiated coefficients and label as string
display_options control columns and column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling

coefflegend   display legend instead of statistics

coefflegend does not appear in the dialog box.

Options

--- SE/Robust ---

svy specifies that estimation results should be modified to reflect the survey design effects according to the svyset specifications, see [SVY] svyset.

The svy option is implied when suest encounters survey estimation results from the svy prefix; see [SVY] svy. Poststratification is allowed only with survey estimation results from the svy prefix.

vce(vcetype) specifies the type of standard error reported, which includes types that are robust to some kinds of misspecification (robust) and that allow for intragroup correlation (cluster clustvar; see [R] vce_option.

The vce() option may not be combined with the svy option or estimation results from the svy prefix.

--- Reporting ---

level(#) specifies the confidence level, as a percentage, for confidence intervals of the coefficients; see [R] level.

dir displays a table describing the models in namelist just like estimates dir namelist.
eform\{string\} displays the coefficient table in exponentiated form: for each coefficient, \(\exp(b)\) rather than \(b\) is displayed, and standard errors and confidence intervals are transformed. \textit{string} is the table header that will be displayed above the transformed coefficients and must be 11 characters or fewer, for example, eform("Odds ratio").

\textit{display_options}: noci, nopvalues, noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(#), fvwrapon(style), cformat(\%fmt), pformat(\%fmt), sformat(\%fmt), and nolstretch; see \textit{[R] Estimation options}.

The following option is available with \texttt{suest} but is not shown in the dialog box: \texttt{coeflegend}; see \textit{[R] Estimation options}.

## Remarks and examples

Remarks are presented under the following headings:

- \textit{Using suest}
- \textit{Remarks on regress}
- Testing the assumption of the independence of irrelevant alternatives
- Testing proportionality
- Testing cross-model hypotheses

### Using suest

If you plan to use \texttt{suest}, you must take precautions when fitting the original models. These restrictions are relaxed when using \texttt{svy} commands; see \textit{[SVY] svy postestimation}.

1. \texttt{suest} works with estimation commands that allow \texttt{predict} to generate equation-level score variables when supplied with the \texttt{score} (or \texttt{scores}) option. For example, equation-level score variables are generated after running \texttt{mlogit} by typing

\begin{verbatim}
. predict sc*, scores
\end{verbatim}

2. Estimation should take place \textit{without} the \texttt{vce(robust)} or \texttt{vce(cluster clustvar)} option. \texttt{suest} always computes the robust estimator of the (co)variance, and \texttt{suest} has a \texttt{vce(cluster clustvar)} option.

The within-model covariance matrices computed by \texttt{suest} are identical to those obtained by specifying a \texttt{vce(robust)} or \texttt{vce(cluster clustvar)} option during estimation. \texttt{suest}, however, also estimates the between-model covariances of parameter estimates.

3. Finally, the estimation results to be combined should be stored by \texttt{estimates store}; see \textit{[R] estimates store}.

After estimating and storing a series of estimation results, you are ready to combine the estimation results with \texttt{suest},

\begin{verbatim}
. suest name1 [ name2 ...] [, vce(cluster clustvar)]
\end{verbatim}

and you can subsequently use postestimation commands, such as \texttt{test}, to test hypotheses. Here an important issue is how \texttt{suest} assigns names to the equations. If you specify one model \texttt{name}, the original equation names are left unchanged; otherwise, \texttt{suest} constructs new equation names. The coefficients of a single-equation model (such as \texttt{logit} and \texttt{poisson}) that was estimate stored under name \texttt{X} are collected under equation \texttt{X}. With a multi-equation model stored under name \texttt{X}, \texttt{suest} prefixes \texttt{X_} to an original equation name \texttt{eq}, forming equation name, \texttt{X_eq}. 
Earlier we said that standard errors from `suest` are identical to those obtained by specifying the `vce(robust)` option with each command individually. Thus if you fit a logistic model using `logit` with the `vce(robust)` option, you will get the same standard errors when you type

```
suest .
```

directly after `logit` using the same data without the `vce(robust)` option.

This is not true for multiple estimation results when the estimation samples are not all the same. The standard errors from `suest` will be slightly smaller than those from individual model fits using the `vce(robust)` option because `suest` uses a larger number of observations to estimate the simultaneous (co)variance matrix.

In rare circumstances, `suest` may have to truncate equation names to 32 characters. When equation names are not unique because of truncation, `suest` numbers the equations within models, using equations named `X#`.

`regress` (see [R] regress) does not include its ancillary parameter, the residual variance, in its coefficient vector and (co)variance matrix. Moreover, while the `score` option is allowed with `predict` after `regress`, a score variable is generated for the mean but not for the variance parameter. `suest` contains special code that assigns the equation name `mean` to the coefficients for the mean, adds the equation `lnvar` for the log variance, and computes the appropriate two score variables itself.

The multinomial logit model and the closely related conditional logit model satisfy a probabilistic version of the assumption of the independence of irrelevant alternatives (IIA), implying that the ratio of the probabilities for two alternatives does not depend on what other alternatives are available.

Hausman and McFadden (1984) proposed a test for this assumption that is implemented in the `hausman` command. The standard Hausman test has several limitations. First, the test statistic may be undefined because the estimated VCE does not satisfy the required asymptotic properties of the test. Second, the classic Hausman test applies only to the test of the equality of two estimators. Third, the test requires access to a fully efficient estimator; such an estimator may not be available, for example, if you are analyzing complex survey data. Using `suest` can overcome these three limitations.

In our first example, we follow the analysis of the type of health insurance reported in [R] mlogit and demonstrate the `hausman` command with the `suest/test` combination. We fit the full multinomial logit model for all three alternatives and two restricted multinomial models in which one alternative is excluded. After fitting each of these models, we store the results by using the `store` subcommand of `estimates.title()` simply documents the models.

Comparing the coefficients between models does not suggest substantial differences. We can formally test that coefficients are the same for the full model m1 and the restricted models m2 and m3 by using the hausman command. hausman expects the models to be specified in the order “always consistent” first and “efficient under $H_0$” second.

b = consistent under Ho and Ha; obtained from mlogit
B = inconsistent under Ha, efficient under Ho; obtained from mlogit

Test: Ho: difference in coefficients not systematic
chi2(3) = (b-B)'[(V_b-V_B)^(-1)](b-B) = -0.18
chi2<0 ==> model fitted on these data fails to meet the asymptotic assumptions of the Hausman test; see suest for a generalized test
According to the test of \( m_1 \) against \( m_2 \), we cannot reject the hypothesis that the coefficients of \( m_1 \) and \( m_2 \) are the same. The second Hausman test is not well defined—something that happens fairly often. The problem is due to the estimator of the variance \( V(b-B) \) as \( V(b) - V(B) \), which is a feasible estimator only asymptotically. Here it simply is not a proper variance matrix, and the Hausman test becomes undefined.

\( \text{suest m1 m2} \) estimates the simultaneous (co)variance of the coefficients of models \( m_1 \) and \( m_2 \). Although \( \text{suest} \) is technically a postestimation command, it acts like an estimation command in that it stores the simultaneous coefficients in \( e(b) \) and the full (co)variance matrix in \( e(V) \). We could have used the \( \text{estat vce} \) command to display the full (co)variance matrix to show that the cross-model covariances were indeed estimated. Typically, we would not have a direct interest in \( e(V) \).

\end{verbatim}

\( \text{suest} \) created equation names by combining the name under which we stored the results using \( \text{estimates store} \) with the original equation names. Thus, in the simultaneous estimation result, equation Prepaid originating in model \( m_1 \) is named \( m_1 \_\text{PrePaid} \). According to the McFadden–Hausman specification of a test for IIA, the coefficients of the equations \( m_1 \_\text{PrePaid} \) and \( m_2 \_\text{PrePaid} \) should be equal. This equality can be tested easily with the \( \text{test} \) command. The \( \text{cons} \) option specifies that the intercept \_cons be included in the test.

\begin{verbatim}
. test [m1_Prepaid = m2_Prepaid], cons
   ( 1) [m1_Prepaid]age - [m2_Prepaid]age = 0
   ( 2) [m1_Prepaid]male - [m2_Prepaid]male = 0
   ( 3) [m1_Prepaid]_cons - [m2_Prepaid]_cons = 0
   ch2( 3) = 0.89
   Prob > ch2 = 0.8266
\end{verbatim}

The Hausman test via \( \text{suest} \) is comparable to that computed by \( \text{hausman} \), but they use different estimators of the variance of the difference of the estimates. The \( \text{hausman} \) command estimates \( V(b-B) \) by \( V(b) - V(B) \), whereas \( \text{suest} \) estimates \( V(b-B) \) by \( V(b) - \text{cov}(b,B) - \text{cov}(B,b) + V(B) \). One advantage of the second estimator is that it is always admissible, so the resulting test is always well defined. This quality is illustrated in the Hausman-type test of IIA comparing models \( m_1 \) and \( m_3 \).

Although the classic Hausman test computed by hausman is not defined here, the suest-based test is just fine. We cannot reject the equality of the common coefficients across m1 and m3.

A second advantage of the suest approach is that we can estimate the (co)variance matrix of the multivariate normal distribution of the estimators of the three models m1, m2, and m3 and test that the common coefficients are equal.

Again we do not find evidence against the correct specification of the multinomial logit for type of insurance. The classic Hausman test assumes that one of the estimators (named B in hausman) is efficient, that is, it has minimal (asymptotic) variance. This assumption ensures that $V(b) - V(B)$ is an admissible, viable estimator for $V(b - B)$. The assumption that we have an efficient estimator is a restrictive one. It is violated, for instance, if our data are clustered. We want to adjust for clustering via a vce(cluster clustvar) option by requesting the cluster-adjusted sandwich estimator of variance. Consequently, in such a case, hausman cannot be used. This problem does not exist with the suest version of the Hausman test. To illustrate this feature, we suppose that the data are clustered by city—we constructed an imaginary variable cityid for this illustration. If we plan to apply suest, we would not specify the vce(cluster clustvar) option at the time of estimation.
suest has a vce(cluster clustvar) option. Thus we do not need to refit the models; we can call suest and test right away.

```
suest m1 m2, vce(cluster cityid) noomitted
```

suest provides some descriptive information about the clustering on cityid. Like any other estimation command, suest informs us that the standard errors are adjusted for clustering. The Hausman-type test obtained from the test command uses a simultaneous (co)variance of m1 and m2 appropriately adjusted for clustering. In this example, we still do not have reason to conclude that the multinomial logit model in this application is misspecified, that is, that IIA is violated.

The multinomial logistic regression model is a special case of the conditional logistic regression model; see [R] clogit. Like the multinomial logistic regression model, the conditional logistic regression model also makes the IIA assumption. Consider an example, introduced in [CM] cmclogit, in which the demand for American, Japanese, and European cars is modeled in terms of the number of local dealers of the respective brands and of some individual attributes incorporated in interaction with the nationality of cars. We want to perform a Hausman-type test for IIA comparing the decision between all nationalities with the decision between non-American cars. The following code fragment demonstrates how to conduct a Hausman test for IIA via suest in this case.

```
clogit choice japan europe maleJap maleEur incJap incEur dealer, group(id)
estimates store allcars
clogit choice japan maleJap incJap dealer if car!=1 , group(id)
estimates store foreign
```
Testing proportionality

The applications of `suest` that we have discussed so far concern Hausman-type tests for mis-specification. To test such a hypothesis, we compared two estimators that have the same probability limit if the hypothesis holds true, but otherwise have different limits. We may also want to compare the coefficients of models (estimators) for other substantive reasons. Although we most often want to test whether coefficients differ between models or estimators, we may occasionally want to test other constraints (see Hausman and Ruud [1987]).

Example 2

In this example, using simulated labor market data for siblings, we consider two dependent variables, income (`inc`) and whether a person was promoted in the last year (`promo`). We apply familiar economic arguments regarding human capital, according to which employees have a higher income and a higher probability of being promoted, by having more human capital. Human capital is acquired through formal education (`edu`) and on-the-job training experience (`exp`). We study whether income and promotion are “two sides of the same coin”, that is, whether they reflect a common latent variable, “human capital”. Accordingly, we want to compare the effects of different aspects of human capital on different outcome variables.

We estimate fairly simple labor market equations. The income model is estimated with `regress`, and the estimation results are stored under the name `Inc`.

```stata
. use https://www.stata-press.com/data/r16/income
. regress inc edu exp male
```

```

Being sibling data, the observations are clustered on family of origin, `famid`. In the estimation of the regression parameters, we did not specify a `vce(cluster famid)` option to adjust standard errors for clustering on family (`famid`). Thus the standard errors reported by `regress` are potentially flawed. This problem will, however, be corrected by specifying a `vce(cluster clustvar)` option with `suest`.

Next we estimate the promotion equation with `probit` and again store the results under an appropriate name.

```stata
. use https://www.stata-press.com/data/r16/income
```

Being sibling data, the observations are clustered on family of origin, `famid`. In the estimation of the regression parameters, we did not specify a `vce(cluster famid)` option to adjust standard errors for clustering on family (`famid`). Thus the standard errors reported by `regress` are potentially flawed. This problem will, however, be corrected by specifying a `vce(cluster clustvar)` option with `suest`.

Next we estimate the promotion equation with `probit` and again store the results under an appropriate name.
The coefficients in the income and promotion equations definitely seem to be different. However, because the scales of the two variables are different, we would not expect the coefficients to be equal. The correct hypothesis here is that the proportionality of the coefficients of the two models, apart from the constant, are equal. This formulation would still reflect that the relative effects of the different aspects of human capital do not differ between the dependent variables. We can obtain a nonlinear Wald test for the hypothesis of proportionality by using the `testnl` command on the combined estimation results of the two estimators. Thus we first have to form the combined estimation results. At this point, we specify the `vce(cluster famid)` option to adjust for the clustering of observations on famid.

```
. suest Inc Promo, vce(cluster famid)
Simultaneous results for Inc, Promo
```

```
. est store Promo
```
The standard errors reported by \texttt{suest} are identical to those reported by the respective estimation commands when invoked with the \texttt{vce(cluster famid)} option. We are now ready to test for proportionality:

\[
H_0: \frac{\beta_{\text{edu}}}{\beta_{\text{Promotion}}} = \frac{\beta_{\text{exp}}}{\beta_{\text{Promotion}}} = \frac{\beta_{\text{male}}}{\beta_{\text{Promotion}}}
\]

It is straightforward to translate this into syntax suitable for \texttt{testnl}, recalling that the coefficient of variable \( v \) in equation \( eq \) is denoted by \([eq]v\).

```
. testnl [Inc_mean]edu/[Promo_promo]edu = [Inc_mean]exp/[Promo_promo]exp =
   [Inc_mean]male/[Promo_promo]male
   (1) [Inc_mean]edu/[Promo_promo]edu = [Inc_mean]exp/[Promo_promo]exp
   (2) [Inc_mean]edu/[Promo_promo]edu = [Inc_mean]male/[Promo_promo]male
   chi2(2) = 0.61
   Prob > chi2 = 0.7385
```

From the evidence, we fail to reject the hypotheses that the coefficients of the income and promotion equations are proportional. Thus it is not unreasonable to assume that income and promotion can be explained by the same latent variable, “labor market success”.

A disadvantage of the nonlinear Wald test is that it is not invariant with respect to representation: a Wald test for a mathematically equivalent formulation of the nonlinear constraint usually leads to a different test result. An equivalent formulation of the proportionality hypothesis is

\[
H_0: \frac{\beta_{\text{edu}}}{\beta_{\text{Promotion}}} = \frac{\beta_{\text{exp}}}{\beta_{\text{Promotion}}} = \frac{\beta_{\text{male}}}{\beta_{\text{Promotion}}}
\]

This formulation is “more linear” in the coefficients. The asymptotic \( \chi^2 \) distribution of the nonlinear Wald statistic can be expected to be more accurate for this representation.

```
. testnl ([Inc_mean]edu*[Promo_promo]exp = [Inc_mean]exp*[Promo_promo]edu)
   > ([Inc_mean]edu*[Promo_promo]male = [Inc_mean]male*[Promo_promo]edu)
   (1) [Inc_mean]edu*[Promo_promo]exp = [Inc_mean]exp*[Promo_promo]edu
   (2) [Inc_mean]edu*[Promo_promo]male = [Inc_mean]male*[Promo_promo]edu
   chi2(2) = 0.46
   Prob > chi2 = 0.7936
```

Here the two representations lead to similar test statistics and \( p \)-values. As before, we fail to reject the hypothesis of proportionality of the coefficients of the two models.

---

**Testing cross-model hypotheses**

**Example 3**

In this example, we demonstrate how some cross-model hypotheses can be tested using the facilities already available in most estimation commands. This demonstration will explain the intricate relationship between the cluster adjustment of the robust estimator of variance and the \texttt{suest} command. It will also be made clear that a new facility is required to perform more general cross-model testing.
We want to test whether the effect of $x_1$ on the binary variable $y_1$ is the same as the effect of $x_2$ on the binary $y_2$; see Clogg, Petkova, and Haritou (1995). In this setting, $x_1$ may equal $x_2$, and $y_1$ may equal $y_2$. We assume that logistic regression models can be used to model the responses, and for simplicity, we ignore further predictor variables in these models. If the two logit models are fit on independent samples so that the estimators are (stochastically) independent, a Wald test for $\hat{b}[x_1] = \hat{b}[x_2]$ rejects the null hypothesis if

$$
\frac{\hat{b}(x_1) - \hat{b}(x_2)}{\left[\hat{\sigma}^2\{\hat{b}(x_1)\} + \hat{\sigma}^2\{\hat{b}(x_2)\}\right]^{1/2}}
$$

is larger than the appropriate $\chi^2_1$ threshold. If the models are fit on the same sample (or on dependent samples), so that the estimators are stochastically dependent, the above test that ignores the covariance between the estimators is not appropriate.

It is instructive to see how this problem can be tackled by "stacking" data. In the stacked format, we doubled the number of observations. The dependent variable is $y_1$ in the first half of the data and is $y_2$ in the second half of the data. The predictor variable $z_1$ is set to $x_1$ in the first half of the expanded data and to 0 in the rest. Similarly, $z_2$ is 0 in the first half and $x_2$ in the second half. The following diagram illustrates the transformation, in the terminology of the reshape command, from wide to long format.

The observations in the long format data organization are clustered on the original subjects and are identified with the identifier id. The clustering on id has to be accounted for when fitting a simultaneous model. The simplest way to deal with clustering is to use the cluster adjustment of the robust or sandwich estimator; see [P] _robust. The data manipulation can be accomplished easily with the stack command; see [D] stack. Subsequently, we fit a simultaneous logit model and perform a Wald test for the hypothesis that the coefficients of $z_1$ and $z_2$ are the same. A full setup to obtain the cross-model Wald test could then be as follows:

```
. generate zero = 0 // a variable that is always 0
. generate one = 1 // a variable that is always 1
. generate two = 2 // a variable that is always 2
. stack id y1 x1 zero one id y2 zero x2 two, into(id y z1 z2 model)
. generate model2 = (model==2)
. logit y model2 z1 z2, vce(cluster id)
. test _b[z1] = _b[z2]
```

The coefficient of $z_1$ represents the effect of $x_1$ on $y_1$, and similarly, $z_2$ for the effect of $x_2$ on $y_2$. The variable model2 is a dummy for the “second model”, which is included to allow the intercept in the second model to differ from that in the first model. The estimates of the coefficient of $z_1$ and its standard error in the combined model are the same as the estimates of the coefficient of $z_1$ and its standard error if we fit the model on the unstacked data.

```
. logit y1 x1, vce(robust)
```
The \texttt{vce(cluster clustvar)} option specified with the \texttt{logit} command for the stacked data ensures that the covariances of \_b[z1] and \_b[z2] are indeed estimated. This estimation ensures that the Wald test for the equality of the coefficients is correct. If we had not specified the \texttt{vce(cluster clustvar)} option, the (co)variance matrix of the coefficients would have been block-diagonal; that is, the covariances of \_b[z1] and \_b[z2] would have been 0. Then \texttt{test} would have effectively used the invalid formula for the Wald test for two independent samples.

In this example, the two logit models were fit on the same data. The same setup would apply, without modification, when the two logit models were fit on overlapping data that resulted, for instance, if the \textit{y} or \textit{x} variables were missing in some observations.

The \texttt{suest} command allows us to obtain the above Wald test more efficiently by avoiding the data manipulation, obviating the need to fit a model with twice the number of coefficients. The test statistic produced by the above code fragment is \textit{identical} to that obtained via \texttt{suest} on the original (unstacked) data:

\begin{verbatim}
. logit y1 x1
. estimates store M1
. logit y2 x2
. estimates store M2
. suest M1 M2
. test [M1]x1=[M2]x2
\end{verbatim}

The stacking method can be applied not only to the testing of cross-model hypotheses for \texttt{logit} models but also to any estimation command that supports the \texttt{vce(cluster clustvar)} option. The stacking approach clearly generalizes to stacking more than two logit or other models, testing more general linear hypotheses, and testing nonlinear cross-model hypotheses (see [R] \texttt{testnl}). In all of these cases, \texttt{suest} would yield identical statistical results but at smaller costs in terms of data management, computer storage, and computer time.

Is \texttt{suest} nothing but a convenience command? No, there are two disadvantages to the stacking method, both of which are resolved via \texttt{suest}. First, if the models include ancillary parameters (in a regression model, the residual variance; in an ordinal response model, the cutpoints; and in lognormal survival-time regression, the time scale parameter), these parameters are constrained to be equal between the stacked models. In \texttt{suest}, this constraint is relaxed. Second, the stacking method does not generalize to compare different statistical models, such as a probit model and a regression model. As demonstrated in the previous section, \texttt{suest} can deal with this situation.
**Stored results**

`suest` stores the following in `e()`:

Scalars
- `e(N)` number of observations
- `e(N_clust)` number of clusters
- `e(rank)` rank of `e(V)`

Macros
- `e(cmd)` `suest`
- `e(eqnames#)` original names of equations of model #
- `e(names)` list of model names
- `e(wtype)` weight type
- `e(wexp)` weight expression
- `e(clustvar)` name of cluster variable
- `e(vce)` `vcetype` specified in `vce()`
- `e(vcetype)` title used to label Std. Err.
- `e(properties)` `b V`

Matrices
- `e(b)` stacked coefficient vector of the models
- `e(V)` variance–covariance matrix of the estimators

Functions
- `e(sample)` marks estimation sample

**Methods and formulas**

The estimation of the simultaneous (co)variance of a series of \( k \) estimators is a nonstandard application of the sandwich estimator, as implemented by the command `[P] _robust`. You may want to read this manual entry before reading further.

The starting point is that we have fit \( k \) different models on the same data—partially overlapping or nonoverlapping data are special cases. We want to derive the simultaneous distribution of these \( k \) estimators, for instance, to test a cross-estimator hypothesis \( H_0 \). As in the framework of Hausman testing, \( H_0 \) will often be of the form that different estimators have the same probability limit under some hypothesis, while the estimators have different limits if the hypothesis is violated.

We consider (vector) estimators \( \hat{\beta}_i \) to be defined as “the” solution of the estimation equations \( G_i \),

\[
G_i(b_i) = \sum_j w_{ij} u_{ij}(b_i) = 0, \quad i = 1, \ldots, k
\]

We refer to the \( u_{ij} \) as the “scores”. Specifying some weights \( w_{ij} = 0 \) trivially accommodates for partially overlapping or even disjointed data. Under “suitable regularity conditions” (see White [1982; 1996] for details), the \( \hat{\beta}_i \) are asymptotically normally distributed, with the variance estimated consistently by the sandwich estimator

\[
V_i = \text{Var}(\hat{\beta}_i) = D_i^{-1} \sum_j w_{ij} u_{ij} u_{ij}' D_i^{-1}
\]
where $D_i$ is the Jacobian of $G_i$ evaluated at $\hat{\beta}_i$. In the context of maximum likelihood estimation, $D_i$ can be estimated consistently by (minus) the Hessian of the log likelihood or by the Fisher information matrix. If the model is also well specified, the sandwiched term $(\sum_j w_{ij}u_{ij}u_{ij}')$ converges in probability to $D_i$, so $V_i$ may be consistently estimated by $D_i^{-1}$.

To derive the simultaneous distribution of the estimators, we consider the “stacked” estimation equation,

$$G(\hat{\beta}) = \left\{ G_1(\hat{\beta}_1)' \ G_1(\hat{\beta}_2)' \ldots \ G_k(\hat{\beta}_k)' \right\}' = 0$$

Under “suitable regularity conditions” (see White [1996] for details), $\hat{\beta}$ is asymptotically jointly normally distributed. The Jacobian and scores of the simultaneous equation are easily expressed in the Jacobian and scores of the separate equations. The Jacobian of $G$, 

$$D(\hat{\beta}) = \left. \frac{dG(\beta)}{d\beta} \right|_{\beta=\hat{\beta}}$$

is block diagonal with blocks $D_1$, $\ldots$, $D_k$. The inverse of $D(\hat{\beta})$ is again block diagonal, with the inverses of $D_i$ on the diagonal. The scores $u$ of $G$ are simply obtained as the concatenated scores of the separate equations:

$$u_j = (u_{1j}' \ u_{2j}' \ldots \ u_{kj}')'$$

Out-of-sample (that is, where $w_{ij} = 0$) values of the score variables are defined as 0 (thus we drop the $i$ subscript from the common weight variable). The sandwich estimator for the asymptotic variance of $\hat{\beta}$ reads

$$V = \text{Var}(\hat{\beta}) = D(\hat{\beta})^{-1} \left( \sum_j w_j u_j u_j' \right) D(\hat{\beta})^{-1}$$

Taking a “partitioned” look at this expression, we see that $V(\hat{\beta}_i)$ is estimated by

$$D_i^{-1} \left( \sum_j w_{ij} u_{ij} u_{ij}' \right) D_i^{-1}$$

which is, yet again, the familiar sandwich estimator for $\hat{\beta}_i$ based on the separate estimation equation $G_i$. Thus considering several estimators simultaneously in this way does not affect the estimators of the asymptotic variances of these estimators. However, as a bonus of stacking, we obtained a sandwich-type estimate of the covariance $V_{ih}$ of estimators $\hat{\beta}_i$ and $\hat{\beta}_h$,

$$V_{ih} = \text{Cov}(\hat{\beta}_i, \hat{\beta}_h) = D_i^{-1} \left( \sum_j w_{ij} u_{ij} u_{hj}' \right) D_h^{-1}$$

which is also obtained by White (1982).

This estimator for the covariance of estimators is an application of the cluster modification of the sandwich estimator proposed by Rogers [1993]. Consider the stacked data format as discussed in the logit example, and assume that Stata would be able to estimate a “stacked model” in which different models apply to different observations, for example, a probit model for the first half, a regression model for the second half, and a one-to-one cluster relation between the first and second half. If there are no common parameters to both models, the score statistics of parameters for the stacked models are zero in the half of the data in which they do not occur. In Rogers’s method, we have to sum the score statistics over the observations within a cluster. This step boils down to concatenating the score statistics at the level of the cluster.
We compare the sandwich estimator of the (co)variance $V_{12}$ of two estimators with the estimator of variance $\tilde{V}_{12}$ applied in the classic Hausman test. Hausman (1978) showed that if $\hat{\beta}_1$ is consistent under $H_0$ and $\hat{\beta}_2$ is efficient under $H_0$, then asymptotically

$$\text{Cov}(\hat{\beta}_1, \hat{\beta}_2) = \text{Var}(\hat{\beta}_2)$$

and so $\text{var}(\hat{\beta}_1 - \hat{\beta}_2)$ is consistently estimated by $V_1 - V_2$.

Acknowledgment

`suest` was written by Jeroen Weesie of the Department of Sociology at Utrecht University, The Netherlands. This research is supported by grant PGS 50-370 by The Netherlands Organization for Scientific Research.

An earlier version of `suest` was published in the *Stata Technical Bulletin* (1999). The current version of `suest` is not backward compatible with the STB version because of the introduction of new ways to manage estimation results via the `estimates` command.

**summarize** — Summary statistics

## Description

`summarize` calculates and displays a variety of univariate summary statistics. If no `varlist` is specified, summary statistics are calculated for all the variables in the dataset.

## Quick start

### Basic summary statistics for continuous variable `v1`

```
summarize v1
```

### Same as above, and include `v2` and `v3`

```
summarize v1-v3
```

### Same as above, and provide additional detail about the distribution

```
summarize v1-v3, detail
```

### Summary statistics reported separately for each level of `catvar`

```
by catvar: summarize v1
```

### With frequency weight `wvar`

```
summarize v1 [fweight=wvar]
```

## Menu

Statistics > Summaries, tables, and tests > Summary and descriptive statistics > Summary statistics
**Syntax**

```
summarize [varlist] [if] [in] [weight] [ , options ]
```

<table>
<thead>
<tr>
<th>options</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Main</strong></td>
<td></td>
</tr>
<tr>
<td><code>detail</code></td>
<td>display additional statistics</td>
</tr>
<tr>
<td><code>meanonly</code></td>
<td>suppress the display; calculate only the mean; programmer’s option</td>
</tr>
<tr>
<td><code>format</code></td>
<td>use variable’s display format</td>
</tr>
<tr>
<td><code>separator(#)</code></td>
<td>draw separator line after every # variables; default is <code>separator(5)</code></td>
</tr>
<tr>
<td><code>display_options</code></td>
<td>control spacing, line width, and base and empty cells</td>
</tr>
</tbody>
</table>

`varlist` may contain factor variables; see [U] 11.4.3 Factor variables.
`varlist` may contain time-series operators; see [U] 11.4.4 Time-series varlists.
`by`, `rolling`, and `statsby` are allowed; see [U] 11.1.10 Prefix commands.
`aweights`, `fweights`, and `iweights` are allowed. However, `iweights` may not be used with the `detail` option; see [U] 11.1.6 weight.

**Options**

`detail` produces additional statistics, including skewness, kurtosis, the four smallest and four largest values, and various percentiles.

`meanonly`, which is allowed only when `detail` is not specified, suppresses the display of results and calculation of the variance. Ado-file writers will find this useful for fast calls.

`format` requests that the summary statistics be displayed using the display formats associated with the variables rather than the default `g` display format; see [U] 12.5 Formats: Controlling how data are displayed.

`separator(#)` specifies how often to insert separation lines into the output. The default is `separator(5)`, meaning that a line is drawn after every five variables. `separator(10)` would draw a line after every 10 variables. `separator(0)` suppresses the separation line.

`display_options`: `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fvwrap(#)`, and `fvwrapon(style)`; see [R] Estimation options.

**Remarks and examples**

`summarize` can produce two different sets of summary statistics. Without the `detail` option, the number of nonmissing observations, the mean and standard deviation, and the minimum and maximum values are presented. With `detail`, the same information is presented along with the variance, skewness, and kurtosis; the four smallest and four largest values; and the 1st, 5th, 10th, 25th, 50th (median), 75th, 90th, 95th, and 99th percentiles.

Also see [R] `ci` for calculating the standard error and confidence intervals of the mean.
Example 1: summarize with the separator() option

We have data containing information on various automobiles, among which is the variable mpg, the mileage rating. We can obtain a quick summary of the mpg variable by typing

```
. use https://www.stata-press.com/data/r16/auto2
   (1978 Automobile Data)
. summarize mpg
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>mpg</td>
<td>74</td>
<td>21.2973</td>
<td>5.785503</td>
<td>12</td>
<td>41</td>
</tr>
</tbody>
</table>

We see that we have 74 observations. The mean of mpg is 21.3 miles per gallon, and the standard deviation is 5.79. The minimum is 12, and the maximum is 41.

If we had not specified the variable (or variables) we wanted to summarize, we would have obtained summary statistics on all the variables in the dataset:

```
. summarize, separator(4)
```

<table>

</tbody>
</table>

There are only 69 observations on rep78, so some of the observations are missing. There are no observations on make because it is a string variable.
The idea of the mean is quite old (Plackett 1958), but its extension to a scheme of moment-based measures was not done until the end of the 19th century. Between 1893 and 1905, Pearson discussed and named the standard deviation, skewness, and kurtosis, but he was not the first to use any of these. Thiele (1889), in contrast, had earlier firmly grasped the notion that the \( m_r \) provide a systematic basis for discussing distributions. However, even earlier anticipations can also be found. For example, Euler in 1778 used \( m_2 \) and \( m_3 \) in passing in a treatment of estimation (Hald 1998, 87), but seemingly did not build on that.

Similarly, the idea of the median is quite old. The history of the interquartile range is tangled up with that of the probable error, a long-popular measure. Extending this in various ways to a more general approach based on quantiles (to use a later term) occurred to several people in the nineteenth century. Galton (1875) is a nice example, particularly because he seems so close to the key idea of the quantiles as a function, which took another century to reemerge strongly.

Thorvald Nicolai Thiele (1838–1910) was a Danish scientist who worked in astronomy, mathematics, actuarial science, and statistics. He made many pioneering contributions to statistics, several of which were overlooked until recently. Thiele advocated graphical analysis of residuals checking for trends, symmetry of distributions, and changes of sign, and he even warned against overinterpreting such graphs.

Example 2: summarize with the detail option

The detail option provides all the information of a normal summarize and more. The format of the output also differs, as shown here:

```
   . summarize mpg, detail

Mileage (mpg)

          Percentiles     Smallest
         1%       12          12
         5%       14          12
        10%       14          14        Obs      74
        25%       18          14        Sum of Wgt. 74
        50%       20          14        Mean     21.2973
        75%       25          34        Std. Dev. 5.785503
       90%       29          35        Variance 33.47205
       95%       34          35         Skewness .9487176
       99%       41          41         Kurtosis 3.975005

```

As in the previous example, we see that the mean of mpg is 21.3 miles per gallon and that the standard deviation is 5.79. We also see the various percentiles. The median of mpg (the 50th percentile) is 20 miles per gallon. The 25th percentile is 18, and the 75th percentile is 25.

When we performed summarize, we learned that the minimum and maximum were 12 and 41, respectively. We now see that the four smallest values in our dataset are 12, 12, 14, and 14. The four largest values are 34, 35, 35, and 41. The skewness of the distribution is 0.95, and the kurtosis is 3.98. (A normal distribution would have a skewness of 0 and a kurtosis of 3.)

Skewness is a measure of the lack of symmetry of a distribution. If the distribution is symmetric, the coefficient of skewness is 0. If the coefficient is negative, the median is usually greater than the mean and the distribution is said to be skewed left. If the coefficient is positive, the median is usually less than the mean and the distribution is said to be skewed right. Kurtosis (from the Greek kyrtosis, meaning curvature) is a measure of peakedness of a distribution. The smaller the coefficient of kurtosis, the flatter the distribution. The normal distribution has a coefficient of kurtosis of 3 and provides a convenient benchmark.
Technical note

The convention of calculating the median of an even number of values by averaging the central two order statistics is of long standing. (That is, given 8 values, average the 4th and 5th smallest values, or given 42, average the 21st and 22nd smallest.) Stigler (1977) filled a much-needed gap in the literature by naming such paired central order statistics as “comedians”, although it remains unclear how far he was joking.

Example 3: summarize with the by prefix

summarize can usefully be combined with the by varlist: prefix. In our dataset, we have a variable, foreign, that distinguishes foreign and domestic cars. We can obtain summaries of mpg and weight within each subgroup by typing

```
. by foreign: summarize mpg weight
```

```
<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>mpg</td>
<td>52</td>
<td>19.82692</td>
<td>4.743297</td>
<td>12</td>
<td>34</td>
</tr>
<tr>
<td>weight</td>
<td>52</td>
<td>3317.115</td>
<td>695.3637</td>
<td>1800</td>
<td>4840</td>
</tr>
</tbody>
</table>
```

```
<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>mpg</td>
<td>22</td>
<td>24.77273</td>
<td>6.611187</td>
<td>14</td>
<td>41</td>
</tr>
<tr>
<td>weight</td>
<td>22</td>
<td>2315.909</td>
<td>433.0035</td>
<td>1760</td>
<td>3420</td>
</tr>
</tbody>
</table>
```

Domestic cars in our dataset average 19.8 miles per gallon, whereas foreign cars average 24.8.

Because by varlist: can be combined with summarize, it can also be combined with summarize, detail:
. by foreign: summarize mpg, detail

-> foreign = Domestic

Mileage (mpg)

Technical note

`summarize` respects display formats if we specify the `format` option. When we type `summarize price weight`, we obtain

```
Variable | Obs | Mean   | Std. Dev.   | Min  | Max |
---------|-----|--------|-------------|------|-----|
price    | 74  | 6,165.26 | 2,949.496 | 3,291 | 15,906 |
weight   | 74  | 3,019.46 | 777.1936 | 1,760 | 4,840  |
```

The display is accurate but is not as aesthetically pleasing as we may wish, particularly if we plan to use the output directly in published work. By placing formats on the variables, we can control how the table appears:

```
. format price weight %9.2fc
. summarize price weight, format
```

```
Variable | Obs | Mean   | Std. Dev.   | Min  | Max |
---------|-----|--------|-------------|------|-----|
price    | 74  | 6,165.26 | 2,949.50  | 3,291.00 | 15,906.00 |
weight   | 74  | 3,019.46 | 777.19    | 1,760.00 | 4,840.00  |
```
If you specify a weight (see [U] 11.1.6 weight), each observation is multiplied by the value of the weighting expression before the summary statistics are calculated so that the weighting expression is interpreted as the discrete density of each observation.

### Example 4: summarize with factor variables

You can also use `summarize` to obtain summary statistics for factor variables. For example, if you type

```
. summarize i.rep78
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>Poor</td>
<td>69</td>
<td>.0289855</td>
<td>.1689948</td>
<td>0</td>
<td>1</td>
</tr>
<tr>
<td>Fair</td>
<td>69</td>
<td>.115942</td>
<td>.3225009</td>
<td>0</td>
<td>1</td>
</tr>
<tr>
<td>Average</td>
<td>69</td>
<td>.4347826</td>
<td>.4993602</td>
<td>0</td>
<td>1</td>
</tr>
<tr>
<td>Good</td>
<td>69</td>
<td>.2608696</td>
<td>.4423259</td>
<td>0</td>
<td>1</td>
</tr>
<tr>
<td>Excellent</td>
<td>69</td>
<td>.1594203</td>
<td>.3687494</td>
<td>0</td>
<td>1</td>
</tr>
</tbody>
</table>

you obtain the sample proportions for the five levels of the `rep78` variable. For example, 11.6% of the 69 cars with nonmissing values of `rep78` have a fair repair record.

We could have used `tabulate oneway rep78` to obtain the sample proportions along with the cumulative proportions. Alternatively, we could have used `proportions rep78` to obtain the sample proportions along with the standard errors of the proportions instead of the standard deviations of the proportions.

### Example 5: summarize with weights

We have 1980 census data on each of the 50 states. Included in our variables is `medage`, the median age of the population of each state. If we type `summarize medage`, we obtain unweighted statistics:

```
. use https://www.stata-press.com/data/r16/census, clear
   (1980 Census data by state)
. summarize medage
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>medage</td>
<td>50</td>
<td>29.54</td>
<td>1.693445</td>
<td>24.2</td>
<td>34.7</td>
</tr>
</tbody>
</table>

Also among our variables is `pop`, the population in each state. Typing `summarize medage [w=pop]` produces population-weighted statistics:
2604  **summarize** — Summary statistics

```stata
. summarize medage [w=pop]  
(analytic weights assumed)

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Weight</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>medage</td>
<td>50</td>
<td>225907472</td>
<td>30.11047</td>
<td>1.66933</td>
<td>24.2</td>
<td>34.7</td>
</tr>
</tbody>
</table>
```

The number listed under Weight is the sum of the weighting variable, `pop`, indicating that there are roughly 226 million people in the United States. The `pop`-weighted mean of `medage` is 30.11 (compared with 29.54 for the unweighted statistic), and the weighted standard deviation is 1.67 (compared with 1.69).

### Example 6: summarize with weights and the detail option

We can obtain detailed summaries of weighted data as well. When we do this, all the statistics are weighted, including the percentiles.

```stata
. summarize medage [w=pop], detail  
(analytic weights assumed)

<table>
<thead>
<tr>
<th>Median age</th>
</tr>
</thead>
</table>

<table>
<thead>
<tr>
<th>Percentiles</th>
<th>Smallest</th>
</tr>
</thead>
<tbody>
<tr>
<td>1%</td>
<td>27.1</td>
</tr>
<tr>
<td>5%</td>
<td>27.7</td>
</tr>
<tr>
<td>10%</td>
<td>28.2</td>
</tr>
<tr>
<td>25%</td>
<td>29.2</td>
</tr>
<tr>
<td>50%</td>
<td>29.9</td>
</tr>
<tr>
<td>75%</td>
<td>30.9</td>
</tr>
<tr>
<td>90%</td>
<td>32.1</td>
</tr>
<tr>
<td>95%</td>
<td>32.2</td>
</tr>
<tr>
<td>99%</td>
<td>34.7</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Statistics</th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td>Obs</td>
<td>50</td>
</tr>
<tr>
<td>Sum of Wgt.</td>
<td>225907472</td>
</tr>
<tr>
<td>Mean</td>
<td>30.11047</td>
</tr>
<tr>
<td>Std. Dev.</td>
<td>1.66933</td>
</tr>
<tr>
<td>Variance</td>
<td>2.786661</td>
</tr>
<tr>
<td>Skewness</td>
<td>.5281972</td>
</tr>
<tr>
<td>Kurtosis</td>
<td>4.494223</td>
</tr>
</tbody>
</table>
```

### Technical note

If you are writing a program and need to access the mean of a variable, the `meanonly` option provides for fast calls. For example, suppose that your program reads as follows:

```stata
program mean  
    summarize `1', meanonly  
    display " mean = " r(mean)  
end
```

The result of executing this is

```stata
. use https://www.stata-press.com/data/r16/auto2  
(1978 Automobile Data)  
. mean price  
    mean = 6165.2568
```
**Video example**

Descriptive statistics in Stata

**Stored results**

`summarize` stores the following in `r()`:

<table>
<thead>
<tr>

<td>kurtosis (detail only)</td>
</tr>
</tbody>
</table>

**Methods and formulas**

Let $x$ denote the variable on which we want to calculate summary statistics, and let $x_i$, $i = 1, \ldots, n$, denote an individual observation on $x$. Let $v_i$ be the weight, and if no weight is specified, define $v_i = 1$ for all $i$.

Define $V$ as the sum of the weight:

$$ V = \sum_{i=1}^{n} v_i $$

Define $w_i$ to be $v_i$ normalized to sum to $n$, $w_i = v_i(n/V)$.

The mean, $\bar{x}$, is defined as

$$ \overline{x} = \frac{1}{n} \sum_{i=1}^{n} w_i x_i $$

The variance, $s^2$, is defined as

$$ s^2 = \frac{1}{n-1} \sum_{i=1}^{n} w_i (x_i - \overline{x})^2 $$

The standard deviation, $s$, is defined as $\sqrt{s^2}$.

Define $m_r$ as the $r$th moment about the mean $\overline{x}$:

$$ m_r = \frac{1}{n} \sum_{i=1}^{n} w_i (x_i - \overline{x})^r $$

The coefficient of skewness is then defined as $m_3m_2^{-3/2}$. The coefficient of kurtosis is defined as $m_4m_2^{-2}$.

Let $x(i)$ refer to the $x$ in ascending order, and let $w(i)$ refer to the corresponding weights of $x(i)$. The four smallest values are $x(1)$, $x(2)$, $x(3)$, and $x(4)$. The four largest values are $x(n)$, $x(n-1)$, $x(n-2)$, and $x(n-3)$. 
To obtain the $p$th percentile, which we will denote as $x[p]$, let $P = np/100$. Let

$$W(i) = \sum_{j=1}^{i} w(j)$$

Find the first index $i$ such that $W(i) > P$. The $p$th percentile is then

$$x[p] = \begin{cases} 
\frac{x(i-1) + x(i)}{2} & \text{if } W(i-1) = P \\
\frac{x(i)}{2} & \text{otherwise}
\end{cases}$$

sunflower — Density-distribution sunflower plots

Description

sunflower draws density-distribution sunflower plots (Plummer and Dupont 2003). Dark sunflowers, light sunflowers, and marker symbols represent high-, medium-, and low-density regions of the data, respectively. These plots are useful for displaying bivariate data whose density is too great for conventional scatterplots to be effective.

Quick start

Density-distribution sunflower plot showing the relationship between x and y

```
sunflower y x
```

Set the center of the reference bin to x = 5 and y = 8

```
sunflower y x, xcenter(5) ycenter(8)
```

As above, but specify the width of the hexagonal bins to be 1.5

```
sunflower y x, xcenter(5) ycenter(8) binwidth(1.5)
```

As above, but set the minimum number of observations needed for a bin to be represented by a light sunflower to 4

```
sunflower y x, xcenter(5) ycenter(8) binwidth(1.5) light(4)
```

Use the s1color scheme

```
sunflower y x, scheme(s1color)
```

Specify that only the petals are shown and the hexagons are omitted

```
sunflower y x, flowersonly
```

Suppress display of the table

```
sunflower y x, notable
```

Menu

Graphics > Smoothing and densities > Density-distribution sunflower plot
## Syntax

```
sunflower  yvar  xvar  [if]  [in]  [weight]  [,  options]
```

</tr>
</tbody>
</table>

All options are rightmost; see [G-4] Concept: repeated options.
fweights are allowed; see [U] 11.1.6 weight.
Options

`nograph` prevents the graph from being generated.

`notable` prevents the summary table from being displayed. This option is implied when the `by()` option is specified.

`marker_options` affect the rendition of markers drawn at the plotted points, including their shape, size, color, and outline; see [G-3] marker_options.

`binwidth(#)` specifies the horizontal width of the hexagonal bins in the same units as `xvar`. By default,

\[
binwidth = \max(rbw, nbw)
\]

where

\[
rbw = \text{range of } xvar / 40
\]

\[
nbw = \text{range of } xvar / \max(1, nb)
\]

and

\[
nb = \text{int}(\min(\sqrt{n}), 10 \times \log10(n)))
\]

where

\[
n = \text{the number of observations in the dataset}
\]

`binar(#)` specifies the aspect ratio for the hexagonal bins. The height of the bins is given by

\[
binheight = binwidth \times # \times 2 / \sqrt{3}
\]

where `binheight` and `binwidth` are specified in the units of `yvar` and `xvar`, respectively. The default is `binar(r)`, where `r` results in the rendering of regular hexagons.

`bin_options` affect how the hexagonal bins are rendered.

`lbstyle(areastyle)` and `dbstyle(areastyle)` specify the look of the light and dark hexagonal bins, respectively. The options listed below allow you to change each attribute, but `lbstyle()` and `dbstyle()` provide the starting points. See [G-4] `areastyle` for a list of available area styles.

`lbcolor(colorstyle)` and `dbcolor(colorstyle)` specify one color to be used both to outline the shape and to fill the interior of the light and dark hexagonal bins, respectively. See [G-4] `colorstyle` for a list of color choices.

`lbfcolor(colorstyle)` and `dbfcolor(colorstyle)` specify the color to be used to fill the interior of the light and dark hexagonal bins, respectively. See [G-4] `colorstyle` for a list of color choices.

`lblstyle(linestyle)` and `dblstyle(linestyle)` specify the overall style of the line used to outline the area, which includes its pattern (solid, dashed, etc.), thickness, and color. The other options listed below allow you to change the line's attributes, but `lblstyle()` and `dblstyle()` are the starting points. See [G-4] `linestyle` for a list of choices.

`lbcolor(colorstyle)` and `dbcolor(colorstyle)` specify the color to be used to outline the light and dark hexagonal bins, respectively. See [G-4] `colorstyle` for a list of color choices.

**Remarks and examples**

A sunflower is several line segments of equal length, called petals, that radiate from a central point. There are two varieties of sunflowers: light and dark. Each petal of a light sunflower represents 1 observation. Each petal of a dark sunflower represents several observations. Dark and light sunflowers represent high- and medium-density regions of the data, and marker symbols represent individual observations in low-density regions.

sunflower divides the plane defined by the variables yvar and xvar into contiguous hexagonal bins. The number of observations contained within a bin determines how the bin will be represented.
• When there are fewer than light(#) observations in a bin, each point is plotted using the usual marker symbols in a scatterplot.

• Bins with at least light(#) but fewer than dark(#) observations are represented by a light sunflower. Each petal of a light sunflower represents one observation in the bin.

• Bins with at least dark(#) observations are represented by a dark sunflower. Each petal of a dark sunflower represents multiple observations.

See Dupont (2009, 87–92) for a discussion of sunflower plots and how to create them using Stata.

Example 1

Using the auto dataset, we want to examine the relationship between weight and mpg. To do that, we type

```
. use https://www.stata-press.com/data/r16/auto
(1978 Automobile Data)
. sunflower mpg weight, binwid(500) petalw(2) dark(8) scheme(s2color)
```

76 74
The three darkly shaded sunflowers immediately catch our eyes, indicating a group of eight cars that are heavy (nearly 4,000 pounds) and fuel inefficient and two groups of cars that get about 20 miles per gallon and weight in the neighborhood of 3,000 pounds, one with 10 cars and one with 8 cars. The lighter sunflowers with seven petals each indicate groups of seven cars that share similar weight and fuel economy characteristics. To obtain the number of cars in each group, we counted the number of petals in each flower and consulted the graph legend to see how many observations each petal represents.

Acknowledgments

We thank William D. Dupont and W. Dale Plummer Jr., both of the Department of Biostatistics at Vanderbilt University, who are the authors of the original sunflower command, for their assistance in producing this version.

References

**sureg** — Zellner’s seemingly unrelated regression

**Description**

`sureg` fits seemingly unrelated regression models (*Zellner 1962; Zellner and Huang 1962; Zellner 1963*). The acronyms SURE and SUR are often used for the estimator.

**Quick start**

Model of \( y_1 \) and \( y_2 \) as a function of \( x_1, x_2, \) and \( x_3 \)

\[
\text{sureg} \ (y_1 \ x_1 \ x_2 \ x_3) \ (y_2 \ x_1 \ x_2 \ x_3)
\]

Same as above

\[
\text{sureg} \ (y_1 \ y_2 = x_1 \ x_2 \ x_3)
\]

As above, but obtain small-sample statistics and use small-sample adjustment

\[
\text{sureg} \ (y_1 \ y_2 = x_1 \ x_2 \ x_3), \text{small dfk}
\]

Also perform Breusch–Pagan test

\[
\text{sureg} \ (y_1 \ y_2 = x_1 \ x_2 \ x_3), \text{small dfk corr}
\]

Model of \( y_1 \) as a function of \( x_1 \) and \( x_2 \) and \( y_2 \) as a function of \( x_2 \) and lag of \( x_2 \) using `tsset` data

\[
\text{sureg} \ (y_1 \ x_1 \ x_2) \ (y_2 \ x_2 \ L.x_2)
\]

**Menu**

Statistics > Linear models and related > Multiple-equation models > Seemingly unrelated regression
Syntax

Basic syntax

\[ \text{sureg (} \text{depvar}_1 \text{ varlist}_1 \text{) (} \text{depvar}_2 \text{ varlist}_2 \text{) \ldots (} \text{depvar}_N \text{ varlist}_N \text{)} \]
\[ \text{[if]} \ [\text{in}] \ [\text{weight}] \]

Full syntax

\[ \text{sureg ([} \text{eqname}_1 : \text{depvar}_1a \ [\text{depvar}_1b \ldots = ] \text{varlist}_1 \ [, \text{noconstant}])} \]
\[ (\text{[eqname}_2 : \text{depvar}_2a \ [\text{depvar}_2b \ldots = ] \text{varlist}_2 \ [, \text{noconstant}]) \]
\[ \ldots \]
\[ (\text{[eqname}_N : \text{depvar}_Na \ [\text{depvar}_Nb \ldots = ] \text{varlist}_N \ [, \text{noconstant}])} \]
\[ \text{[if]} \ [\text{in}] \ [\text{weight}] \ [, \text{options}] \]

Explicit equation naming (eqname:) cannot be combined with multiple dependent variables in an equation specification.

\begin{tabular}{ll}
\textbf{options} & \textbf{Description} \\
\hline
\textit{SURE} & iterate until estimates converge \\
\textit{constraints} & apply specified linear constraints \\
\textit{df adj.} & \\
\textit{small} & report small-sample statistics \\
\textit{dfk} & use small-sample adjustment \\
\textit{dfk2} & use alternate adjustment \\
\textit{Reporting} & \\
\textit{level(\#)} & set confidence level; default is \textit{level(95)} \\
\textit{corr} & perform Breusch–Pagan test \\
\textit{nocnsreport} & do not display constraints \\
\textit{display_options} & control columns and column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling \\
\textit{Optimization} & \\
\textit{optimization_options} & control the optimization process; seldom used \\
\textit{noheader} & suppress header table from above coefficient table \\
\textit{notable} & suppress coefficient table \\
\textit{coeflegend} & display legend instead of statistics \\
\end{tabular}

\textit{varlist}_1, \ldots, \textit{varlist}_N may contain factor variables; see [U] 11.4.3 Factor variables. You must have the same levels of factor variables in all equations that have factor variables.

\textit{depvars} and the \textit{varlists} may contain time-series operators; see [U] 11.4.4 Time-series varlists.

\textit{bootstrap}, \textit{by}, \textit{fp}, \textit{jackknife}, \textit{rolling}, and \textit{statsby} are allowed; see [U] 11.1.10 Prefix commands.
Weights are not allowed with the bootstrap prefix; see [R] bootstrap.
aweights are not allowed with the jackknife prefix; see [R] jackknife.
aweights and fweights are allowed; see [U] 11.1.6 weight.
noheader, notable, and coeflegend do not appear in the dialog box.
See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

Options

isure specifies that sureg iterate over the estimated disturbance covariance matrix and parameter estimates until the parameter estimates converge. Under seemingly unrelated regression, this iteration converges to the maximum likelihood results. If this option is not specified, sureg produces two-step estimates.

constraints(constraints); see [R] Estimation options.

df adj.
small specifies that small-sample statistics be computed. It shifts the test statistics from chi-squared and z statistics to F statistics and t statistics. Although the standard errors from each equation are computed using the degrees of freedom for the equation, the degrees of freedom for the t statistics are all taken to be those for the first equation.

dfk specifies the use of an alternative divisor in computing the covariance matrix for the equation residuals. As an asymptotically justified estimator, sureg by default uses the number of sample observations (n) as a divisor. When the dfk option is set, a small-sample adjustment is made and the divisor is taken to be \(\sqrt{(n - k_i)(n - k_j)}\), where \(k_i\) and \(k_j\) are the number of parameters in equations \(i\) and \(j\), respectively.

dfk2 specifies the use of an alternative divisor in computing the covariance matrix for the equation residuals. When the dfk2 option is set, the divisor is taken to be the mean of the residual degrees of freedom from the individual equations.

level(#); see [R] Estimation options.
corr displays the correlation matrix of the residuals between equations and performs a Breusch–Pagan test for independent equations; that is, the disturbance covariance matrix is diagonal.
nocnsreport; see [R] Estimation options.

display_options: noci, nopvalues, noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fwrap(#), fvwrapon(style), cformat(%,fmt), pformat(%,fmt), sformat(%,fmt), and nolstretch; see [R] Estimation options.

optimization_options control the iterative process that minimizes the sum of squared errors when isure is specified. These options are seldom used.

iterate(#) specifies the maximum number of iterations. When the number of iterations equals #, the optimizer stops and presents the current results, even if the convergence tolerance has not been reached. The default value of iterate() is the current value of set maxiter, which is iterate(16000) if maxiter has not been changed.
trace adds to the iteration log a display of the current parameter vector log and nolog specify whether to display the iteration log. The iteration log is displayed by default unless you used set iterlog off to suppress it; see set iterlog in [R] set iter. tolerance(#) specifies the tolerance for the coefficient vector. When the relative change in the coefficient vector from one iteration to the next is less than or equal to #, the optimization process is stopped. tolerance(1e-6) is the default.

The following options are available with sureg but are not shown in the dialog box:

- noheader suppresses display of the header reporting $F$ statistics, $R$-squared, and root mean squared error above the coefficient table.
- notable suppresses display of the coefficient table.
- coeflegend; see [R] Estimation options.

Remarks and examples

Seemingly unrelated regression models are so called because they appear to be joint estimates from several regression models, each with its own error term. The regressions are related because the (contemporaneous) errors associated with the dependent variables may be correlated. Chapter 5 of Cameron and Trivedi (2010) contains a discussion of the seemingly unrelated regression model and the feasible generalized least-squares estimator underlying it.

Example 1

When we fit models with the same set of right-hand-side variables, the seemingly unrelated regression results (in terms of coefficients and standard errors) are the same as fitting the models separately (using, say, regress). The same is true when the models are nested. Even in such cases, sureg is useful when we want to perform joint tests. For instance, let us assume that we think

\[
\text{price} = \beta_0 + \beta_1 \text{foreign} + \beta_2 \text{length} + u_1 \\
\text{weight} = \gamma_0 + \gamma_1 \text{foreign} + \gamma_2 \text{length} + u_2
\]

Because the models have the same set of explanatory variables, we could estimate the two equations separately. Yet, we might still choose to estimate them with sureg because we want to perform the joint test $\beta_1 = \gamma_1 = 0$. 

We use the small and dfk options to obtain small-sample statistics comparable with regress or mvreg.

```stata
. use https://www.stata-press.com/data/r16/auto
   (1978 Automobile Data)
. sureg (price foreign length) (weight foreign length), small dfk
```

Seemingly unrelated regression

<table>
<thead>
<tr>

<th>RMSE</th>
<th>&quot;R-sq&quot;</th>
<th>F-Stat</th>
<th>P</th>
</tr>
</thead>
<tbody>
<tr>
<td>price</td>
<td>74</td>
<td>2</td>
<td>2474.593</td>
<td>0.3154</td>
<td>16.35</td>
<td>0.0000</td>
</tr>
<tr>
<td>weight</td>
<td>74</td>
<td>2</td>
<td>250.2515</td>
<td>0.8992</td>
<td>316.54</td>
<td>0.0000</td>
</tr>
</tbody>
</table>

| price      | Coef.  | Std. Err. | t   | P>|t| | [95% Conf. Interval] |
|------------|--------|------------|-----|------|---------------------|
| foreign    | 2801.143 | 766.117   | 3.66 | 0.000 | 1286.674 - 4315.611 |
| length     | 90.21239 | 15.83368  | 5.70 | 0.000 | 58.91219 - 121.5126 |
| _cons      | -11621.35 | 3124.436  | -3.72 | 0.000 | -17797.77 - 5444.93 |

| weight     | Coef.  | Std. Err. | t   | P>|t| | [95% Conf. Interval] |
|------------|--------|------------|-----|------|---------------------|
| foreign    | -133.6775 | 77.47615  | -1.73 | 0.087 | -286.8332 - 19.4782 |
| length     | 31.44455 | 1.601234  | 19.64 | 0.000 | 28.27921 - 34.60989 |
| _cons      | -2850.25 | 315.9691  | -9.02 | 0.000 | -3474.861 - 2225.639 |

These two equations have a common set of regressors, and we could have used a shorthand syntax to specify the equations:

```stata
. sureg (price weight = foreign length), small dfk
```

Here the results presented by sureg are the same as if we had estimated the equations separately:

```stata
. regress price foreign length
   (output omitted)
. regress weight foreign length
   (output omitted)
```

There is, however, a difference. We have allowed \( u_1 \) and \( u_2 \) to be correlated and have estimated the full variance–covariance matrix of the coefficients. sureg has estimated the correlations, but it does not report them unless we specify the corr option. We did not remember to specify corr when we fit the model, but we can redisplay the results:

```stata
. sureg, notable noheader corr
```

Correlation matrix of residuals:

<table>
<thead>
<tr>
<th></th>
<th>price</th>
<th>weight</th>
</tr>
</thead>
<tbody>
<tr>
<td>price</td>
<td>1.0000</td>
<td></td>
</tr>
<tr>
<td>weight</td>
<td>0.5840</td>
<td>1.0000</td>
</tr>
</tbody>
</table>

Breusch-Pagan test of independence: chi2(1) = 25.237, Pr = 0.0000

The notable and noheader options prevented sureg from redisplaying the header and coefficient tables. We find that, for the same cars, the correlation of the residuals in the price and weight equations is 0.5840 and that we can reject the hypothesis that this correlation is zero.

We can test that the coefficients on foreign are jointly zero in both equations—as we set out to do—by typing test foreign; see [R] test. When we type a variable without specifying the equation, that variable is tested for zero in all equations in which it appears:
Example 2

When the models do not have the same set of explanatory variables and are not nested, `sureg` may lead to more efficient estimates than running the models separately as well as allowing joint tests. This time, let us assume that we believe

\[
\text{price} = \beta_0 + \beta_1 \text{foreign} + \beta_2 \text{mpg} + \beta_3 \text{displ} + u_1
\]

\[
\text{weight} = \gamma_0 + \gamma_1 \text{foreign} + \gamma_2 \text{length} + u_2
\]

To fit this model, we type

```
sureg (price foreign mpg displ) (weight foreign length), corr
```

</tr>
<tr>
<td>Total</td>
<td>635065396</td>
<td>73</td>
<td>8699525.97</td>
<td>R-squared = 0.4631</td>
</tr>
</tbody>
</table>

| price       | Coef. | Std. Err. | t   | P>|t|    | [95% Conf. Interval] |
|-------------|-------|-----------|-----|--------|----------------------|
| foreign     | 3545.484 | 712.7763  | 4.97| 0.000  | 2123.897 4967.072    |
| mpg         | -98.88559 | 63.17063  | -1.57| 0.122  | -224.8754 27.10426   |
| displacement| 22.40416 | 4.634239  | 4.83| 0.000  | 13.16146 31.64686    |
| _cons       | 2796.91  | 2137.873  | 1.31| 0.195  | -1466.943 7060.763   |

The coefficients are slightly different, but the standard errors are uniformly larger. This would still be true if we specified the dfk option to make a small-sample adjustment to the estimated covariance of the disturbances.

- Technical note

Constraints can be applied to SURE models using Stata’s standard syntax for constraints. For a general discussion of constraints, see [R] constraint; for examples similar to seemingly unrelated regression models, see [R] reg3.

- Stored results

sureg stores the following in e():

Scalars
- e(N) number of observations
- e(k) number of parameters
- e(k_eq) number of equations in e(b)
- e(mss_) model sum of squares for equation #
- e(df_m#) model degrees of freedom for equation #
- e(rss_) residual sum of squares for equation #
- e(df_r) residual degrees of freedom
- e(r2_#) R-squared for equation #
- e(F_#) F statistic for equation # (small only)
- e(rmse_) root mean squared error for equation #
- e(dfk2_adj) divisor used with VCE when dfk2 specified
- e(ll) log likelihood
- e(chi2_) \( \chi^2 \) for equation #
- e(p_) p-value for equation #
- e(cons_) 1 if equation # has a constant, 0 otherwise
- e(chi2_bp) Breusch–Pagan \( \chi^2 \)
- e(df_bp) degrees of freedom for Breusch–Pagan \( \chi^2 \) test
- e(rank) rank of e(V)
- e(ic) number of iterations
Methods and formulas

`sureg` uses the asymptotically efficient, feasible, generalized least-squares algorithm described in Greene (2018, 328–339). The computing formulas are given on page 328–335.

The $R$-squared reported is the percent of variance explained by the predictors. It may be used for descriptive purposes, but $R$-squared is not a well-defined concept when GLS is used.

`sureg` will refuse to compute the estimators if the same equation is named more than once or the covariance matrix of the residuals is singular.

The Breusch and Pagan (1980) $\chi^2$ statistic—a Lagrange multiplier statistic—is given by

$$\lambda = T \sum_{m=1}^{M} \sum_{n=1}^{m-1} r_{mn}^2$$

where $r_{mn}$ is the estimated correlation between the residuals of the $M$ equations and $T$ is the number of observations. It is distributed as $\chi^2$ with $M(M-1)/2$ degrees of freedom.

Arnold Zellner (1927–2010) was born in New York. He studied physics at Harvard and economics at Berkeley, and then he taught economics at the Universities of Washington and Wisconsin before settling in Chicago in 1966. Among his many major contributions to econometrics and statistics are his work on seemingly unrelated regression, three-stage least squares, and Bayesian econometrics.

**predict**

**Description for predict**

`predict` creates a new variable containing predictions such as linear predictions, standard errors, residuals, and differences between the linear predictions.

**Menu for predict**

Statistics  >  Postestimation

**Syntax for predict**

```
predict [type] newvar [if] [in] [, equation(eqno[,eqno]) statistic]
```

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>xb</td>
<td>linear prediction; the default</td>
</tr>
<tr>
<td>stdp</td>
<td>standard error of the linear prediction</td>
</tr>
<tr>
<td>residuals</td>
<td>residuals</td>
</tr>
<tr>
<td>difference</td>
<td>difference between the linear predictions of two equations</td>
</tr>
<tr>
<td>stddp</td>
<td>standard error of the difference in linear predictions</td>
</tr>
</tbody>
</table>

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

**Options for predict**

- `equation(eqno[,eqno])` specifies to which equation(s) you are referring.

  `equation()` is filled in with one `eqno` for the `xb`, `stdp`, and `residuals` options. `equation(#1)` would mean that the calculation is to be made for the first equation, `equation(#2)` would mean the second, and so on. You could also refer to the equations by their names. `equation(income)` would refer to the equation named income and `equation(hours)` to the equation named hours.

  If you do not specify `equation()`, the results are the same as if you specified `equation(#1)`. `difference` and `stddp` refer to between-equation concepts. To use these options, you must specify two equations, for example, `equation(#1,#2)` or `equation(income,hours)`. When two equations must be specified, `equation()` is required.

- `xb`, the default, calculates the linear prediction (fitted values)—the prediction of $x_j b$ for the specified equation.

- `stdp` calculates the standard error of the prediction for the specified equation. It can be thought of as the standard error of the predicted expected value or mean for the observation’s covariate pattern. The standard error of the prediction is also referred to as the standard error of the fitted value.

- `residuals` calculates the residuals.
difference calculates the difference between the linear predictions of two equations in the system.

With equation(#1,#2), difference computes the prediction of equation(#1) minus the prediction of equation(#2).

stddp is allowed only after you have previously fit a multiple-equation model. The standard error of the difference in linear predictions \((x_{1j}b - x_{2j}b)\) between equations 1 and 2 is calculated.

For more information on using predict after multiple-equation estimation commands, see [R] predict.

**margins**

**Description for margins**

margins estimates margins of response for linear predictions and differences between the linear predictions.

**Menu for margins**

Statistics > Postestimation

**Syntax for margins**

\[
\text{margins} \quad \text{[marginlist]} \quad \text{[, options]}
\]

\[
\text{margins} \quad \text{[marginlist]} \quad \text{, predict(statistic ...)} \quad \text{[predict(statistic ...) ...]} \quad \text{[options]}
\]

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>default</td>
<td>linear predictions for each equation</td>
</tr>
<tr>
<td>xb</td>
<td>linear prediction for a specified equation</td>
</tr>
<tr>
<td>difference</td>
<td>difference between the linear predictions of two equations</td>
</tr>
<tr>
<td>stdp</td>
<td>not allowed with margins</td>
</tr>
<tr>
<td>residuals</td>
<td>not allowed with margins</td>
</tr>
<tr>
<td>stddp</td>
<td>not allowed with margins</td>
</tr>
</tbody>
</table>

xb defaults to the first equation.

Statistics not allowed with margins are functions of stochastic quantities other than \(e(b)\).

For the full syntax, see [R] margins.
Remarks and examples

For an example of cross-equation testing of parameters using the `test` command, see example 1 in [R] `sureg`.

Example 1

In example 1 of [R] `sureg`, we fit a seemingly unrelated regressions model of `price` and `weight`. Here we obtain the fitted values.

```
. use https://www.stata-press.com/data/r16/auto
   (1978 Automobile Data)
. sureg (price foreign length) (weight foreign length), small dfk
   (output omitted)
. predict phat, equation(price)
   (option `xb' assumed; fitted values)
. predict what, equation(weight)
   (option `xb' assumed; fitted values)
. summarize price phat weight what
```

<table>

Just as in single-equation OLS regression, in a SURE model the sample mean of the fitted values for an equation equals the sample mean of the dependent variable.

Example 2

Suppose that for whatever reason we were interested in the difference between the predicted values of `price` and `weight`. `predict` has an option to compute this difference in one step:

```
. predict diff, equation(price, weight) difference
```

diff is the same as `phat - what`:

```
. generate mydiff = phat - what
. summarize diff mydiff
```

<table>

[U] 20 Estimation and postestimation commands
swilk — Shapiro–Wilk and Shapiro–Francia tests for normality

Description
swilk performs the Shapiro–Wilk $W$ test for normality for each variable in the specified varlist. Likewise, sfrancia performs the Shapiro–Francia $W'$ test for normality. See [MV] mvtest normality for multivariate tests of normality.

Quick start

Shapiro–Wilk test of normality
Shapiro–Wilk test for v1
swilk v1
Separate tests of normality for v1 and v2
swilk v1 v2
Generate new variable w containing $W$ test coefficients
swilk v1, generate(w)
Specify that average ranks should not be used for tied values
swilk v1 v2, noties
Test that v3 is distributed lognormally
generate lnv3 = ln(v3)
swilk lnv3

Shapiro–Francia test of normality
Shapiro–Francia test for v1
sfrancia v1
Separate tests of normality for v1 and v2
sfrancia v1 v2
As above, but use the Box–Cox transformation
sfrancia v1 v2, boxcox
Specify that average ranks should not be used for tied values
sfrancia v1 v2, noties

</tbody>
</table>

by is allowed with `swilk` and `sfrancia`; see [D] by.

Options for `swilk`

```
generate(newvar) | creates new variable `newvar` containing the `W` test coefficients.
lnnormal | specifies that the test be for three-parameter lognormality, meaning that \( \ln(X - k) \) is tested for normality, where \( k \) is calculated from the data as the value that makes the skewness coefficient zero. When simply testing \( \ln(X) \) for normality, do not specify this option. See [R] lnskew0 for estimation of \( k \).
noties | suppresses use of averaged ranks for tied values when calculating the `W` test coefficients.
```
**Options for sfrancia**

`boxcox` specifies that the Box–Cox transformation of Royston (1983) for calculating $W'$ test coefficients be used instead of the default log transformation (Royston 1993a). Under the Box–Cox transformation, the normal approximation to the sampling distribution of $W'$, used by `sfrancia`, is valid for $5 \leq n \leq 1000$. Under the log transformation, it is valid for $10 \leq n \leq 5000$.

`noties` suppresses use of averaged ranks for tied values when calculating the $W'$ test coefficients.

**Remarks and examples**

`swwilk` can be used with $4 \leq n \leq 2000$ observations. `sfrancia` can be used with $10 \leq n \leq 5000$ observations; however, if the `boxcox` option is specified, it can be used with $5 \leq n \leq 1000$ observations.

Also see [R] `sktest` for the skewness and kurtosis test described by D’Agostino, Belanger, and D’Agostino (1990) with the empirical correction developed by Royston (1991b). While the Shapiro–Wilk and Shapiro–Francia tests for normality are, in general, preferred for nonaggregated data (Gould and Rogers 1991; Gould 1992b; Royston 1991b), the skewness and kurtosis test will permit more observations. Moreover, a normal quantile plot should be used with any test for normality; see [R] *Diagnostic plots* for more information.

> **Example 1**

Using our automobile dataset, we will test whether the variables `mpg` and `trunk` are normally distributed:

```
. use https://www.stata-press.com/data/r16/auto
   (1978 Automobile Data)
. swilk mpg trunk
   Shapiro-Wilk W test for normal data
   Variable |   Obs  W    V   z  Prob>|z|
-------------+--------+--------+------------------------+----------
      mpg |    74 0.94821 3.335 2.627  0.00430
      trunk |    74 0.97921 1.339 0.637  0.26215
. sfrancia mpg trunk
   Shapiro-Francia W' test for normal data
   Variable |   Obs  W'   V'   z  Prob>|z|
-------------+--------+--------+--------+----------+----------
      mpg |    74 0.94872 3.650 2.510  0.00604
      trunk |    74 0.98446 1.106 0.195  0.42271
```

We can reject the hypothesis that `mpg` is normally distributed, but we cannot reject that `trunk` is normally distributed.

The values reported under $W$ and $W'$ are the Shapiro–Wilk and Shapiro–Francia test statistics. The tests also report $V$ and $V'$, which are more appealing indexes for departure from normality. The median values of $V$ and $V'$ are 1 for samples from normal populations. Large values indicate nonnormality. The 95% critical values of $V$ ($V'$), which depend on the sample size, are between 1.2 and 2.4 (2.0 and 2.8); see Royston (1991d). There is no more information in $V$ ($V'$) than in $W$ ($W'$)—one is just the transform of the other.
Example 2

We have data on a variable called `studytime`, which we suspect is distributed lognormally:

```
use https://www.stata-press.com/data/r16/cancer
(Patient Survival in Drug Trial)
generate lnstudytime = ln(studytime)
swilk lnstudytime
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>W</th>
<th>V</th>
<th>z</th>
<th>Prob&gt;z</th>
</tr>
</thead>
<tbody>
<tr>
<td>lnstudytime</td>
<td>48</td>
<td>0.92731</td>
<td>3.311</td>
<td>2.547</td>
<td>0.00543</td>
</tr>
</tbody>
</table>

We can reject the lognormal assumption. We do not specify the `lnnormal` option when testing for lognormality. The `lnnormal` option is for three-parameter lognormality.

Example 3

Having discovered that `ln(studytime)` is not distributed normally, we now test that `ln(studytime + k)` is normally distributed, where `k` is chosen so that the resulting skewness is zero. We obtain the estimate for `k` from `lnskew0`; see [R] `lnskew0`:

```
lnskew0 lnstudytimek = studytime, level(95)
```

<table>
<thead>
<tr>
<th>Transform</th>
<th>k</th>
<th>[95% Conf. Interval]</th>
<th>Skewness</th>
</tr>
</thead>
<tbody>
<tr>
<td>ln(studytime-k)</td>
<td>-11.01181</td>
<td>-infinity</td>
<td>-.9477328</td>
</tr>
</tbody>
</table>

```
swilk lnstudytimek, lnnormal
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>W</th>
<th>V</th>
<th>z</th>
<th>Prob&gt;z</th>
</tr>
</thead>
<tbody>
<tr>
<td>lnstudytimek</td>
<td>48</td>
<td>0.97064</td>
<td>1.337</td>
<td>1.261</td>
<td>0.10363</td>
</tr>
</tbody>
</table>

We cannot reject the hypothesis that `ln(studytime + 11.01181)` is distributed normally. We do specify the `lnnormal` option when using an estimated value of `k`.

Stored results

`swilk` and `sfrancia` store the following in `r()`:

Scalars
- `r(N)` number of observations
- `r(p)` p-value
- `r(z)` z statistic
- `r(W)` W or W′
- `r(V)` V or V′

Methods and formulas

The Shapiro–Francia test (Shapiro and Francia 1972; Royston 1983; Royston 1993a) is an approximate test that is similar to the Shapiro–Wilk test for very large samples.

The relative merits of the Shapiro–Wilk and Shapiro–Francia tests the versus skewness and kurtosis test have been a subject of debate. The interested reader is directed to the articles in the Stata Technical Bulletin. Our recommendation is to use the Shapiro–Francia test whenever possible, that is, whenever dealing with nonaggregated or ungrouped data (Gould and Rogers 1991; Gould 1992b); see [R] swilk. If normality is rejected, use sktest to determine the source of the problem. As both D’Agostino, Belanger, and D’Agostino (1990) and Royston (1991c) mention, researchers should also examine the normal quantile plot to determine normality rather than blindly relying on a few test statistics. See the qnorm command documented in [R] Diagnostic plots for more information on normal quantile plots.

Samuel Sanford Shapiro (1930– ) earned degrees in statistics and engineering from City College of New York, Columbia, and Rutgers. After employment in the U.S. Army and industry, he joined the faculty at Florida International University in 1972. Shapiro has coauthored various texts in statistics and published several papers on distributional testing and other statistical topics.

Acknowledgment

swilk and sfrancia were written by Patrick Royston of the MRC Clinical Trials Unit, London and coauthor of the Stata Press book Flexible Parametric Survival Analysis Using Stata: Beyond the Cox Model.

**Description**

`symmetry` performs asymptotic symmetry and marginal homogeneity tests, as well as an exact symmetry test on $K \times K$ tables where there is a 1-to-1 matching of cases and controls (nonindependence). This testing is used to analyze matched-pair case–control data with multiple discrete levels of the exposure (outcome) variable. In genetics, the test is known as the transmission/disequilibrium test (TDT) and is used to test the association between transmitted and nontransmitted parental marker alleles to an affected child (Spieldman, McGinnis, and Ewens 1993). For $2 \times 2$ tables, the asymptotic test statistics reduce to the McNemar test statistic, and the exact symmetry test produces an exact McNemar test; see [R] Epitab. For many exposure variables, `symmetry` can optionally perform a test for linear trend in the log relative risk.

`symmetry` expects the data to be in the wide format; that is, each observation contains the matched case and control values in variables `casevar` and `controlvar`. Variables can be numeric or string.

`symmi` is the immediate form of `symmetry`. The `symmi` command uses the values specified on the command line; rows are separated by '\\', and options are the same as for `symmetry`. See [U] 19 Immediate commands for a general introduction to immediate commands.

fweights are allowed; see [U] 11.1.6 weight.

Options

notable suppresses the output of the contingency table. By default, symmetry displays the $n \times n$ contingency table at the top of the output.

contrib reports the contribution of each off-diagonal cell pair to the overall symmetry $\chi^2$.

effect performs an exact test of table symmetry. This option is recommended for sparse tables.

CAUTION: The exact test requires substantial amounts of time and memory for large tables.

mh performs two marginal homogeneity tests that do not require the inversion of the variance–covariance matrix.

By default, symmetry produces the Stuart–Maxwell test statistic, which requires the inversion of the nondiagonal variance–covariance matrix, $V$. When the table is sparse, the matrix may not be of full rank, and then the command substitutes a generalized inverse $V^*$ for $V^{-1}$. mh calculates optional marginal homogeneity statistics that do not require the inversion of the variance–covariance matrix. These tests may be preferred in certain situations. See Methods and formulas and Bickebøller and Clerget-Darpoux (1995) for details on these test statistics.
trend performs a test for linear trend in the (log) relative risk (RR). This option is allowed only for numeric exposure (outcome) variables, and its use should be restricted to measurements on the ordinal or the interval scales.

cc specifies that the continuity correction be used when calculating the test for linear trend. This correction should be specified only when the levels of the exposure variable are equally spaced.

Remarks and examples

symmetry and symmi may be used to analyze 1-to-1 matched case–control data with multiple discrete levels of the exposure (outcome) variable.

Example 1

Consider a survey of 344 individuals (BMDP 1990, 267–270) who were asked in October 1986 whether they agreed with President Reagan’s handling of foreign affairs. In January 1987, after the Iran-Contra affair became public, these same individuals were surveyed again and asked the same question. We would like to know if public opinion changed over this period.

We first describe the dataset and list a few observations.

```
. use https://www.stata-press.com/data/r16/iran
. describe
Contains data from https://www.stata-press.com/data/r16/iran.dta
    obs:             344    29 Jan 2018 02:37
  vars:              2

storage  display value
variable name      type    format   label      variable label
before             byte    %8.0g   vlab        Public Opinion before IC
after              byte    %8.0g   vlab        Public Opinion after IC
```

Sorted by:

```
. list in 1/5
  before  after
    1.  agree  agree
    2.  agree  disagree
    3.  agree  unsure
    4.  disagree  agree
    5.  disagree  disagree
```

Each observation corresponds to one of the 344 individuals. The data are in wide form so that each observation has a before and an after measurement. We now perform the test without options.
The test first tabulates the data in a $K \times K$ table and then performs Bowker’s (1948) test for table symmetry and the Stuart–Maxwell (Stuart 1955; Maxwell 1970) test for marginal homogeneity.

Both the symmetry test and the marginal homogeneity test are highly significant, thus indicating a shift in public opinion.

An exact test of symmetry is provided for use on sparse tables. This test is computationally intensive, so it should not be used on large tables. Because we are working on a fast computer, we will run the symmetry test again and this time include the exact option. We will suppress the output of the contingency table by specifying notable and include the contrib option so that we may further examine the cells responsible for the significant result.

The largest contribution to the symmetry $\chi^2$ is due to cells $n_{12}$ and $n_{21}$. These correspond to changes between the agree and disagree categories. Of the 344 individuals, 56 (16.3%) changed from the agree to the disagree response, whereas only 28 (8.1%) changed in the opposite direction.

For these data, the results from the exact test are similar to those from the asymptotic test.
Example 2

Breslow and Day (1980, 163) reprinted data from Mack et al. (1976) from a case–control study of the effect of exogenous estrogen on the risk of endometrial cancer. The data consist of 59 elderly women diagnosed with endometrial cancer and 59 disease-free control subjects living in the same community as the cases. Cases and controls were matched on age, marital status, and time living in the community. The data collected included information on the daily dose of conjugated estrogen therapy. Breslow and Day analyzed these data by creating four levels of the dose variable. Here are the data as entered into a Stata dataset:

```stata
use https://www.stata-press.com/data/r16/bd163
list, noobs divider
```

<table>

</tr>
</tbody>
</table>

This dataset is in a different format from that of the previous example. Instead of each observation representing one matched pair, each observation represents possibly multiple pairs indicated by the `count` variable. For instance, the first observation corresponds to six matched pairs where neither the case nor the control was on estrogen, the second observation corresponds to two matched pairs where the case was not on estrogen and the control was on 0.1 to 0.299 mg/day, etc.

To use `symmetry` to analyze this dataset, we must specify `fweight` to indicate that in our data there are observations corresponding to more than one matched pair.

chi2     df  Prob>chi2

Symmetry (asymptotic)  17.10  6  0.0089
Marginal homogeneity (Stuart-Maxwell)  16.96  3  0.0007

Both the test of symmetry and the test of marginal homogeneity are highly significant, thus leading us to reject the null hypothesis that there is no effect of exposure to estrogen on the risk of endometrial cancer.

Breslow and Day perform a test for trend assuming that the estrogen exposure levels were equally spaced by recoding the exposure levels as 1, 2, 3, and 4.

We can easily reproduce their results by recoding our data in this way and by specifying the trend option. Two new numeric variables were created, ca and co, corresponding to the variables case and control, respectively. Below we list some of the data and our results from symmetry:

. encode case, gen(ca)
. encode control, gen(co)
. label values ca
. label values co
. list in 1/4

<table>
<thead>
<tr>
<th>case</th>
<th>control</th>
<th>count</th>
<th>ca</th>
<th>co</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>0</td>
<td>0</td>

</tr>
<tr>
<td>4</td>
<td>0</td>
<td>0.626+</td>
<td>1</td>
<td>1</td>
</tr>
</tbody>
</table>

. symmetry ca co [fw=count], notable trend cc

chi2     df  Prob>chi2

Symmetry (asymptotic)  17.10  6  0.0089
Marginal homogeneity (Stuart-Maxwell)  16.96  3  0.0007

Linear trend in the (log) RR  14.43  1  0.0001

We requested the continuity correction by specifying cc. Doing so is appropriate because our coded exposure levels are equally spaced.

The test for trend was highly significant, indicating an increased risk of endometrial cancer with increased dosage of conjugated estrogen.

You must be cautious: the way in which you code the exposure variable affects the linear trend statistic. If instead of coding the levels as 1, 2, 3, and 4, we had instead used 0, 0.2, 0.46, and 0.7
(roughly the midpoint in the range of each level), we would have obtained a $\chi^2$ statistic of 11.19 for these data.

Stored results

`symmetry` stores the following in `r()`:

Scalars
- `r(N_pair)` number of matched pairs
- `r(df)` asymptotic symmetry $\chi^2$
- `r(p)` asymptotic symmetry $p$-value
- `r(chi2_sm)` MH (Stuart–Maxwell) $\chi^2$
- `r(df_sm)` MH (Stuart–Maxwell) degrees of freedom
- `r(p_sm)` MH (Stuart–Maxwell) $p$-value
- `r(chi2_b)` MH (Bickenb¨oller) $\chi^2$
- `r(df_b)` MH (Bickenb¨oller) degrees of freedom
- `r(p_b)` MH (Bickenb¨oller) $p$-value
- `r(chi2_nd)` MH (no diagonals) $\chi^2$
- `r(df_nd)` MH (no diagonals) degrees of freedom
- `r(p_nd)` MH (no diagonals) $p$-value
- `r(chi2_t)` $\chi^2$ for linear trend
- `r(p_trend)` $p$-value for linear trend
- `r(p_exact)` exact symmetry $p$-value

Methods and formulas

Methods and formulas are presented under the following headings:

Asymptotic tests

Exact symmetry test

Asymptotic tests

Consider a square table with $K$ exposure categories, that is, $K$ rows and $K$ columns. Let $n_{ij}$ be the count corresponding to row $i$ and column $j$ of the table, $N_{ij} = n_{ij} + n_{ji}$, for $i, j = 1, 2, \ldots, K$, and $n_{i.}$, and let $n_{.j}$ be the marginal totals for row $i$ and column $j$, respectively. Asymptotic tests for symmetry and marginal homogeneity for this $K \times K$ table are calculated as follows:

The null hypothesis of complete symmetry $p_{ij} = p_{ji}$, $i \neq j$, is tested by calculating the test statistic (Bowker 1948)

$$T_{cs} = \sum_{i<j} \frac{(n_{ij} - n_{ji})^2}{n_{ij} + n_{ji}}$$

which is asymptotically distributed as $\chi^2$ with $K(K-1)/2 - R$ degrees of freedom, where $R$ is the number of off-diagonal cells with $N_{ij} = 0$. 
The null hypothesis of marginal homogeneity, $p_i. = p_.i$, is tested by calculating the Stuart–Maxwell test statistic (Stuart 1955; Maxwell 1970),

$$T_{sm} = d'V^{-1}d$$

where $d$ is a column vector with elements equal to the differences $d_i = n_i. - n_.i$ for $i = 1, 2, \ldots, K$, and $V$ is the variance–covariance matrix with elements

$$v_{ii} = n_i. + n_.i - 2n_{ii},$$
$$v_{ij} = -(n_{ij} + n_{ji}), \quad i \neq j$$

$T_{sm}$ is asymptotically $\chi^2$ with $K - 1$ degrees of freedom.

This test statistic properly accounts for the dependence between the table’s rows and columns. When the matrix $V$ is not of full rank, a generalized inverse $V^*$ is substituted for $V^{-1}$.

The Bickebøller and Clerget-Darpoux (1995) marginal homogeneity test statistic is calculated by

$$T_{mh}^0 = \sum_i \frac{(n_i. - n_.i)^2}{n_i. + n_.i}$$

This statistic is asymptotically distributed, under the assumption of marginal independence, as $\chi^2$ with $K - 1$ degrees of freedom.

The marginal homogeneity (no diagonals) test statistic $T_{mh}^0$ is calculated in the same way as $T_{mh}$, except that the diagonal elements do not enter into the calculation of the marginal totals. Unlike the previous test statistic, $T_{mh}^0$ reduces to a McNemar test statistic for $2 \times 2$ tables. The test statistic $\{(K - 1)/2\}T_{mh}^0$ is asymptotically distributed as $\chi^2$ with $K - 1$ degrees of freedom (Cleves, Olson, and Jacobs 1997; Spieldman and Ewens 1996).

Breslow and Day’s test statistic for linear trend in the (log) of RR is

$$\frac{\left\{\sum_{i<j}(n_{ij} - n_{ji})(X_j - X_i) - cc\right\}^2}{\sum_{i<j}(n_{ij} + n_{ji})(X_j - X_i)^2}$$

where the $X_j$ are the doses associated with the various levels of exposure and $cc$ is the continuity correction; it is asymptotically distributed as $\chi^2$ with 1 degree of freedom.

The continuity correction option is applicable only when the levels of the exposure variable are equally spaced.

**Exact symmetry test**

The exact test is based on a permutation algorithm applied to the null distribution. The distribution of the off-diagonal elements $n_{ij}, i \neq j$, conditional on the sum of the complementary off-diagonal cells, $N_{ij} = n_{ij} + n_{ji}$, can be written as the product of $K(K - 1)/2$ binomial random variables,

$$P(n) = \prod_{i<j} \binom{N_{ij}}{n_{ij}} \pi_{ij}^{n_{ij}} (1 - \pi_{ij})^{n_{ij}}$$

where $n$ is a vector with elements $n_{ij}$ and $\pi_{ij} = E(n_{ij}/N_{ij}|N_{ij})$. Under the null hypothesis of complete symmetry, $\pi_{ij} = \pi_{ji} = 1/2$, and thus the permutation distribution is given by
\[ P_0(n) = \prod_{i<j} \left( \frac{N_{ij}}{n_{ij}} \right) \left( \frac{1}{2} \right)^{N_{ij}} \]

The exact significance test is performed by evaluating

\[ P_{cs} = \sum_{n \in \mathcal{P}} P_0(n) \]

where \( p = \{ n : P_0(n) < P_0(n^*) \} \) and \( n^* \) is the observed contingency table data vector. The algorithm evaluates \( p_{cs} \) exactly. For information about permutation tests, see Good (2005, 2006).

Description
table calculates and displays tables of statistics.

Quick start
Table of number of nonmissing observations in each category of catvar1 by catvar2
table catvar1 catvar2
Add supercolumns defined by catvar3 and superrows defined by catvar4
table catvar1 catvar2 catvar3, by(catvar4)
Table of mean and SD of v1 for each combination of catvar1 and catvar2
table catvar1 catvar2, contents(mean v1 sd v1)
Add total row showing mean and SD of v1 for each value of catvar2
table catvar1 catvar2, contents(mean v1 sd v1) row
Add total column showing mean and SD of v1 for each value of catvar1
table catvar1 catvar2, contents(mean v1 sd v1) by(catvar3) row col
25th, 50th, and 75th percentiles of v1 for each level of catvar1 displayed using the %7.1fc format
table catvar1, contents(p25 v1 p50 v1 p75 v1) format(%7.1fc)
Means of v1, v2, and v3 for each level of catvar2 centered in columns of width 10
table catvar2, contents(mean v1 mean v2 mean v3) cellwidth(10) center

### Options

- **Main**
  - **contents(clist)** specifies the contents of the table's cells; if not specified, **contents(freq)** is used by default. **contents(freq)** produces a table of frequencies. **contents(mean mpg)** produces a table of the means of variable mpg. **contents(freq mean mpg sd mpg)** produces a table of frequencies together with the mean and standard deviation of variable mpg. Up to five statistics may be specified.
  
  **by(superrowvarlist)** specifies that numeric or string variables be treated as superrows. Up to four variables may be specified in **superrowvarlist**. The by() option may be specified with the by prefix.

- **Options**
  - **cellwidth(#)** specifies the width of the cell in units of digit widths; 10 means the space occupied by 10 digits, which is 0123456789. The default **cellwidth()** is not a fixed number, but a number chosen by table to spread the table out while presenting a reasonable number of columns across the page.
  
  **csepwidth(#)** specifies the separation between columns in units of digit widths. The default is not a fixed number, but a number chosen by table to present the results best.
  
  **stubwidth(#)** specifies the width, in units of digit widths, to be allocated to the left stub of the table. The default is not a fixed number, but a number chosen by table according to what it thinks looks best.
  
  **scsepwidth(#)** specifies the separation between supercolumns in units of digit widths. The default is not a fixed number, but a number chosen by table to present the results best.

  **center** specifies that results be centered in the table's cells. The default is to right-align results. For centering to work well, you typically need to specify a display format as well. **center format(%9.2f)** is popular.
left specifies that column labels be left-aligned. The default is to right-align column labels to distinguish them from supercolumn labels, which are left-aligned.

cw specifies casewise deletion. If cw is not specified, all observations possible are used to calculate each of the specified statistics. cw is relevant only when you request a table containing statistics on multiple variables. For instance, contents(mean mpg mean weight) would produce a table reporting the means of variables mpg and weight. Consider an observation in which mpg is known but weight is missing. By default, that observation will be used in the calculation of the mean of mpg. If you specify cw, the observation will be excluded in the calculation of the means of both mpg and weight.

row specifies that a row be added to the table reflecting the total across the rows.

column specifies that a column be added to the table reflecting the total across columns.

scolumn specifies that a supercolumn be added to the table reflecting the total across supercolumns.

concise specifies that rows with all missing entries not be displayed.

missing specifies that missing statistics be shown in the table as periods (Stata’s missing-value indicator). The default is that missing entries be left blank.

replace specifies that the data in memory be replaced with data containing 1 observation per cell (row, column, supercolumn, and superrow) and with variables containing the statistics designated in contents().

This option is rarely specified. If you do not specify this option, the data in memory remain unchanged.

If you do specify this option, the first statistic will be named table1, the second table2, and so on. For instance, if contents(mean mpg sd mpg) was specified, the means of mpg would be in variable table1 and the standard deviations in table2.

name(string) is relevant only if you specify replace. name() allows changing the default stub name that replace uses to name the new variables associated with the statistics. If you specify name(stat), the first statistic will be placed in variable stat1, the second in stat2, and so on.

format(\%fmt) specifies the display format for presenting numbers in the table’s cells. format(\%9.0g) is the default; format(\%9.2f) and format(\%9.2fc) are popular alternatives. The width of the format you specify does not matter, except that \%fmt must be valid. The width of the cells is chosen by table to present the results best. The cellwidth() option allows you to override table’s choice.
Limits

Up to four variables may be specified in the by(), so with the three row, column, and supercolumn variables, seven-way tables may be displayed.

Up to five statistics may be displayed in each cell of the table.

The sum of the number of rows, columns, supercolumns, and superrows is called the number of margins. A table may contain up to 3,000 margins. Thus a one-way table may contain 3,000 rows. A two-way table could contain 2,998 rows and two columns, 2,997 rows and three columns, . . . , 1,500 rows and 1,500 columns, . . . , two rows and 2,998 columns. A three-way table is similarly limited by the sum of the number of rows, columns, and supercolumns. A $r \times c \times d$ table is feasible if $r + c + d \leq 3,000$. The limit is set in terms of the sum of the rows, columns, supercolumns, and superrows, and not, as you might expect, in terms of their product.

Remarks and examples

Remarks are presented under the following headings:

One-way tables
Two-way tables
Three-way tables
Four-way and higher-dimensional tables
Video example

One-way tables

Example 1

From the automobile dataset, here is a simple one-way table:

```
. use https://www.stata-press.com/data/r16/auto2
(1978 Automobile Data)
. table rep78, contents(mean mpg)
```

<table>
<thead>
<tr>
<th>Repair Record 1978</th>
<th>mean(mpg)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Poor</td>
<td>21</td>
</tr>
<tr>
<td>Fair</td>
<td>19.125</td>
</tr>
<tr>
<td>Average</td>
<td>19.4333</td>
</tr>
<tr>
<td>Good</td>
<td>21.6667</td>
</tr>
<tr>
<td>Excellent</td>
<td>27.3636</td>
</tr>
</tbody>
</table>

We are not limited to including only one statistic:

```
. table rep78, c(n mpg mean mpg sd mpg median mpg)
```

<table>
<thead>
<tr>
<th>Repair Record 1978</th>
<th>N(mpg)</th>
<th>mean(mpg)</th>
<th>sd(mpg)</th>
<th>med(mpg)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Poor</td>
<td>2</td>
<td>21</td>
<td>4.24264</td>
<td>21</td>
</tr>
<tr>
<td>Fair</td>
<td>8</td>
<td>19.125</td>
<td>3.758324</td>
<td>18</td>
</tr>
<tr>
<td>Average</td>
<td>30</td>
<td>19.4333</td>
<td>4.141325</td>
<td>19</td>
</tr>
<tr>
<td>Good</td>
<td>18</td>
<td>21.6667</td>
<td>4.93487</td>
<td>22.5</td>
</tr>
<tr>
<td>Excellent</td>
<td>11</td>
<td>27.3636</td>
<td>8.732385</td>
<td>30</td>
</tr>
</tbody>
</table>
We abbreviated `contents()` as `c()`. The `format()` option will allow us to better format the numbers in the table:

```
. table rep78, c(n mpg mean mpg sd mpg median mpg) format(%9.2f)
```

<table>
<thead>
<tr>
<th>Repair Record 1978</th>
<th>N(mpg)</th>
<th>mean(mpg)</th>
<th>sd(mpg)</th>
<th>med(mpg)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Poor</td>
<td>2</td>
<td>21.00</td>
<td>4.24</td>
<td>21.00</td>
</tr>
<tr>
<td>Fair</td>
<td>8</td>
<td>19.12</td>
<td>3.76</td>
<td>18.00</td>
</tr>
<tr>
<td>Average</td>
<td>30</td>
<td>19.43</td>
<td>4.14</td>
<td>19.00</td>
</tr>
<tr>
<td>Good</td>
<td>18</td>
<td>21.67</td>
<td>4.93</td>
<td>22.50</td>
</tr>
<tr>
<td>Excellent</td>
<td>11</td>
<td>27.36</td>
<td>8.73</td>
<td>30.00</td>
</tr>
</tbody>
</table>

The `center` option will center the results under the headings:

```
. table rep78, c(n mpg mean mpg sd mpg median mpg) format(%9.2f) center
```

<table>
<thead>
<tr>
<th>Repair Record 1978</th>
<th>N(mpg)</th>
<th>mean(mpg)</th>
<th>sd(mpg)</th>
<th>med(mpg)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Poor</td>
<td>2</td>
<td>21.00</td>
<td>4.24</td>
<td>21.00</td>
</tr>
<tr>
<td>Fair</td>
<td>8</td>
<td>19.12</td>
<td>3.76</td>
<td>18.00</td>
</tr>
<tr>
<td>Average</td>
<td>30</td>
<td>19.43</td>
<td>4.14</td>
<td>19.00</td>
</tr>
<tr>
<td>Good</td>
<td>18</td>
<td>21.67</td>
<td>4.93</td>
<td>22.50</td>
</tr>
<tr>
<td>Excellent</td>
<td>11</td>
<td>27.36</td>
<td>8.73</td>
<td>30.00</td>
</tr>
</tbody>
</table>

**Two-way tables**

> Example 2

In example 1, when we typed `table rep78, ...`, we obtained a one-way table. If we were to type `table rep78 foreign, ...`, we would obtain a two-way table:

```
. table rep78 foreign, c(mean mpg)
```

<table>
<thead>
<tr>
<th>Repair Record 1978</th>
<th>Car type</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Domestic</td>
</tr>
<tr>
<td>Poor</td>
<td>21</td>
</tr>
<tr>
<td>Fair</td>
<td>19.125</td>
</tr>
<tr>
<td>Average</td>
<td>19</td>
</tr>
<tr>
<td>Good</td>
<td>18.4444</td>
</tr>
<tr>
<td>Excellent</td>
<td>32</td>
</tr>
</tbody>
</table>

Note the missing cells. Certain combinations of repair record and car type do not exist in our dataset.

As with one-way tables, we can specify a display format for the cells and center the numbers within the cells if we wish.
We can obtain row totals by specifying the `row` option and obtain column totals by specifying the `col` option. We specify both below:

```
/table rep78 foreign, c(mean mpg) format(%9.2f) center row col
```

<table>
<thead>
<tr>
<th>Repair Record 1978</th>
<th>Car type</th>
<th>Domestic</th>
<th>Foreign</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>Poor</td>
<td></td>
<td>21.00</td>
<td></td>
<td>21.00</td>
</tr>
<tr>
<td>Fair</td>
<td></td>
<td>19.12</td>
<td></td>
<td>19.12</td>
</tr>
<tr>
<td>Average</td>
<td></td>
<td>19.00</td>
<td>23.33</td>
<td>19.43</td>
</tr>
<tr>
<td>Good</td>
<td></td>
<td>18.44</td>
<td>24.89</td>
<td>21.67</td>
</tr>
<tr>
<td>Excellent</td>
<td></td>
<td>32.00</td>
<td>26.33</td>
<td>27.36</td>
</tr>
<tr>
<td>Total</td>
<td></td>
<td>19.54</td>
<td>25.29</td>
<td>21.29</td>
</tr>
</tbody>
</table>

Table can display multiple statistics within cells, but once we move beyond one-way tables, the table becomes busy:

```
/table foreign rep78, c(mean mpg n mpg) format(%9.2f) center
```

<table>
<thead>
<tr>
<th>Car type</th>
<th>Repair Record 1978</th>
<th>Poor</th>
<th>Fair</th>
<th>Average</th>
<th>Good</th>
<th>Excellent</th>
</tr>
</thead>
<tbody>
<tr>
<td>Domestic</td>
<td></td>
<td>21.00</td>
<td>19.12</td>
<td>19.00</td>
<td>18.44</td>
<td>32.00</td>
</tr>
<tr>
<td></td>
<td></td>
<td>2</td>
<td>8</td>
<td>27</td>
<td>9</td>
<td>2</td>
</tr>
<tr>
<td>Foreign</td>
<td></td>
<td>23.33</td>
<td>24.89</td>
<td>26.33</td>
<td></td>
<td>29</td>
</tr>
<tr>
<td></td>
<td></td>
<td>3</td>
<td>9</td>
<td>9</td>
<td></td>
<td>9</td>
</tr>
</tbody>
</table>

This two-way table with two statistics per cell works well here. That was, in part, helped along by our interchanging the rows and columns. We turned the table around by typing `table foreign rep78` rather than `table rep78 foreign`. 
Another way to display two-way tables is to specify a row and superrow rather than a row and column. We do that below and display three statistics per cell:

```
. table foreign, by(rep78) c(mean mpg sd mpg n mpg) format(%9.2f) center
```

<table>
<thead>
<tr>
<th>Repair Record 1978 and Car type</th>
<th>mean(mpg)</th>
<th>sd(mpg)</th>
<th>N(mpg)</th>
</tr>
</thead>
<tbody>
<tr>
<td>Poor Domestic</td>
<td>21.00</td>
<td>4.24</td>
<td>2</td>
</tr>
<tr>
<td>Fair Domestic</td>
<td>19.12</td>
<td>3.76</td>
<td>8</td>
</tr>
<tr>
<td>Average Domestic</td>
<td>19.00</td>
<td>4.09</td>
<td>27</td>
</tr>
<tr>
<td>Good Domestic</td>
<td>18.44</td>
<td>4.59</td>
<td>9</td>
</tr>
<tr>
<td>Excellent Domestic</td>
<td>32.00</td>
<td>2.83</td>
<td>2</td>
</tr>
<tr>
<td>Foreign</td>
<td>23.33</td>
<td>2.52</td>
<td>3</td>
</tr>
<tr>
<td></td>
<td>20.19</td>
<td>4.64</td>
<td>2</td>
</tr>
<tr>
<td></td>
<td>19.00</td>
<td>3.98</td>
<td>8</td>
</tr>
<tr>
<td></td>
<td>19.00</td>
<td>4.09</td>
<td>27</td>
</tr>
<tr>
<td></td>
<td>19.00</td>
<td>4.09</td>
<td>27</td>
</tr>
<tr>
<td></td>
<td>19.00</td>
<td>4.09</td>
<td>27</td>
</tr>
</tbody>
</table>

Three-way tables

Example 3

We have data on the prevalence of byssinosis, a form of pneumoconiosis to which workers exposed to cotton dust are susceptible. The dataset is on 5,419 workers in a large cotton mill. We know whether each worker smokes, his or her race, and the dustiness of the work area. The categorical variables are

- **smokes**: Smoker or nonsmoker in the last five years.
- **race**: White or other.
- **workplace**: 1 (most dusty), 2 (less dusty), 3 (least dusty).

Moreover, this dataset includes a frequency-weight variable **pop**. Here is a three-way table showing the fraction of workers with byssinosis:

```
. use https://www.stata-press.com/data/r16/byssin
```

(Byssinosis incidence)

```
. table workplace smokes race [fw=pop], c(mean prob)
```

<table>
<thead>
<tr>
<th>Dustiness of workplace</th>
<th>Race and Smokes</th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>other</td>
<td>white</td>
<td></td>
</tr>
<tr>
<td>least</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td></td>
<td>0.0107527</td>
<td>0.0081549</td>
<td>0.0162774</td>
</tr>
<tr>
<td>less</td>
<td>0.02</td>
<td>0.0136612</td>
<td>0.0143149</td>
</tr>
<tr>
<td>most</td>
<td>0.0820896</td>
<td>0.0833333</td>
<td>0.2295082</td>
</tr>
</tbody>
</table>
This table would look better if we showed the fraction to four digits:

```
. table workplace smokes race [fw=pop], c(mean prob) format(%9.4f)
```

<table>
<thead>
<tr>
<th>Dustiness of workplace</th>
<th>Race and Smokes</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>—— other ——</td>
</tr>
<tr>
<td></td>
<td>no</td>
</tr>
<tr>
<td>least</td>
<td>0.0108</td>
</tr>
<tr>
<td>less</td>
<td>0.0200</td>
</tr>
<tr>
<td>most</td>
<td>0.0821</td>
</tr>
</tbody>
</table>

In this table, the rows are the dustiness of the workplace, the columns are whether the worker smokes, and the supercolumns are the worker’s race.

Now we request that the table include the supercolumn totals by specifying the `sctotal` option, which we can abbreviate as `sc`:

```
. table workplace smokes race [fw=pop], c(mean prob) format(%9.4f) sc
```

<table>
<thead>
<tr>
<th>Dustiness of workplace</th>
<th>Race and Smokes</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>—— other ——</td>
</tr>
<tr>
<td></td>
<td>no</td>
</tr>
<tr>
<td>least</td>
<td>0.0108</td>
</tr>
<tr>
<td>less</td>
<td>0.0200</td>
</tr>
<tr>
<td>most</td>
<td>0.0821</td>
</tr>
</tbody>
</table>

The supercolumn total is the total over `race` and is divided into its columns based on `smokes`. Here is the table with the column rather than the supercolumn totals:

```
. table workplace smokes race [fw=pop], c(mean prob) format(%9.4f) col
```

<table>
<thead>
<tr>
<th>Dustiness of workplace</th>
<th>Race and Smokes</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>—— other ——</td>
</tr>
<tr>
<td>least</td>
<td>0.0108</td>
</tr>
<tr>
<td>less</td>
<td>0.0200</td>
</tr>
<tr>
<td>most</td>
<td>0.0821</td>
</tr>
</tbody>
</table>

Here is the table with both column and supercolumn totals:

```
. table workplace smokes race [fw=pop], c(mean prob) format(%9.4f) sc col
```

<table>
<thead>
<tr>
<th>Dustiness of workplace</th>
<th>Race and Smokes</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>—— other ——</td>
</tr>
<tr>
<td></td>
<td>no</td>
</tr>
<tr>
<td>least</td>
<td>0.0108</td>
</tr>
<tr>
<td>less</td>
<td>0.0200</td>
</tr>
<tr>
<td>most</td>
<td>0.0821</td>
</tr>
</tbody>
</table>

`table` is struggling to keep this table from becoming too wide—notice how it divided the words in the title in the top-left stub. Here, if the table had more columns, or, if we demanded more digits, `table` would be forced to segment the table and present it in pieces, which it would do:
. table workplace smokes race [fw=pop], c(mean prob) format(%9.6f) sc col

<table>
<thead>
<tr>
<th>Dustiness of workplace</th>
<th>other</th>
<th>Race and Smokes</th>
<th>white</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>no</td>
<td>yes Total</td>
<td>no</td>
<td>yes Total</td>
</tr>
<tr>
<td>least</td>
<td>0.010753</td>
<td>0.010417</td>
<td>0.008155</td>
<td>0.012949</td>
</tr>
<tr>
<td>less</td>
<td>0.020000</td>
<td>0.013483</td>
<td>0.013661</td>
<td>0.014035</td>
</tr>
<tr>
<td>most</td>
<td>0.082090</td>
<td>0.139303</td>
<td>0.083333</td>
<td>0.183521</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>Dustiness of workplace</th>
<th>Race and Smokes</th>
<th>Total</th>

<td>yes</td>
</tr>
<tr>
<td>least</td>
<td>0.008990</td>
<td>0.014471</td>
</tr>
<tr>
<td>less</td>
<td>0.015901</td>
<td>0.012262</td>
</tr>
<tr>
<td>most</td>
<td>0.082569</td>
<td>0.192905</td>
</tr>
</tbody>
</table>

Here three digits is probably enough, so here is the table including all the row, column, and supercolumn totals:

. table workplace smokes race [fw=pop], c(mean prob) format(%9.3f) sc col row

<table>
<thead>
<tr>
<th>Dustiness of workplace</th>
<th>other</th>
<th>Race and Smokes</th>
<th>white</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>no</td>
<td>yes Total</td>
<td>no</td>
<td>yes Total</td>
</tr>
<tr>
<td>least</td>
<td>0.011</td>
<td>0.010</td>
<td>0.008</td>
<td>0.013</td>
</tr>
<tr>
<td>less</td>
<td>0.020</td>
<td>0.013</td>
<td>0.014</td>
<td>0.014</td>
</tr>
<tr>
<td>most</td>
<td>0.082</td>
<td>0.139</td>
<td>0.083</td>
<td>0.184</td>
</tr>
<tr>
<td>Total</td>
<td>0.025</td>
<td>0.038</td>
<td>0.014</td>
<td>0.026</td>
</tr>
</tbody>
</table>

We can show multiple statistics:

. table workplace smokes race [fw=pop], c(mean prob n prob) format(%9.3f) sc > col row

<table>
<thead>
<tr>
<th>Dustiness of workplace</th>
<th>other</th>
<th>Race and Smokes</th>
<th>white</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>no</td>
<td>yes Total</td>

<td>0.038</td>
<td>0.014</td>
<td>0.026</td>
</tr>
</tbody>
</table>
Four-way and higher-dimensional tables

Example 4

Let’s pretend that our byssinosis dataset also recorded each worker’s sex (it does not, and we have made up this extra information). We obtain a four-way table just as we would a three-way table, but we specify the fourth variable as a superrow by including it in the by() option:

```
. use https://www.stata-press.com/data/r16/byssin1 (Byssinosis incidence)
. table workplace smokes race [fw=pop], by(sex) c(mean prob) format(%9.3f) sc > col row
```

<table>
<thead>
<tr>
<th>Sex and Dustiness of workplace</th>
<th>other</th>
<th>race and smokes</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>no</td>
<td>yes</td>
<td>Total</td>
</tr>
<tr>
<td>Female least</td>
<td>0.006</td>
<td>0.009</td>
<td>0.008</td>
</tr>
<tr>
<td>Female less</td>
<td>0.020</td>
<td>0.008</td>
<td>0.010</td>
</tr>
<tr>
<td>Female most</td>
<td>0.057</td>
<td>0.154</td>
<td>0.141</td>
</tr>
<tr>
<td>Total</td>
<td>0.017</td>
<td>0.051</td>
<td>0.043</td>
</tr>
</tbody>
</table>

| Male least                    | 0.013 | 0.011           | 0.012 |
| Male less                     | 0.020 | 0.000           | 0.019 |
| Male most                     | 0.091 | 0.244           | 0.136 |
| Total                         | 0.029 | 0.041           | 0.033 |

If our dataset also included work group and we wanted a five-way table, we could include both the sex and work-group variables in the by() option. You may include up to four variables in by(), and so produce up to 7-way tables.

Video example
Combining cross-tabulations and descriptives in Stata

Methods and formulas
The contents of cells are calculated by `collapse` and are displayed by `tabdisp`; see [D] `collapse` and [P] `tabdisp`.

[P] tabdisp — Display tables
Description

`tabstat` displays summary statistics for a series of numeric variables in one table. It allows you to specify the list of statistics to be displayed. Statistics can be calculated (conditioned on) another variable. `tabstat` allows substantial flexibility in terms of the statistics presented and the format of the table.

Quick start

Mean of `v1` displayed using `v1`’s display format

```
  tabstat v1, format
```

As above, but use format with 2 significant digits and a comma

```
  tabstat v1, format(%9.2fc)
```

Nonmissing observations, mean, standard error, and coefficient of variation for `v1`

```
  tabstat v1, statistics(n mean semean cv)
```

Quartiles and interquartile range of `v1` and `v2`

```
  tabstat v1 v2, statistics(q iqr)
```

As above, but report statistics separately for each level of `catvar`

```
  tabstat v1 v2, by(catvar) statistics(q iqr)
```

As above, but display a separate column for each statistic

```
  tabstat v1 v2, by(catvar) statistics(q iqr) columns(statistics)
```
Syntax

\texttt{tabstat \ varlist \ [if] \ [in] \ [weight] \ [\ , \ options]} \\

</tbody>
</table>

\texttt{by} is allowed; see \[D] \texttt{by}.

\texttt{aweights} and \texttt{fweights} are allowed; see \[U] 11.1.6 \texttt{weight}.

\textbf{Options}

by\texttt{(varname)} specifies that the statistics be displayed separately for each unique value of \texttt{varname}; \texttt{varname} may be numeric or string. For instance, \texttt{tabstat height} would present the overall mean of height. \texttt{tabstat height, by(sex)} would present the mean height of males, and of females, and the overall mean height. Do not confuse the \texttt{by()} option with the \texttt{by} prefix (see \[D] \texttt{by}); both may be specified.

\texttt{statistics}\texttt{(statname \ [...]}) specifies the statistics to be displayed; the default is equivalent to specifying \texttt{statistics(mean)}. (\texttt{stats()} is a synonym for \texttt{statistics()}. ) Multiple statistics may be specified and are separated by white space, such as \texttt{statistics(mean sd)}. Available statistics are

Options:

- `labelwidth(#)` specifies the maximum width to be used within the stub to display the labels of the `by()` variable. The default is `labelwidth(16)`. $8 \leq # \leq 32$.
- `varwidth(#)` specifies the maximum width to be used within the stub to display the names of the variables. The default is `varwidth(12)`. `varwidth()` is effective only with `columns(statistics)`. Setting `varwidth()` implies `longstub`. $8 \leq # \leq 32$.
- `columns(variables|statistics)` specifies whether to display variables or statistics in the columns of the table. `columns(variables)` is the default when more than one variable is specified.
- `format` and `format(\%fmt)` specify how the statistics are to be formatted. The default is to use a `\%9.0g` format.
  - `format` specifies that each variable’s statistics be formatted with the variable’s display format; see [D] `format`.
  - `format(\%fmt)` specifies the format to be used for all statistics. The maximum width of the specified format should not exceed nine characters.
- `casewise` specifies casewise deletion of observations. Statistics are to be computed for the sample that is not missing for any of the variables in `varlist`. The default is to use all the nonmissing values for each variable.
- `nototal` is for use with `by()`; it specifies that the overall statistics not be reported.
- `missing` specifies that missing values of the `by()` variable be treated just like any other value and that statistics should be displayed for them. The default is not to report the statistics for the `by()==missing` group. If the `by()` variable is a string variable, `by()==""` is considered to mean missing.
- `noseparator` specifies that a separator line between the `by()` categories not be displayed.
- `longstub` specifies that the left stub of the table be made wider so that it can include names of the statistics or variables in addition to the categories of `by(varname)`. The default is to describe the statistics or variables in a header. `longstub` is ignored if `by(varname)` is not specified.
- `save` specifies that the summary statistics be returned in `r()`. The overall (unconditional) statistics are returned in matrix `r(StatTotal)` (rows are statistics, columns are variables). The conditional statistics are returned in the matrices `r(Stat1), r(Stat2), ...,` and the names of the corresponding variables are returned in the macros `r(name1), r(name2), ...`
Remarks and examples

This command is probably most easily understood by going through a series of examples.

Example 1

We have data on the price, weight, mileage rating, and repair record of 22 foreign and 52 domestic 1978 automobiles. We want to summarize these variables for the different origins of the automobiles.

```
. use https://www.stata-press.com/data/r16/auto
   (1978 Automobile Data)
. tabstat price weight mpg rep78, by(foreign)
Summary statistics: mean
   by categories of: foreign (Car type)
    foreign | price    weight   mpg    rep78
              |    mean   mean     mean   mean
    Foreign |  6384.7 |   2315.9 |   24.8 |   4.3
    Domestic|  6072.4 |   3317.1 |   19.8 |   3.0
    Total  |  6165.3 |   3019.5 |   21.3 |   3.4
```

More summary statistics can be requested via the `statistics()` option. The group totals can be suppressed with the `nototal` option.

```
. tabstat price weight mpg rep78, by(foreign) stat(mean sd min max) nototal
Summary statistics: mean, sd, min, max
   by categories of: foreign (Car type)
    foreign | price    weight   mpg    rep78
              |    mean   mean     mean    mean
    Foreign |  6384.7 |  2315.9 |   24.8 |   4.3
             |  2621.9 |   433.0 |   6.6 |   .7
    Domestic|  6072.4 |  3317.1 |   19.8 |   3.0
             |  3097.1 |   695.4 |   4.7 |   .8
    Total  |  6165.3 |  3019.5 |   21.3 |   3.4
```

Although the header of the table describes the statistics running vertically in the “cells”, the table may become hard to read, especially with many variables or statistics. The `longstub` option specifies that a column be added describing the contents of the cells. The `format` option can be issued to specify that `tabstat` display the statistics by using the display format of the variables rather than the overall default `%9.0g`. 
We can specify a layout of the table in which the statistics run horizontally and the variables run vertically by specifying the `col(statistics)` option.

Finally, `tabstat` can also be used to enhance `summarize` so we can specify the statistics to be displayed. For instance, we can display the number of observations, the mean, the coefficient of variation, and the 25%, 50%, and 75% quantiles for a list of variables.

Because we did not specify the `by()` option, these statistics were not displayed for the subgroups of the data formed by the categories of the `by()` variable.
Video example

Descriptive statistics in Stata

Acknowledgments

The `tabstat` command was written by Jeroen Weesie and Vincent Buskens both of the Department of Sociology at Utrecht University, The Netherlands.

[R] `summarize` — Summary statistics
[R] `table` — Flexible table of summary statistics
[R] `tabulate, summarize()` — One- and two-way tables of summary statistics
[D] `collapse` — Make dataset of summary statistics
Description

`tabulate` produces a one-way table of frequency counts.

For information on a two-way table of frequency counts along with measures of association, including the common Pearson $\chi^2$, the likelihood-ratio $\chi^2$, Cramér’s V, Fisher’s exact test, Goodman and Kruskal’s gamma, and Kendall’s $\tau_b$, see [R] `tabulate twoway`.

`tab1` produces a one-way tabulation for each variable specified in `varlist`.

Also see [R] `table` and [R] `tabstat` if you want one-, two-, or $n$-way table of frequencies and a wide variety of statistics. See [R] `tabulate, summarize()` for a description of `tabulate` with the `summarize()` option; it produces a table (breakdowns) of means and standard deviations. `table` is better than `tabulate, summarize()`, but `tabulate, summarize()` is faster. See [R] `Epitab` for a $2 \times 2$ table with statistics of interest to epidemiologists.

Quick start

One-way table of frequencies for `v1`
```
tabulate v1
```

Sort table in descending order of frequency
```
tabulate v1, sort
```

Generate indicator variables `v1_1`, `v1_2`, … representing the levels of `v1`
```
tabulate v1, generate(v1_)
```

Treat missing values like other values of `v1`
```
tabulate v1, missing
```

Display numeric values of `v1` rather than value labels
```
tabulate v1, nolabel
```

Create one-way tables for `v1`, `v2`, and `v3`
```
tab1 v1 v2 v3
```

Menu

</table>

by is allowed with \text{tabulate} and \text{tab1}; see [D] \text{by}.

\text{fweight}s, \text{aweight}s, and \text{iweight}s are allowed; see [U] 11.1.6 weight.

**Options**

\[ \text{subpop}(\text{varname}) \] excludes observations for which \( \text{varname} = 0 \) in tabulating frequencies. The mathematical results of \text{tabulate} \ldots , \text{subpop}(\text{myvar}) are the same as \text{tabulate} \ldots \text{if} \text{myvar }!=0, but the table may be presented differently. The identities of the rows and columns will be determined from all the data, including the \text{myvar }=0 \text{ group}, so there may be entries in the table with frequency 0.
Consider tabulating \texttt{answer}, a variable that takes on values 1, 2, and 3, but consider tabulating it just for the \texttt{male==1} subpopulation. Assume that \texttt{answer} is never 2 in this group. \texttt{tabulate answer if male==1} produces a table with two rows: one for answer 1 and one for answer 3. There will be no row for answer 2 because answer 2 was never observed. \texttt{tabulate answer, subpop(male)} produces a table with three rows. The row for answer 2 will be shown as having 0 frequency. \texttt{missing} requests that missing values be treated like other values in calculations of counts, percentages, and other statistics. \texttt{nofreq} suppresses the printing of the frequencies. \texttt{nolabel} causes the numeric codes to be displayed rather than the value labels. \texttt{plot} produces a bar chart of the relative frequencies in a one-way table. (Also see [R] histogram.) \texttt{sort} puts the table in descending order of frequency (and ascending order of the variable within equal values of frequency).

\begin{itemize}
\item \texttt{generate(stubname)} creates a set of indicator variables (\texttt{stubname1}, \texttt{stubname2}, \ldots) reflecting the observed values of the tabulated variable. The \texttt{generate()} option may not be used with the by prefix.
\item \texttt{matcell(matname)} saves the reported frequencies in \texttt{matname}. This option is for use by programmers. \texttt{matrow(matname)} saves the numeric values of the $r \times 1$ row stub in \texttt{matname}. This option is for use by programmers. \texttt{matrow()} may not be specified if the row variable is a string.
\end{itemize}

Limits

A one-way table may have a maximum of 12,000 rows (Stata/MP and Stata/SE) or 3,000 rows (Stata/IC).

\section*{Remarks and examples}

Remarks are presented under the following headings:

\begin{itemize}
\item \texttt{tabulate}
\item \texttt{tab1}
\item Video example
\end{itemize}

For each value of a specified variable, \texttt{tabulate} reports the number of observations with that value. The number of times a value occurs is called its \texttt{frequency}.

\section*{tabulate}

\subsection*{Example 1}

We have data summarizing the speed limit and the accident rate per million vehicle miles along various Minnesota highways in 1973. The variable containing the speed limit is called \texttt{spdlimit}. If we \texttt{summarize} the variable, we obtain its mean and standard deviation:
The average speed limit is 55 miles per hour. We can learn more about this variable by tabulating it:

```
. tabulate spdlimit
```

<table>
<thead>
<tr>
<th>Speed Limit</th>
<th>Freq.</th>
<th>Percent</th>
<th>Cum.</th>
</tr>
</thead>
<tbody>
<tr>
<td>40</td>
<td>1</td>
<td>2.56</td>
<td>2.56</td>
</tr>
<tr>
<td>45</td>
<td>3</td>
<td>7.69</td>
<td>10.26</td>
</tr>
<tr>
<td>50</td>
<td>7</td>
<td>17.95</td>
<td>28.21</td>
</tr>
<tr>
<td>55</td>
<td>15</td>
<td>38.46</td>
<td>66.67</td>
</tr>
<tr>
<td>60</td>
<td>11</td>
<td>28.21</td>
<td>94.87</td>
</tr>
<tr>
<td>65</td>
<td>1</td>
<td>2.56</td>
<td>97.44</td>
</tr>
<tr>
<td>70</td>
<td>1</td>
<td>2.56</td>
<td>100.00</td>
</tr>
<tr>
<td><strong>Total</strong></td>
<td><strong>39</strong></td>
<td><strong>100.00</strong></td>
<td></td>
</tr>
</tbody>
</table>

We see that one highway has a speed limit of 40 miles per hour, three have speed limits of 45, 7 of 50, and so on. The column labeled Percent shows the percentage of highways in the dataset that have the indicated speed limit. For instance, 38.46% of highways in our dataset have a speed limit of 55 miles per hour. The final column shows the cumulative percentage. We see that 66.67% of highways in our dataset have a speed limit of 55 miles per hour or less.

---

### Example 2

The plot option places a sideways histogram alongside the table:

```
. tabulate spdlimit, plot
```

Of course, `graph` can produce better-looking histograms; see `[R] histogram`.

---

### Example 3

`tabulate` labels tables using `variable` and `value labels` if they exist. To demonstrate how this works, let’s add a new variable to our dataset that categorizes `spdlimit` into three categories. We will call this new variable `spdcat`:

```
. generate spdcat = recode(spdlimit, 50, 60, 70)
```
The `recode()` function divides `spdlimit` into 50 miles per hour or below, 51–60, and above 60; see [FN] Programming functions. We specified the breakpoints in the arguments (`spdlimit,50,60,70`). The first argument is the variable to be recoded. The second argument is the first breakpoint, the third argument is the second breakpoint, and so on. We can specify as many breakpoints as we wish.

`recode()` used our arguments not only as the breakpoints but also to label the results. If `spdlimit` is less than or equal to 50, `spdcat` is set to 50; if `spdlimit` is between 51 and 60, `spdcat` is 60; otherwise, `spdcat` is arbitrarily set to 70. (See [U] 26 Working with categorical data and factor variables.)

Because we just created the variable `spdcat`, it is not yet labeled. When we make a table using this variable, `tabulate` uses the variable’s name to label it:

```
. tabulate spdcat

 spdcat | Freq. Percent  Cum.  
---------|------------|------------
       50 |      11    28.21    28.21
       60 |      26    66.67   94.87
       70 |       2     5.13  100.00
     Total |      39    100.00
```

Even through the table is not well labeled, `recode()`’s coding scheme provides us with clues as to the table’s meaning. The first line of the table corresponds to 50 miles per hour and below, the next to 51 through 60 miles per hour, and the last to above 60 miles per hour.

We can improve this table by labeling the values and variables:

```
. label define scat 50 "40 to 50" 60 "55 to 60" 70 "Above 60"
. label values spdcat scat
. label variable spdcat "Speed Limit Category"
```

We define a `value label` called `scat` that attaches labels to the numbers 50, 60, and 70 using the `label define` command; see [U] 12.6.3 Value labels. We label the value 50 as ‘40 to 50’, because we looked back at our original tabulation in the first example and saw that the speed limit was never less than 40. Similarly, we could have labeled the last category ‘65 to 70’ because the speed limit is never greater than 70 miles per hour.

Next we requested that Stata label the values of the new variable `spdcat` using the value label `scat`. Finally, we labeled our variable `Speed Limit Category`. We are now ready to `tabulate` the result:

```
. tabulate spdcat

 Speed Limit Category | Freq. | Percent | Cum.  
----------------------|-------|---------|-------
    40 to 50          | 11    | 28.21   | 28.21
   55 to 60           | 26    | 66.67   | 94.87
   Above 60           | 2     | 5.13    | 100.00
     Total            | 39    | 100.00  |
```

Example 4

If we have missing values in our dataset, `tabulate` ignores them unless we explicitly indicate otherwise. We have no missing data in our example, so let’s add some:

```
. replace spdcat=. in 39
   (1 real change made, 1 to missing)
```

We changed the first observation on `spdcat` to *missing*. Let’s now *tabulate* the result:

```stata
.tabulate spdcat
```

<table>
<thead>
<tr>
<th>Speed Limit Category</th>
<th>Freq.</th>
<th>Percent</th>
<th>Cum.</th>
</tr>
</thead>
<tbody>
<tr>
<td>40 to 50</td>
<td>11</td>
<td>28.95</td>
<td>28.95</td>
</tr>
<tr>
<td>55 to 60</td>
<td>26</td>
<td>68.42</td>
<td>97.37</td>
</tr>
<tr>
<td>Above 60</td>
<td>1</td>
<td>2.63</td>
<td>100.00</td>
</tr>
<tr>
<td><strong>Total</strong></td>
<td><strong>38</strong></td>
<td><strong>100.00</strong></td>
<td></td>
</tr>
</tbody>
</table>

Comparing this output with that in the previous example, we see that the total frequency count is now one less than it was—38 rather than 39. Also, the ‘Above 60’ category now has only one observation where it used to have two, so we evidently changed a road with a high speed limit.

We want *tabulate* to treat missing values just as it treats numbers, so we specify the `missing` option:

```stata
.tabulate spdcat, missing
```

<table>
<thead>
<tr>
<th>Speed Limit Category</th>
<th>Freq.</th>
<th>Percent</th>
<th>Cum.</th>
</tr>
</thead>
<tbody>
<tr>
<td>40 to 50</td>
<td>11</td>
<td>28.21</td>
<td>28.21</td>
</tr>
<tr>
<td>55 to 60</td>
<td>26</td>
<td>66.67</td>
<td>94.87</td>
</tr>
<tr>
<td>Above 60</td>
<td>1</td>
<td>2.56</td>
<td>97.44</td>
</tr>
<tr>
<td>.</td>
<td>1</td>
<td>2.56</td>
<td>100.00</td>
</tr>
<tr>
<td><strong>Total</strong></td>
<td><strong>39</strong></td>
<td><strong>100.00</strong></td>
<td></td>
</tr>
</tbody>
</table>

We now see our missing value—the last category, labeled ‘.’, shows a frequency count of 1. The table sum is once again 39.

Let’s put our dataset back as it was originally:

```stata
.replace spdcat=70 in 39
```

(1 real change made)

*Technical note*

*tabulate* also can automatically create indicator variables from categorical variables. We will briefly review that capability here, but see [U] 26 Working with categorical data and factor variables for a complete description. Let’s begin by describing our highway dataset:

```stata
.describe
Contains data from https://www.stata-press.com/data/r16/hiway.dta
obs: 39 Minnesota Highway Data, 1973
vars: 3 16 Nov 2018 12:39
```

<table>
<thead>
<tr>
<th>variable name</th>

Sorted by:

Note: Dataset has changed since last saved.

When we typed `tabulate` with the `generate()` option, Stata responded by producing a one-way frequency table, so it appeared that the option did nothing. Yet when we describe our dataset, we find that we now have six variables instead of the original three. The new variables are named `spd1`, `spd2`, and `spd3`.

When we specify the `generate()` option, we are telling Stata to not only produce the table but also create a set of indicator variables that correspond to that table. Stata adds a numeric suffix to the name we specify in the parentheses. `spd1` refers to the first line of the table, `spd2` to the second line, and so on. Also Stata labels the variables so that we know what they mean. `spd1` is an indicator variable that is true (takes on the value 1) when `spdcat` is between 40 and 50; otherwise, it is zero. (There is an exception: if `spdcat` is missing, so are the `spd1`, `spd2`, and `spd3` variables. This did not happen in our dataset.)

We want to prove our claim. Because we have not yet introduced two-way tabulations, we will use the `summarize` statement:

```
. summarize spdlimit if spd1==1
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>spdlimit</td>
<td>11</td>
<td>47.73</td>
<td>3.47</td>
<td>40</td>
<td>50</td>
</tr>
</tbody>
</table>

```
. summarize spdlimit if spd2==1
```

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>spdlimit</td>
<td>26</td>
<td>57.11</td>
<td>2.52</td>
<td>55</td>
<td>60</td>
</tr>
</tbody>
</table>
Notice the indicated minimum and maximum in each of the tables above. When we restrict the sample to spd1, spdlimit is between 40 and 50; when we restrict the sample to spd2, spdlimit is between 55 and 60; when we restrict the sample to spd3, spdlimit is between 65 and 70.

Thus tabulate provides an easy way to create indicator (sometimes called dummy) variables. For an overview of indicator and categorical variables, see [U] 26 Working with categorical data and factor variables.

**tab1**

`tab1` is a convenience tool. Typing

```
.tab1 myvar thisvar thatvar, plot
```

is equivalent to typing

```
.tabulate myvar, plot
.tabulate thisvar, plot
.tabulate thatvar, plot
```

**Video example**

*Tables and cross-tabulations in Stata*

**Stored results**

`tabulate` and `tab1` store the following in `r()`:

Scalars

- `r(N)` number of observations
- `r(r)` number of rows

[U] 12.6.3 Value labels

[U] 26 Working with categorical data and factor variables
Description

tabulate produces a two-way table of frequency counts, along with various measures of association, including the common Pearson’s $\chi^2$, the likelihood-ratio $\chi^2$, Cramér’s $V$, Fisher’s exact test, Goodman and Kruskal’s gamma, and Kendall’s $\tau_b$.

Line size is respected. That is, if you resize the Results window before running tabulate, the resulting two-way tabulation will take advantage of the available horizontal space. Stata for Unix(console) users can instead use the set linesize command to take advantage of this feature.

tab2 produces all possible two-way tabulations of the variables specified in varlist.

tabi displays the $r \times c$ table, using the values specified; rows are separated by ‘\’. If no options are specified, it is as if exact were specified for a $2 \times 2$ table and chi2 were specified otherwise. See [U] 19 Immediate commands for a general description of immediate commands. See Tables with immediate data below for examples using tabi.

See [R] tabulate oneway if you want a one-way table of frequencies. See [R] table and [R] tabstat if you want one-, two-, or $n$-way table of frequencies and a wide variety of summary statistics. See [R] tabulate, summarize() for a description of tabulate with the summarize() option; it produces a table (breakdowns) of means and standard deviations. table is better than tabulate, summarize(), but tabulate, summarize() is faster. See [R] Epitab for a $2 \times 2$ table with statistics of interest to epidemiologists.

Quick start

Two-way table of frequencies for v1 and v2
    tabulate v1 v2

Add row percentages
    tabulate v1 v2, row

Frequencies only for observations where v3 = 1
    tabulate v1 v2 if v3==1

Weighted cell counts using frequency weights defined by wvar
    tabulate v1 v2 [fweight=wvar]

Pearson’s $\chi^2$ test and each cell’s contribution
    tabulate v1 v2, chi2 cchi2

All available measures of association
    tabulate v1 v2, all

2669
All possible two-way tables for v1, v2, and v3
   \texttt{tab2 v1 v2 v3}

Input cell frequencies and perform $\chi^2$ test
   \texttt{tabi 30 18 38 \ 13 7 22, chi2}

**Advanced**

```
matcell(matname) save frequencies in matname; programmer’s option
matrow(matname) save unique values of varname_1 in matname; programmer’s option
matcol(matname) save unique values of varname_2 in matname; programmer’s option
‡replace replace current data with given cell frequencies
all equivalent to specifying chi2 lrchi2 V gamma taub
```
*firstonly is available only for tab2.
‡ replace is available only for tabi.
by is allowed with tabulate and tab2; see [D] by.
fweights, aweights, and iweights are allowed by tabulate. fweights are allowed by tab2. See [U] 11.1.6 weight. all does not appear in the dialog box.

Options

Main

chi2 calculates and displays Pearson’s $\chi^2$ for the hypothesis that the rows and columns in a two-way table are independent. chi2 may not be specified if aweights or iweights are specified.

exact[(#)] displays the significance calculated by Fisher’s exact test and may be applied to $r \times c$ as well as to $2 \times 2$ tables. For $2 \times 2$ tables, both one- and two-sided probabilities are displayed. For $r \times c$ tables, two-sided probabilities are displayed. The optional positive integer # is a multiplier on the amount of memory that the command is permitted to consume. The default is 1. This option should not be necessary for reasonable $r \times c$ tables. If the command terminates with error 910, try exact(2). The maximum row or column dimension allowed when computing Fisher’s exact test is the maximum row or column dimension for tabulate (see [R] Limits).

gamma displays Goodman and Kruskal’s gamma along with its asymptotic standard error. gamma is appropriate only when both variables are ordinal. gamma may not be specified if aweights or iweights are specified.

lrchi2 displays the likelihood-ratio $\chi^2$ statistic. lrchi2 may not be specified if aweights or iweights are specified.

taub displays Kendall’s $\tau_b$ along with its asymptotic standard error. taub is appropriate only when both variables are ordinal. taub may not be specified if aweights or iweights are specified.

V (note capitalization) displays Cramér’s V. V may not be specified if aweights or iweights are specified.

cchi2 displays each cell’s contribution to Pearson’s chi-squared in a two-way table.

column displays the relative frequency of each cell within its column in a two-way table.

row displays the relative frequency of each cell within its row in a two-way table.

clrchi2 displays each cell’s contribution to the likelihood-ratio chi-squared in a two-way table.

cell displays the relative frequency of each cell in a two-way table.

expected displays the expected frequency of each cell in a two-way table.

nofreq suppresses the printing of the frequencies.

rowsort and colsort specify that the rows and columns, respectively, be presented in order of observed frequency.

By default, rows and columns are presented in ascending order of the row and column variable. For instance, if you type tabulate a b and a takes on the values 2, 3, and 5, then the first row of the table will correspond to a = 2; the second row will correspond to a = 3; and the third row will correspond to a = 5.

rowsort specifies that the rows instead be presented in descending order of observed frequency of the values. If you type twoway a b, rowsort, the most frequently observed value of a will be listed in the first row, the second most frequently observed value of a in the second row, and so on. If there are rows with equal frequencies, they will be presented in ascending order of the
values of a. If \( a = 5 \) occurs with frequency 1,000 and values \( a = 2 \) and \( a = 3 \) each occur with frequency 500, the rows will be presented in the order \( a = 5, a = 2, \) and \( a = 3 \).

colsort does the same as rowsort, except with the columns and the column variable.

rowsort and colsort may be specified together.

missing requests that missing values be treated like other values in calculations of counts, percentages, and other statistics.

wrap requests that Stata take no action on wide, two-way tables to make them readable. Unless wrap is specified, wide tables are broken into pieces to enhance readability.

[no]key suppresses or forces the display of a key above two-way tables. The default is to display the key if more than one cell statistic is requested, and otherwise to omit it. key forces the display of the key. nokey suppresses its display.

nolabel causes the numeric codes to be displayed rather than the value labels.

nolog suppresses the display of the log for Fisher’s exact test. Using Fisher’s exact test requires counting all tables that have a probability exceeding that of the observed table given the observed row and column totals. The log counts down each stage of the network computations, starting from the number of columns and counting down to 1, displaying the number of nodes in the network at each stage. A log is not displayed for \( 2 \times 2 \) tables.

firstonly, available only with tab2, restricts the output to only those tables that include the first variable in varlist. Use this option to interact one variable with a set of others.

\[ \text{matcell(} \text{matname} \text{)} \] saves the reported frequencies in \text{matname}. This option is for use by programmers.

\[ \text{matrow(} \text{matname} \text{)} \] saves the numeric values of the \( r \times 1 \) row stub in \text{matname}. This option is for use by programmers. \text{matrow()} may not be specified if the row variable is a string.

\[ \text{matcol(} \text{matname} \text{)} \] saves the numeric values of the \( 1 \times c \) column stub in \text{matname}. This option is for use by programmers. \text{matcol()} may not be specified if the column variable is a string.

replace indicates that the immediate data specified as arguments to the tabi command be left as the current data in place of whatever data were there.

The following option is available with \text{tabulate} but is not shown in the dialog box:

\[ \text{all} \] is equivalent to specifying \text{chi2 lrchi2 V gamma taub}. Note the omission of \text{exact}. When \text{all} is specified, \text{no} may be placed in front of the other options. \text{all noV} requests all association measures except Cramér’s \( V \) (and Fisher’s exact). \text{all exact} requests all association measures, including Fisher’s exact test. \text{all} may not be specified if \text{aweights} or \text{iweights} are specified.

Limits

Two-way tables may have a maximum of 1,200 rows and 80 columns (Stata/MP and Stata/SE) or 300 rows and 20 columns (Stata/IC). If larger tables are needed, see [R] \text{table}.
Remarks and examples

Remarks are presented under the following headings:

- `tabulate`
- Measures of association
- N-way tables
- Weighted data
- Tables with immediate data
- `tab2`
- Video examples

For each value of a specified variable (or a set of values for a pair of variables), `tabulate` reports the number of observations with that value. The number of times a value occurs is called its `frequency`.

`tabulate` example

`tabulate` will make two-way tables if we specify two variables following the word `tabulate`. In our highway dataset, we have a variable called `rate` that divides the accident rate into three categories: below 4, 4–7, and above 7 per million vehicle miles. Let’s make a table of the speed limit category and the accident-rate category:

```
. use https://www.stata-press.com/data/r16/hiway2
   (Minnesota Highway Data, 1973)
. tabulate spdcat rate
```

<table>
<thead>
<tr>
<th>Speed Limit Category</th>
<th>Accident rate per million vehicle miles</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Below 4</td>
<td>4-7</td>
</tr>
<tr>
<td>40 to 50</td>
<td>3</td>
<td>5</td>
</tr>
<tr>
<td>55 to 50</td>
<td>19</td>
<td>6</td>
</tr>
<tr>
<td>Above 60</td>
<td>2</td>
<td>0</td>
</tr>
<tr>
<td>Total</td>
<td>24</td>
<td>11</td>
</tr>
</tbody>
</table>

The table indicates that three stretches of highway have an accident rate below 4 and a speed limit of 40 to 50 miles per hour. The table also shows the row and column sums (called the `marginals`). The number of highways with a speed limit of 40 to 50 miles per hour is 11, which is the same result we obtained in our previous one-way tabulations.

Stata can present this basic table in several ways—16, to be precise—and we will show just a few below. It might be easier to read the table if we included the row percentages. For instance, of 11 highways in the lowest speed limit category, three are also in the lowest accident-rate category. Three-elevenths amounts to some 27.3%. We can ask Stata to fill in this information for us by using the `row` option:
The number listed below each frequency is the percentage of cases that each cell represents out of its row. That is easy to remember because we see 100% listed in the “Total” column. The bottom row is also informative. We see that 61.54% of all the highways in our dataset fall into the lowest accident-rate category, that 28.21% are in the middle category, and that 10.26% are in the highest.

`tabulate` can calculate column percentages and cell percentages, as well. It does so when we specify the `column` or `cell` options, respectively. We can even specify them together. Below is a table that includes everything:

<table>
<thead>
<tr>
<th>Speed Limit Category</th>
<th>Accident rate per million vehicle miles</th>
<th></th>
<th></th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Below 4</td>
<td>4-7</td>
<td>Above 7</td>
<td></td>
</tr>
<tr>
<td>40 to 50</td>
<td>3</td>
<td>5</td>
<td>3</td>
<td>11</td>
</tr>
<tr>
<td></td>
<td>27.27</td>
<td>45.45</td>
<td>27.27</td>
<td>100.00</td>
</tr>
<tr>
<td>55 to 50</td>
<td>19</td>
<td>6</td>
<td>1</td>
<td>26</td>
</tr>
<tr>
<td></td>
<td>73.08</td>
<td>23.08</td>
<td>3.85</td>
<td>100.00</td>
</tr>
<tr>
<td>Above 60</td>
<td>2</td>
<td>0</td>
<td>0</td>
<td>2</td>
</tr>
<tr>
<td></td>
<td>100.00</td>
<td>0.00</td>
<td>0.00</td>
<td>100.00</td>
</tr>
<tr>
<td>Total</td>
<td>24</td>
<td>11</td>
<td>4</td>
<td>39</td>
</tr>
<tr>
<td></td>
<td>61.54</td>
<td>28.21</td>
<td>10.26</td>
<td>100.00</td>
</tr>
</tbody>
</table>
The number at the top of each cell is the frequency count. The second number is the row percentage—they sum to 100% going across the table. The third number is the column percentage—they sum to 100% going down the table. The bottom number is the cell percentage—they sum to 100% going down all the columns and across all the rows. For instance, highways with a speed limit above 60 miles per hour and in the lowest accident rate category account for 100% of highways with a speed limit above 60 miles per hour; 8.33% of highways in the lowest accident-rate category; and 5.13% of all our data.

A fourth option, nofreq, tells Stata not to print the frequency counts. To construct a table consisting of only row percentages, we type

```
.tabulate spdcat rate, row nofreq
```

---

<table>
<thead>
<tr>
<th>Speed Limit Category</th>
<th>Accident rate per million vehicle miles</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Below 4</td>
<td>4-7</td>
</tr>
<tr>
<td>40 to 50</td>
<td>27.27</td>
<td>45.45</td>
</tr>
<tr>
<td>55 to 50</td>
<td>73.08</td>
<td>23.08</td>
</tr>
<tr>
<td>Above 60</td>
<td>100.00</td>
<td>0.00</td>
</tr>
<tr>
<td>Total</td>
<td>61.54</td>
<td>28.21</td>
</tr>
</tbody>
</table>
Measures of association

Example 2

tabulate will calculate the Pearson $\chi^2$ test for the independence of the rows and columns if we specify the chi2 option. Suppose that we have 1980 census data on 956 cities in the United States and wish to compare the age distribution across regions of the country. Assume that agecat is the median age in each city and that region denotes the region of the country in which the city is located.

```

</tbody>
</table>

Pearson chi2(6) = 61.2877 Pr = 0.000

We obtain the standard two-way table and, at the bottom, a summary of the $\chi^2$ test. Stata informs us that the $\chi^2$ associated with this table has 6 degrees of freedom and is 61.29. The observed differences are significant.

The table is, perhaps, easier to understand if we suppress the frequencies and print just the row percentages:

```
tabulate region agecat, row nofreq chi2
```

<table>
<thead>
<tr>
<th>Census Region</th>
<th>19-29</th>
<th>30-34</th>

</tbody>
</table>

Pearson chi2(6) = 61.2877 Pr = 0.000

Example 3

We have data on dose level and outcome for a set of patients and wish to evaluate the association between the two variables. We can obtain all the association measures by specifying the all and exact options:
. use https://www.stata-press.com/data/r16/dose
. tabulate dose function, all exact

Enumerating sample-space combinations:
  stage 3: enumerations = 1
  stage 2: enumerations = 9
  stage 1: enumerations = 0

<table>
<thead>
<tr>
<th>Dosage</th>
<th>Function</th>
<th>&lt; 1 hr</th>
<th>1 to 4</th>
<th>4+</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>1/day</td>
<td></td>
<td>20</td>
<td>10</td>
<td>2</td>
<td>32</td>
</tr>
<tr>
<td>2/day</td>
<td></td>
<td>16</td>
<td>12</td>
<td>4</td>
<td>32</td>
</tr>
<tr>
<td>3/day</td>
<td></td>
<td>10</td>
<td>16</td>
<td>6</td>
<td>32</td>
</tr>
<tr>
<td>Total</td>
<td></td>
<td>46</td>
<td>38</td>
<td>12</td>
<td>96</td>
</tr>
</tbody>
</table>

Pearson chi2(4) = 6.7780 Pr = 0.148
likelihood-ratio chi2(4) = 6.9844 Pr = 0.137
Cramér’s V = 0.1879
        gamma = 0.3689 ASE = 0.129
        Kendall’s tau-b = 0.2378 ASE = 0.086
        Fisher’s exact = 0.145

We find evidence of association but not enough to be truly convincing.

If we had not also specified the exact option, we would not have obtained Fisher’s exact test. Stata can calculate this statistic both for $2 \times 2$ tables and for $r \times c$. For $2 \times 2$ tables, the calculation is almost instant. On more general tables, however, the calculation can take longer.

We carefully constructed our example so that all would be meaningful. Kendall’s $\tau_b$ and Goodman and Kruskal’s gamma are relevant only when both dimensions of the table can be ordered, say, from low to high or from worst to best. The other statistics, however, are always applicable.

?? Technical note

Be careful when attempting to compute the $p$-value for Fisher’s exact test because the number of tables that contribute to the $p$-value can be extremely large and a solution may not be feasible. The errors that are indicative of this situation are errors 910, exceeded memory limitations, and 1401, integer overflow due to large row-margin frequencies. If execution terminates because of memory limitations, use `exact(2)` to permit the algorithm to consume twice the memory, `exact(3)` for three times the memory, etc. The default memory usage should be sufficient for reasonable tables.

??

N-way tables

If you need more than two-way tables, your best alternative to is use `table`, not `tabulate`; see [R] `table`.

The technical note below shows you how to use `tabulate` to create a sequence of two-way tables that together form, in effect, a three-way table, but using `table` is easy and produces prettier results:
We can make $n$-way tables by combining the `by varlist:` prefix with `tabulate`. Continuing with the dataset of 956 cities, say that we want to make a table of age category by birth-rate category by region of the country. The birth-rate category variable is named `birthcat` in our dataset. To make separate tables for each age category, we would type

```
. by agecat, sort: tabulate birthcat region
```

### Technical note

```
<table>
<thead>
<tr>
<th>birthcat</th>
<th>agecat and Census Region</th>
<th>19-29</th>
<th>30-34</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>

</tbody>
</table>
```

```
Total | 83 | 88 | 67 | 71 | 309
```
Weighted data

Example 4

tabulate can process weighted as well as unweighted data. As with all Stata commands, we indicate the weight by specifying the [weight] modifier; see [U] 11.1.6 weight.

Continuing with our dataset of 956 cities, we also have a variable called pop, the population of each city. We can make a table of region by age category, weighted by population, by typing

```
.tabulate region agecat [freq=pop]
```

<table>
<thead>
<tr>
<th>Census Region</th>
<th>19-29</th>
<th>30-34</th>
<th>35+</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>NE</td>
<td>4721387</td>
<td>10421387</td>
<td>5323610</td>
<td>20466384</td>
</tr>
<tr>
<td>N Ctrl</td>
<td>16901550</td>
<td>8964756</td>
<td>4015593</td>
<td>29881899</td>
</tr>
<tr>
<td>South</td>
<td>13894254</td>
<td>7686531</td>
<td>4141863</td>
<td>25722648</td>
</tr>
<tr>
<td>West</td>
<td>16698276</td>
<td>7755255</td>
<td>2375118</td>
<td>26828649</td>
</tr>
<tr>
<td>Total</td>
<td>52215467</td>
<td>34827929</td>
<td>15856184</td>
<td>102899580</td>
</tr>
</tbody>
</table>

If we specify the cell, column, or row options, they will also be appropriately weighted. Below we repeat the table, suppressing the counts and substituting row percentages:

```
.tabulate region agecat [freq=pop], nofreq row
```

<table>
<thead>
<tr>
<th>Census Region</th>
<th>19-29</th>
<th>30-34</th>
<th>35+</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>NE</td>
<td>23.07</td>
<td>50.92</td>
<td>26.01</td>
<td>100.00</td>
</tr>
<tr>
<td>N Ctrl</td>
<td>56.56</td>
<td>30.00</td>
<td>13.44</td>
<td>100.00</td>
</tr>
<tr>
<td>South</td>
<td>54.02</td>
<td>29.88</td>
<td>16.10</td>
<td>100.00</td>
</tr>
<tr>
<td>West</td>
<td>62.24</td>
<td>28.91</td>
<td>8.85</td>
<td>100.00</td>
</tr>
<tr>
<td>Total</td>
<td>50.74</td>
<td>33.85</td>
<td>15.41</td>
<td>100.00</td>
</tr>
</tbody>
</table>
Tables with immediate data

Example 5

`tabi` ignores the dataset in memory and uses as the table the values that we specify on the command line:

```
. tabi 30 18 \ 38 14
```

<table>
<thead>
<tr>
<th>row</th>
<th>1</th>
<th>2</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>30</td>
<td>18</td>
<td>48</td>
</tr>
<tr>
<td>2</td>
<td>38</td>
<td>14</td>
<td>52</td>
</tr>
</tbody>
</table>

Total | 68 | 32 | 100 |

Fisher's exact = 0.289
1-sided Fisher's exact = 0.179

We may specify any of the options of `tabulate` and are not limited to $2 \times 2$ tables:

```
. tabi 30 18 38 \ 13 7 22, chi2 exact
```

Enumerating sample-space combinations:
stage 3: enumerations = 1
stage 2: enumerations = 3
stage 1: enumerations = 0

<table>
<thead>
<tr>
<th>row</th>
<th>1</th>
<th>2</th>
<th>3</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>30</td>
<td>18</td>
<td>38</td>
<td>86</td>
</tr>
<tr>
<td>2</td>
<td>13</td>
<td>7</td>
<td>22</td>
<td>42</td>
</tr>
</tbody>
</table>

Total | 43 | 25 | 60 | 128 |

Pearson chi2(2) = 0.7967 Pr = 0.671
Fisher's exact = 0.707

```
. tabi 30 13 \ 18 7 \ 38 22, all exact col
```

<table>
<thead>
<tr>
<th>row</th>
<th>1</th>
<th>2</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>30</td>
<td>13</td>
<td>43</td>
</tr>
<tr>
<td>2</td>
<td>18</td>
<td>7</td>
<td>25</td>
</tr>
<tr>
<td>3</td>
<td>38</td>
<td>22</td>
<td>60</td>
</tr>
</tbody>
</table>

Total | 86 | 42 | 128 |

100.00 100.00 100.00
Pearson chi²(2) = 0.7967  Pr = 0.671
likelihood-ratio chi²(2) = 0.7985  Pr = 0.671
Cramr’s V = 0.0789
gamma = 0.1204  ASE = 0.160
Kendall’s tau-b = 0.0630  ASE = 0.084
Fisher’s exact = 0.707

For 2 × 2 tables, both one- and two-sided Fisher’s exact probabilities are displayed; this is true of both `tabulate` and `tabi`. See `Cumulative incidence data` and `Case–control data` in [R] `Epitab` for more discussion on the relationship between one- and two-sided probabilities.

## Technical note

`tabi`, as with all immediate commands, leaves any data in memory undisturbed. With the `replace` option, however, the data in memory are replaced by the data from the table:

```
. tabi 30 18 \ 38 14, replace
```

```
row | col
---|---
1  | 30 18  48
2  | 38 14  52
```

```
Fisher's exact = 0.289
1-sided Fisher's exact = 0.179
```

```
. list
```

```
<table>
<thead>
<tr>
<th>row</th>
<th>col</th>
<th>pop</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>1</td>
<td>30</td>
</tr>
<tr>
<td>2</td>
<td>2</td>
<td>18</td>
</tr>
<tr>
<td>3</td>
<td>2</td>
<td>38</td>
</tr>
<tr>
<td>4</td>
<td>2</td>
<td>14</td>
</tr>
</tbody>
</table>
```

With this dataset, you could re-create the above table by typing

```
. tabulate row col [freq=pop], exact
```

```
row | col
---|---
1  | 30 18  48
2  | 38 14  52
```

```
Fisher's exact = 0.289
1-sided Fisher's exact = 0.179
```
**tab2**

`tab2` is a convenience tool. Typing

```
.tab2 myvar thisvar thatvar, chi2
```

is equivalent to typing

```
.tabulate myvar thisvar, chi2
.tabulate myvar thatvar, chi2
.tabulate thisvar thatvar, chi2
```

**Video examples**

Pearson’s chi2 and Fisher’s exact test in Stata

Tables and cross-tabulations in Stata

Cross-tabulations and chi-squared tests calculator

**Stored results**

`tabulate`, `tab2`, and `tabi` store the following in `r()`:

Scalars

- `r(N)` number of observations
- `r(r)` number of rows
- `r(c)` number of columns
- `r(chi2)` Pearson’s $\chi^2$
- `r(p)` $p$-value for of Pearson’s $\chi^2$ test
- `r(gamma)` gamma
- `r(p1_exact)` one-sided Fisher’s exact $p$
- `r(chi2_lr)` likelihood-ratio $\chi^2$
- `r(p_lr)` $p$-value for likelihood-ratio test
- `r(CramersV)` Cramér’s V
- `r(ase_gam)` ASE of gamma
- `r(taub)` ASE of $\tau_b$
- `r(p1_exact)` is defined only for $2 \times 2$ tables. Also, the `matrow()`, `matcol()`, and `matcell()` options allow you to obtain the row values, column values, and frequencies, respectively.

**Methods and formulas**

Let $n_{ij}$, $i = 1, \ldots, I$ and $j = 1, \ldots, J$, be the number of observations in the $i$th row and $j$th column. If the data are not weighted, $n_{ij}$ is just a count. If the data are weighted, $n_{ij}$ is the sum of the weights of all data corresponding to the $(i, j)$ cell.

Define the row and column marginals as

$$n_{i.} = \sum_{j=1}^{J} n_{ij} \quad \text{and} \quad n_{.j} = \sum_{i=1}^{I} n_{ij}$$

and let $n = \sum_{i} \sum_{j} n_{ij}$ be the overall sum. Also, define the concordance and discordance as

$$A_{ij} = \sum_{k>i} \sum_{l>j} n_{kl} + \sum_{k<i} \sum_{l<j} n_{kl} \quad \text{and} \quad D_{ij} = \sum_{k>i} \sum_{l<j} n_{kl} + \sum_{k<i} \sum_{l>j} n_{kl}$$

along with twice the number of concordances $P = \sum_{i} \sum_{j} n_{ij} A_{ij}$ and twice the number of discordances $Q = \sum_{i} \sum_{j} n_{ij} D_{ij}$. 
The Pearson $\chi^2$ statistic with $(I - 1)(J - 1)$ degrees of freedom (so called because it is based on Pearson (1900); see Conover [1999, 240] and Fienberg [1980, 9]) is defined as

$$X^2 = \sum_{i} \sum_{j} \frac{(n_{ij} - m_{ij})^2}{m_{ij}}$$

where $m_{ij} = n_i n_j / n$.

The likelihood-ratio $\chi^2$ statistic with $(I - 1)(J - 1)$ degrees of freedom (Fienberg 1980, 40) is defined as

$$G^2 = 2 \sum_{i} \sum_{j} n_{ij} \ln(n_{ij}/m_{ij})$$

Cramér’s $V$ (Cramér 1946) is a measure of association designed so that the attainable upper bound is 1. For $2 \times 2$ tables, $-1 \leq V \leq 1$, and otherwise, $0 \leq V \leq 1$.

$$V = \begin{cases} 
\frac{(n_{11}n_{22} - n_{12}n_{21})/(n_1 n_2 n_3 n_4)^{1/2}}{\min(I - 1, J - 1)} & \text{for } 2 \times 2 \\
\{(X^2/n)/\min(I - 1, J - 1)\}^{1/2} & \text{otherwise}
\end{cases}$$

Gamma (Goodman and Kruskal 1954, 1959, 1963, 1972; also see Agresti [2010,186–188]) ignores tied pairs and is based only on the number of concordant and discordant pairs of observations, $-1 \leq \gamma \leq 1$,

$$\gamma = (P - Q)/(P + Q)$$

with asymptotic variance

$$16 \sum_{i} \sum_{j} n_{ij} (QA_{ij} - PD_{ij})^2/(P + Q)^4$$

Kendall’s $\tau_b$ (Kendall 1945; also see Agresti 2010, 188–189), $-1 \leq \tau_b \leq 1$, is similar to gamma, except that it uses a correction for ties,

$$\tau_b = (P - Q)/(w_r w_c)^{1/2}$$

with asymptotic variance

$$\frac{\sum_{i} \sum_{j} n_{ij}(2w_r w_c d_{ij} + \tau_b v_{ij})^2 - n^3 \tau_b^2 (w_r + w_c)^2}{(w_r w_c)^4}$$
where

\[w_r = n^2 - \sum_i n_i^2,\]
\[w_c = n^2 - \sum_j n_j^2,\]
\[d_{ij} = A_{ij} - D_{ij},\]
\[v_{ij} = n_i w_c + n_j w_r,\]

Fisher’s exact test (Fisher 1935; Finney 1948; see Zelterman and Louis [1992, 293–301] for the 2 × 2 case) yields the probability of observing a table that gives at least as much evidence of association as the one actually observed under the assumption of no association. Holding row and column marginals fixed, the hypergeometric probability \( P \) of every possible table \( A \) is computed, and the

\[P = \sum_{T \in A} \Pr(T)\]

where \( A \) is the set of all tables with the same marginals as the observed table, \( T^* \), such that \( \Pr(T) \leq \Pr(T^*) \). For 2 × 2 tables, the one-sided probability is calculated by further restricting \( A \) to tables in the same tail as \( T^* \). The first algorithm extending this calculation to \( r \times c \) tables was Pagano and Halvorsen (1981); the one implemented here is the FEXACT algorithm by Mehta and Patel (1986). This is a search-tree clipping method originally published by Mehta and Patel (1983) with further refinements by Joe (1988) and Clarkson, Fan, and Joe (1993). Fisher’s exact test is a permutation test. For more information on permutation tests, see Good (2005 and 2006) and Pesarin (2001).

tabulate, summarize() — One- and two-way tables of summary statistics

Description

`tabulate, summarize()` produces one- and two-way tables (breakdowns) of means and standard deviations. See [R] `tabulate oneway` and [R] `tabulate twoway` for one- and two-way frequency tables. See [R] `table` for a more flexible command that produces one-, two-, and $n$-way tables of frequencies and a wide variety of summary statistics. `table` is better, but `tabulate, summarize()` is faster. Also see [R] `tabstat` for yet another alternative.

Quick start

Tabulation of `v1`, reporting means and standard deviations of `x` and frequencies

```
tabulate v1, summarize(x)
```

As above, but report summary statistics for the two-way tabulation of `v1` and `v2`

```
tabulate v1 v2, summarize(x)
```

Weighted summary statistics using frequency weight `wvar`

```
tabulate v1 v2 [fweight=wvar], summarize(x)
```

Report only the mean of `x` for each group

```
tabulate v1 v2, summarize(x) means
```

Do not report standard deviations

```
tabulate v1 v2, summarize(x) nostandard
```

Show numeric values of `v1` and `v2` rather than value labels

```
tabulate v1 v2, summarize(x) nolabel
```

Menu

Statistics > Summaries, tables, and tests > Other tables > Table of means, std. dev., and frequencies
tabulate varname1 [varname2] [if] [in] [weight] [, options]

options Description

Main
summarize(varname3) report summary statistics for varname3
[no]means include or suppress means
[no]standard include or suppress standard deviations
[no]freq include or suppress frequencies
[no]obs include or suppress number of observations
nolabel show numeric codes, not labels
wrap do not break wide tables
missing treat missing values of varname1 and varname2 as categories

by is allowed; see [D] by.
aweights and fweights are allowed; see [U] 11.1.6 weight.

Options

summarize(varname3) identifies the name of the variable for which summary statistics are to be reported. If you do not specify this option, a table of frequencies is produced; see [R] tabulate oneway and [R] tabulate twoway. The description here concerns tabulate when this option is specified.

[no]means includes or suppresses only the means from the table.

The summarize() table normally includes the mean, standard deviation, frequency, and, if the data are weighted, number of observations. Individual elements of the table may be included or suppressed by the [no]means, [no]standard, [no]freq, and [no]obs options. For example, typing

.tabulate category, summarize(myvar) means standard

produces a summary table by category containing only the means and standard deviations of myvar. You could also achieve the same result by typing

.tabulate category, summarize(myvar) nofreq

[no]standard includes or suppresses only the standard deviations from the table; see [no]means option above.

[no]freq includes or suppresses only the frequencies from the table; see [no]means option above.

[no]obs includes or suppresses only the reported number of observations from the table. If the data are not weighted, the number of observations is identical to the frequency, and by default only the frequency is reported. If the data are weighted, the frequency refers to the sum of the weights. See [no]means option above.

nolabel causes the numeric codes to be displayed rather than the label values.

wrap requests that no action be taken on wide tables to make them readable. Unless wrap is specified, wide tables are broken into pieces to enhance readability.

missing requests that missing values of varname1 and varname2 be treated as categories rather than as observations to be omitted from the analysis.
Remarks and examples

`tabulate` with the `summarize()` option produces one- and two-way tables of summary statistics. When combined with the `by` prefix, it can produce `n`-way tables as well.

Remarks are presented under the following headings:

*One-way tables*

*Two-way tables*

One-way tables

Example 1

We have data on 74 automobiles. Included in our dataset are the variables `foreign`, which marks domestic and foreign cars, and `mpg`, the car’s mileage rating. Typing `tabulate foreign` displays a breakdown of the number of observations we have by the values of the `foreign` variable.

```
. use https://www.stata-press.com/data/r16/auto
   (1978 Automobile Data)
. tabulate foreign

<table>
<thead>
<tr>
<th>Car type</th>
<th>Freq.</th>
<th>Percent</th>
<th>Cum.</th>
</tr>
</thead>
<tbody>
<tr>
<td>Domestic</td>
<td>52</td>
<td>70.27%</td>
<td>70.27%</td>
</tr>
</tbody>
</table>
| Foreign  | 22    | 29.73%  | 100.00%

```

We discover that we have 52 domestic cars and 22 foreign cars in our dataset. If we add the `summarize(`varname`)` option, however, `tabulate` produces a table of summary statistics for `varname`:

```
. tabulate foreign, summarize(mpg)

<table>
<thead>
<tr>
<th>Car type</th>
<th>Summary of Mileage (mpg)</th>
<th>Freq.</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Mean</td>
<td>Std. Dev.</td>
</tr>
<tr>
<td>Domestic</td>
<td>19.826923</td>
<td>4.7432972</td>
</tr>
<tr>
<td>Foreign</td>
<td>24.772727</td>
<td>6.6111869</td>
</tr>
<tr>
<td>Total</td>
<td>21.297297</td>
<td>5.7855032</td>
</tr>
</tbody>
</table>
```

We also discover that the average gas mileage for domestic cars is about 20 mpg and the average foreign is almost 25 mpg. Overall, the average is 21 mpg in our dataset.

Technical note

We might now wonder if the difference in gas mileage between foreign and domestic cars is statistically significant. We can use the `oneway` command to find out; see [R] oneway. To obtain an analysis-of-variance table of `mpg` on `foreign`, we type

```
. oneway mpg foreign

<table>
<thead>
<tr>
<th>Source</th>
<th>Analysis of Variance</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>SS</td>
</tr>
<tr>
<td>Between groups</td>
<td>378.153515</td>
</tr>
<tr>
<td>Within groups</td>
<td>2065.30594</td>
</tr>
<tr>
<td>Total</td>
<td>2443.45946</td>
</tr>
</tbody>
</table>

Bartlett’s test for equal variances: `chi2(1) = 3.4818` Prob>chi2 = 0.062
```
The $F$ statistic is 13.18, and the difference between foreign and domestic cars’ mileage ratings is significant at the 0.05% level.

There are several ways that we could have statistically compared mileage ratings—see, for instance, \texttt{[R] anova}, \texttt{[R] oneway}, \texttt{[R] regress}, and \texttt{[R] ttest}—but \texttt{oneway} seemed the most convenient.

---

### Two-way tables

#### Example 2

\texttt{tabulate, summarize} can be used to obtain two-way as well as one-way breakdowns. For instance, we obtained summary statistics on \texttt{mpg} decomposed by \texttt{foreign} by typing \texttt{tabulate foreign, summarize(mpg)}. We can specify up to two variables before the comma:

\begin{verbatim}
. generate wgtcat = autocode(weight,4,1760,4840)
. tabulate wgtcat foreign, summarize(mpg)
\end{verbatim}

<table>
<thead>
<tr>
<th>wgtcat</th>
<th>Car type</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>Domestic</td>
</tr>
<tr>
<td>2530</td>
<td>28.285714</td>
</tr>
<tr>
<td></td>
<td>3.0937725</td>
</tr>
<tr>
<td></td>
<td>7</td>
</tr>
<tr>
<td>3300</td>
<td>21.75</td>
</tr>
<tr>
<td></td>
<td>2.4083189</td>
</tr>
<tr>
<td></td>
<td>16</td>
</tr>
<tr>
<td>4070</td>
<td>17.26087</td>
</tr>
<tr>
<td></td>
<td>1.8639497</td>
</tr>
<tr>
<td></td>
<td>23</td>
</tr>
<tr>
<td>4840</td>
<td>14.666667</td>
</tr>
<tr>
<td></td>
<td>3.32666</td>
</tr>
<tr>
<td></td>
<td>6</td>
</tr>
<tr>
<td>Total</td>
<td>19.826923</td>
</tr>
<tr>
<td></td>
<td>4.7432972</td>
</tr>
<tr>
<td></td>
<td>52</td>
</tr>
</tbody>
</table>

In addition to the means, standard deviations, and frequencies for each weight–mileage cell, also reported are the summary statistics by weight, by mileage, and overall. For instance, the last row of the table reveals that the average mileage of domestic cars is 19.83 and that of foreign cars is 24.77—domestic cars yield poorer mileage than foreign cars. But we now see that domestic cars yield better gas mileage within weight class—the reason domestic cars yield poorer gas mileage is because they are, on average, heavier.

#### Example 3

If we do not specify the statistics to be included in a table, \texttt{tabulate} reports the mean, standard deviation, and frequency. We can specify the statistics that we want to see using the \texttt{means}, \texttt{standard}, and \texttt{freq} options:
. tabulate wgtcat foreign, summarize(mpg) means

Means of Mileage (mpg)

<table>
<thead>
<tr>
<th>Car type</th>
<th>Domestic</th>
<th>Foreign</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>25.30</td>
<td>28.285714</td>
<td>27.0625</td>
</tr>
<tr>
<td></td>
<td>33.00</td>
<td>21.75</td>
<td>19.6</td>
</tr>
<tr>
<td></td>
<td>40.70</td>
<td>17.26087</td>
<td>14</td>
</tr>
<tr>
<td></td>
<td>48.40</td>
<td>14.66667</td>
<td>.</td>
</tr>
<tr>
<td>Total</td>
<td>19.826923</td>
<td>24.772727</td>
<td>21.297297</td>
</tr>
</tbody>
</table>

When we specify one or more of the means, standard, and freq options, only those statistics are displayed. Thus we could obtain a table containing just the means and standard deviations by typing means standard after the summarize(mpg) option. We can also suppress selected statistics by placing no in front of the option name. Another way of obtaining only the means and standard deviations is to add the nofreq option:

. tabulate wgtcat foreign, summarize(mpg) nofreq

Means and Standard Deviations of Mileage (mpg)

<table>
<thead>
<tr>
<th>Car type</th>
<th>Domestic</th>
<th>Foreign</th>
<th>Total</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>25.30</td>
<td>28.285714</td>
<td>27.0625</td>
</tr>
<tr>
<td></td>
<td>33.00</td>
<td>21.75</td>
<td>19.6</td>
</tr>
<tr>
<td></td>
<td>40.70</td>
<td>17.26087</td>
<td>14</td>
</tr>
<tr>
<td></td>
<td>48.40</td>
<td>14.66667</td>
<td>.</td>
</tr>
<tr>
<td>Total</td>
<td>19.826923</td>
<td>24.772727</td>
<td>21.297297</td>
</tr>
</tbody>
</table>

Description

test performs Wald tests of simple and composite linear hypotheses about the parameters of the most recently fit model.

test supports svy estimators (see [SVY] svy estimation), carrying out an adjusted Wald test by default in such cases. test can be used with svy estimation results, see [SVY] svy postestimation.

testparm provides a useful alternative to test that permits varlist rather than a list of coefficients (which is often nothing more than a list of variables), allowing the use of standard Stata notation, including ‘−’ and ‘∗’, which are given the expression interpretation by test.

test and testparm perform Wald tests. For likelihood-ratio tests, see [R] lrtest. For Wald-type tests of nonlinear hypotheses, see [R] testnl. To display estimates for one-dimensional linear or nonlinear expressions of coefficients, see [R] lincom and [R] nlcom.

See [R] anova postestimation for additional test syntax allowed after anova.
See [MV] manova postestimation for additional test syntax allowed after manova.

Quick start

Linear tests after single-equation models

Joint test that the coefficients on x1 and x2 are equal to 0

test x1 x2

Joint test that coefficients on factor indicators 2.a and 3.a are equal to 0

test 2.a 3.a

Test that coefficients on indicators 2.a and 3.a are equal

test 2.a = 3.a

Joint test that coefficients on indicators 1.a, 2.a, and 3.a are all equal

test (1.a=2.a) (1.a=3.a)

Same as above

test 1.a=2.a=3.a

As above, but add separate tests for each pairing

test 1.a=2.a=3.a, mtest

As above, but with p-values adjusted for multiple comparisons using Šidák’s method

test (1.a=2.a) (1.a=3.a), mtest(sidak)
Test that the sum of the coefficients for \( x_1 \) and \( x_2 \) is equal to 4
\[
\text{test } x_1 + x_2 = 4
\]

Test the equality of two linear expressions involving coefficients on \( x_1 \) and \( x_2 \)
\[
\text{test } 2x_1 = 3x_2
\]

**Shorthand varlist notation**

Joint test that all coefficients on the indicators for \( a \) are equal to 0
\[
\text{testparm i.a}
\]

Joint test that all coefficients on the indicators for \( a \) and \( b \) are equal to 0
\[
\text{testparm i.a i.b}
\]

Joint test that all coefficients associated with the interaction of factor variables \( a \) and \( b \) are equal to 0
\[
\text{testparm i.a#i.b}
\]

Joint test that the coefficients on all variables \( x^* \) are equal to 0
\[
\text{testparm x*}
\]

**Linear tests after multiple-equation models**

Joint test that the coefficient on \( x_1 \) is equal to 0 in all equations
\[
\text{test } x_1
\]

Joint test that the coefficients for \( x_1 \) and \( x_2 \) are equal to 0 in equation \( y_3 \)
\[
\text{test } [y_3]x_1 [y_3]x_2
\]

Test that the coefficients for \( x_1 \) are equal in equations \( y_1 \) and \( y_3 \)
\[
\text{test } [y_1]x_1=[y_3]x_1
\]

Same as above
\[
\text{test } [y_1=y_3]: x_1
\]

Joint test of the equality of coefficients for \( x_1 \) and \( x_2 \) across equations \( y_1 \) and \( y_3 \)
\[
\text{test } [y_1=y_3]: x_1 x_2
\]

Add coefficients for \( x_1 \) and \( x_2 \) from equation \( y_4 \) to test
\[
\text{test } [y_1=y_3=y_4]: x_1 x_2
\]

Test that all coefficients in the equation for \( y_1 \) are equal to those in the equation for \( y_2 \)
\[
\text{test } [y_1=y_2]
\]

As above, but only for coefficients on variables common to both equations
\[
\text{test } [y_1=y_2], \text{ common}
\]
Shorthand `varlist` notation

Joint test that all coefficients on the indicators for `a` are 0 in all equations
```
testparm i.a
```

Joint test that all coefficients on the indicators for `a` are equal to each other in the first equation
```
testparm i.a, equal
```

As above, but for the equation for `y4`
```
testparm i.a, equal equation(y4)
```

Joint test that the coefficients on the indicators for `a` and `b` are equal to 0 in all equations
```
testparm i.a i.b
```

Joint test that all coefficients associated with the interaction of factors `a` and `b` are 0
```
testparm i.a#i.b
```

</tbody>
</table>

`coeflist` and `varlist` may contain factor variables and time-series operators; see [U] 11.4.3 Factor variables and [U] 11.4.4 Time-series varlists.

matvlc(matname) and df(#) do not appear in the dialog box.
Syntax 1 tests that coefficients are 0.
Syntax 2 tests that linear expressions are equal.
Syntax 3 tests that coefficients in \textit{eqno} are 0.
Syntax 4 tests equality of coefficients between equations.

\textit{spec} is one of

\begin{verbatim}
  coeflist
  \hspace{1em} exp=exp[=exp]
  \hspace{1em} [eqno] [ : coeflist]
  \hspace{1em} [eqno_1=eqno_2 [=\ldots ] ] [ : coeflist]
\end{verbatim}

\textit{coeflist} is

\begin{verbatim}
  coef [ coef \ldots ]
  \hspace{1em} [eqno] coef \hspace{1em} [ [eqno] coef \ldots ]
  \hspace{1em} [eqno] _b[coef] \hspace{1em} [ [eqno] _b[coef] \ldots ]
\end{verbatim}

\textit{exp} is a linear expression containing

\begin{verbatim}
  coef
  \hspace{1em} _b[coef]
  \hspace{1em} _b[eqno:coef]
  \hspace{1em} [eqno] coef
  \hspace{1em} [eqno] _b[coef]
\end{verbatim}

\textit{eqno} is

\begin{verbatim}
  ##
  name
\end{verbatim}

\textit{coef} identifies a coefficient in the model. \textit{coef} is typically a variable name, a level indicator, an interaction indicator, or an interaction involving continuous variables. Level indicators identify one level of a factor variable and interaction indicators identify one combination of levels of an interaction; see \cite{U} \texttt{11.4.3 Factor variables}. \textit{coef} may contain time-series operators; see \cite{U} \texttt{11.4.4 Time-series varlists}.

Distinguish between [], which are to be typed, and [], which indicate optional arguments.

Although not shown in the syntax diagram, parentheses around \textit{spec} are required only with multiple specifications. Also, the diagram does not show that \texttt{test} may be called without arguments to redisplay the results from the last \texttt{test}.

\texttt{anova} and \texttt{manova} (see \cite{R} \texttt{anova} and \cite{MV} \texttt{manova}) allow the \texttt{test} syntax above plus more (see \cite{R} \texttt{anova postestimation} for \texttt{test} after \texttt{anova}; see \cite{MV} \texttt{manova postestimation} for \texttt{test} after \texttt{manova}).

**Options for testparm**

\texttt{equal} tests that the variables appearing in \texttt{varlist}, which also appear in the previously fit model, are equal to each other rather than jointly equal to zero.
equation(eqno) is relevant only for multiple-equation models, such as mvreg, mlogit, and heckman. It specifies the equation for which the all-zero or all-equal hypothesis is tested. equation(#1) specifies that the test be conducted regarding the first equation #1. equation(price) specifies that the test concern the equation named price.

nosvyadjust is for use with svy estimation commands; see [SVY] svy estimation. It specifies that the Wald test be carried out without the default adjustment for the design degrees of freedom. That is, the test is carried out as $W/k \sim F(k, d)$ rather than as $(d - k + 1)W/(kd) \sim F(k, d - k + 1)$, where $k =$ the dimension of the test and $d =$ the total number of sampled PSUs minus the total number of strata. When the df() option is used, it will override the default design degrees of freedom.

The following option is available with testparm but is not shown in the dialog box:

df(#) specifies that the $F$ distribution with # denominator degrees of freedom be used for the reference distribution of the test statistic. The default is to use $e(df_r)$ degrees of freedom or the chi-squared distribution if $e(df_r)$ is missing. With survey data, # is the design degrees of freedom unless nosvyadjust is specified.

Options for test

---

**Options**

mtest[(opt)] specifies that tests be performed for each condition separately. opt specifies the method for adjusting $p$-values for multiple testing. Valid values for opt are

- bonferroni: Bonferroni’s method
- holm: Holm’s method
- sidak: Šidák’s method
- noadjust: no adjustment is to be made

Specifying mtest without an argument is equivalent to mtest(noadjust).

coef specifies that the constrained coefficients be displayed.

accumulate allows a hypothesis to be tested jointly with the previously tested hypotheses.

notest suppresses the output. This option is useful when you are interested only in the joint test of several hypotheses, specified in a subsequent call of test, accumulate.

common specifies that when you use the [eqno1=eqno2[]=…] form of spec, the variables common to the equations eqno1, eqno2, etc., be tested. The default action is to complain if the equations have variables not in common.

constant specifies that _cons be included in the list of coefficients to be tested when using the [eqno1=eqno2[]=…] or [eqno] forms of spec. The default is not to include _cons.

nosvyadjust is for use with svy estimation commands; see [SVY] svy estimation. It specifies that the Wald test be carried out without the default adjustment for the design degrees of freedom. That is, the test is carried out as $W/k \sim F(k, d)$ rather than as $(d - k + 1)W/(kd) \sim F(k, d - k + 1)$, where $k =$ the dimension of the test and $d =$ the total number of sampled PSUs minus the total number of strata. When the df() option is used, it will override the default design degrees of freedom.
minimum is a highly technical option. It first performs the test with the constant added. If this test is singular, coefficients are dropped until the test becomes nonsingular. Then the test without the constant is performed with the remaining terms.

The following options are available with test but are not shown in the dialog box:

\texttt{matvcl(matname)} , a programmer’s option, saves the variance–covariance matrix of the linear combinations involved in the suite of tests. For the test of the linear constraints $Lb = c$, \texttt{matname} contains $LVL'$, where $V$ is the estimated variance–covariance matrix of $b$.

\texttt{df(#)} specifies that the $F$ distribution with # denominator degrees of freedom be used for the reference distribution of the test statistic. The default is to use $e(df_r)$ degrees of freedom or the chi-squared distribution if $e(df_r)$ is missing. With survey data, # is the design degrees of freedom unless \texttt{nosvyadjust} is specified.

### Remarks and examples

Remarks are presented under the following headings:

- Introductory examples
- Special syntaxes after multiple-equation estimation
- Constrained coefficients
- Multiple testing

#### Introductory examples

\texttt{test} performs $F$ or $\chi^2$ tests of linear restrictions applied to the most recently fit model (for example, \texttt{regress} or \texttt{svy: regress} in the linear regression case; \texttt{logit}, \texttt{stcox}, \texttt{svy: logit}, ... in the single-equation maximum-likelihood case; and \texttt{mlogit}, \texttt{mvreg}, \texttt{streg}, ... in the multiple-equation maximum-likelihood case). \texttt{test} may be used after any estimation command, although for maximum likelihood techniques, \texttt{test} produces a Wald test that depends only on the estimate of the covariance matrix—you may prefer to use the more computationally expensive likelihood-ratio test; see \texttt{[U] 20 Estimation and postestimation commands} and \texttt{[R] lrtest}.

There are several variations on the syntax for \texttt{test}. The second syntax,

\texttt{test exp=exp[=...]} 

is allowed after any form of estimation. After fitting a model of \texttt{depvar} on \texttt{x1}, \texttt{x2}, and \texttt{x3}, typing \texttt{test x1+x2=x3} tests the restriction that the coefficients on \texttt{x1} and \texttt{x2} sum to the coefficient on \texttt{x3}. The expressions can be arbitrarily complicated; for instance, typing \texttt{test x1+2*(x2+x3)=x2+3*x3} is the same as typing \texttt{test x1+x2=x3}.

As a convenient shorthand, \texttt{test} also allows you to specify equality for multiple expressions; for example, \texttt{test x1+x2 = x3+x4 = x5+x6} tests that the three specified pairwise sums of coefficients are equal.

\texttt{test} understands that when you type \texttt{x1}, you are referring to the coefficient on \texttt{x1}. You could also more explicitly type \texttt{test _b[x1]+_b[x2]=_b[x3]}; or you could \texttt{test _coef[x1]+_coef[x2]=_coef[x3]}, or \texttt{test [#1]x1+[#1]x2=#1x3}, or many other things because there is more than one way to refer to an estimated coefficient; see \texttt{[U] 13.5 Accessing coefficients and standard errors}. The shorthand involves less typing. On the other hand, you must be more explicit after estimation of multiple-equation models because there may be more than one coefficient associated
with an independent variable. You might type, for instance, `test [#2]x1+[#2]x2=[#2]x3` to test the constraint in equation 2 or, more readably, `test [ford]x1+[ford]x2=[ford]x3`, meaning that Stata will test the constraint on the equation corresponding to `ford`, which might be equation 2. `ford` would be an equation name after, say, `sureg`, or, after `mlogit`, `ford` would be one of the outcomes. For `mlogit`, you could also type `test [2]x1+[2]x2=[2]x3`—note the lack of the #—meaning not equation 2, but the equation corresponding to the numeric outcome 2. You can even test constraints across equations: `test [ford]x1+[ford]x2=[buick]x3`.

The syntax

```
test coeflist
```

is available after all estimation commands and is a convenient way to test that multiple coefficients are zero following estimation. A `coeflist` can simply be a list of variable names,

```
test varname [ varname ...]
```

and it is most often specified that way. After you have fit a model of `depvar` on `x1`, `x2`, and `x3`, typing `test x1 x3` tests that the coefficients on `x1` and `x3` are jointly zero. After multiple-equation estimation, this would test that the coefficients on `x1` and `x3` are zero in all equations that contain them. You can also be more explicit and type, for instance, `test [ford]x1 [ford]x3` to test that the coefficients on `x1` and `x3` are zero in the equation for `ford`.

In the multiple-equation case, there are more alternatives. You could also test that the coefficients on `x1` and `x3` are zero in the equation for `ford` by typing `test [ford]: x1 x3`. You could test that all coefficients except the coefficient on the constant are zero in the equation for `ford` by typing `test [ford]`. You could test that the coefficients on `x1` and `x3` in the equation for `ford` are equal to the corresponding coefficients in the equation corresponding to `buick` by typing `test[ford=buick]: x1 x3`. You could test that all the corresponding coefficients except the constant in three equations are equal by typing `test [ford=buick=volvo]`.

`testparm` is much like the first syntax of `test`. Its usefulness will be demonstrated below.

The examples below use `regress`, but what is said applies equally after any single-equation estimation command (such as `logistic`). It also applies after multiple-equation estimation commands as long as references to coefficients are qualified with an equation name or number in square brackets placed before them. The convenient syntaxes for dealing with tests of many coefficients in multiple-equation models are demonstrated in `Special syntaxes after multiple-equation estimation` below.

> **Example 1: Testing for a single coefficient against zero**

We have 1980 census data on the 50 states recording the birth rate in each state (`brate`), the median age (`medage`), and the region of the country in which each state is located.

The `region` variable is 1 if the state is in the Northeast, 2 if the state is in the North Central, 3 if the state is in the South, and 4 if the state is in the West. We estimate the following regression:
. use https://www.stata-press.com/data/r16/census3
(1980 Census data by state)
. reg brate medage c.medage#c.medage i.region

/* Technical note */

The F statistic with 1 numerator and 44 denominator degrees of freedom is 3.47. The significance level of the test is 6.91%—we can reject the hypothesis at the 10% level but not at the 5% level.

This result from test is identical to one presented in the output from regress, which indicates that the t statistic on the 3.region coefficient is 1.863 and that its significance level is 0.069. The t statistic presented in the output can be used to test the hypothesis that the corresponding coefficient is zero, although it states the test in slightly different terms. The F distribution with 1 numerator degree of freedom is, however, identical to the t² distribution. We note that 1.863² ≈ 3.47 and that the significance levels in each test agree, although one extra digit is presented by the test command.

After all estimation commands, including those that use the maximum likelihood method, the test that one variable is zero is identical to that reported by the command’s output. The tests are performed in the same way—using the estimated covariance matrix—and are known as Wald tests. If the estimation command reports significance levels and confidence intervals using z rather than t statistics, test reports results using the χ² rather than the F statistic.
Example 2: Testing the value of a single coefficient

If that were all test could do, it would be useless. We can use test, however, to perform other tests. For instance, we can test the hypothesis that the coefficient on 2.region is 21 by typing

```
.test 2.region=21
  ( 1) 2.region = 21
    F(  1,    44) = 1.99
    Prob > F = 0.1654
```

We find that we cannot reject that hypothesis, or at least we cannot reject it at any significance level below 16.5%.

Example 3: Testing the equality of two coefficients

The previous test is useful, but we could almost as easily perform it by hand using the results presented in the regression output if we were well read on our statistics. We could type

```
.display Ftail(1,44,(_coef[2.region]-21)/4.252068)^2)
.16544873
```

So, now let’s test something a bit more difficult: whether the coefficient on 2.region is the same as the coefficient on 4.region:

```
.test 2.region=4.region
  ( 1) 2.region - 4.region = 0
    F(  1,    44) = 2.84
    Prob > F = 0.0989
```

We find that we cannot reject the equality hypothesis at the 5% level, but we can at the 10% level.

Example 4

When we tested the equality of the 2.region and 4.region coefficients, Stata rearranged our algebra. When Stata displayed its interpretation of the specified test, it indicated that we were testing whether 2.region minus 4.region is zero. The rearrangement is innocuous and, in fact, allows Stata to perform much more complicated algebra, for instance,

```
  ( 1) 2.region - 3.region = 0
    F(  1,    44) = 5.06
    Prob > F = 0.0295
```

Although we requested what appeared to be a lengthy hypothesis, once Stata simplified the algebra, it realized that all we wanted to do was test whether the coefficient on 2.region is the same as the coefficient on 3.region.

Technical note

Stata’s ability to simplify and test complex hypotheses is limited to linear hypotheses. If you attempt to test a nonlinear hypothesis, you will be told that it is not possible:

```
.test 2.region/3.region=2.region+3.region
not possible with test
r(131);
```

To test a nonlinear hypothesis, see [R] testnl.
Example 5: Testing joint hypotheses

The real power of `test` is demonstrated when we test joint hypotheses. Perhaps we wish to test whether the region variables, taken as a whole, are significant by testing whether the coefficients on `2.region`, `3.region`, and `4.region` are simultaneously zero. `test` allows us to specify multiple conditions to be tested, each embedded within parentheses.

```
.test (2.region=0) (3.region=0) (4.region=0)
( 1) 2.region = 0
( 2) 3.region = 0
( 3) 4.region = 0
F( 3, 44) = 8.85
Prob > F = 0.0001
```

test displays the set of conditions and reports an $F$ statistic of 8.85. `test` also reports the degrees of freedom of the test to be 3, the "dimension" of the hypothesis, and the residual degrees of freedom, 44. The significance level of the test is close to 0, so we can strongly reject the hypothesis of no difference between the regions.

An alternative method to specify simultaneous hypotheses uses the convenient shorthand of conditions with multiple equality operators.

```
.test 2.region=3.region=4.region=0
( 1) 2.region - 3.region = 0
( 2) 2.region - 4.region = 0
( 3) 2.region = 0
F( 3, 44) = 8.85
Prob > F = 0.0001
```

Technical note

Another method to test simultaneous hypotheses is to specify a `test` for each constraint and accumulate it with the previous constraints:

```
.test 2.region=0
( 1) 2.region = 0
F( 1, 44) = 12.45
Prob > F = 0.0010

.test 3.region=0, accumulate
( 1) 2.region = 0
( 2) 3.region = 0
F( 2, 44) = 6.42
Prob > F = 0.0036

.test 4.region=0, accumulate
( 1) 2.region = 0
( 2) 3.region = 0
( 3) 4.region = 0
F( 3, 44) = 8.85
Prob > F = 0.0001
```

We tested the hypothesis that the coefficient on `2.region` was zero by typing `test 2.region=0`. We then tested whether the coefficient on `3.region` was also zero by typing `test 3.region=0, accumulate`. The `accumulate` option told Stata that this was not the start of a new test but a continuation of a previous one. Stata responded by showing us the two equations and reporting an $F$ statistic of 6.42. The significance level associated with those two coefficients being zero is 0.36%.
When we added the last constraint \texttt{test 4.region=0, accumulate}, we discovered that the three region variables are significant. If all we wanted was the overall significance and we did not want to bother seeing the interim results, we could have used the \texttt{notest} option:

\begin{verbatim}
. test 2.region=0, notest
  ( 1) 2.region = 0
. test 3.region=0, accumulate notest
  ( 1) 2.region = 0
  ( 2) 3.region = 0
. test 4.region=0, accumulate
  ( 1) 2.region = 0
  ( 2) 3.region = 0
  ( 3) 4.region = 0
  F( 3, 44) = 8.85
  Prob > F = 0.0001
\end{verbatim}

\section*{Example 6: Quickly testing coefficients against zero}

Because tests that coefficients are zero are so common in applied statistics, the \texttt{test} command has a more convenient syntax to accommodate this case:

\begin{verbatim}
. test 2.region 3.region 4.region
  ( 1) 2.region = 0
  ( 2) 3.region = 0
  ( 3) 4.region = 0
  F( 3, 44) = 8.85
  Prob > F = 0.0001
\end{verbatim}

\section*{Example 7: Specifying varlists}

We will now show how to use \texttt{testparm}. In its first syntax, \texttt{test} accepts a list of variable names but not a \texttt{varlist}.

\begin{verbatim}
. test i(2/4).region
i not found
r(111);
\end{verbatim}

In the varlist, \texttt{i(2/4).region} means all the level variables from 2.region through 4.region, yet we received an error. \texttt{test} does not actually understand varlists, but \texttt{testparm} does. In fact, it understands only varlists.

\begin{verbatim}
. testparm i(2/4).region
  ( 1) 2.region = 0
  ( 2) 3.region = 0
  ( 3) 4.region = 0
  F( 3, 44) = 8.85
  Prob > F = 0.0001
\end{verbatim}

Another way to test all the \texttt{region} variables is to type \texttt{testparm i.region}.

That \texttt{testparm} accepts varlists has other advantages that do not involve factor variables. Suppose that we have a dataset that has dummy variables \texttt{reg2}, \texttt{reg3}, and \texttt{reg4}, rather than the categorical variable \texttt{region}.
. use https://www.stata-press.com/data/r16/census4
(birth rate, median age)
. regress brate medage c.medage#c.medage reg2 reg3 reg4
(output omitted)
. test reg2-reg4
   - not found
   r(111);

In a varlist, reg2–reg4 means variables reg2 and reg4 and all the variables between, yet we received an error. test is confused because the - has two meanings: it means subtraction in an expression and “through” in a varlist. Similarly, ‘*’ means “any set of characters” in a varlist and multiplication in an expression. testparm avoids this confusion—it allows only a varlist.

. testparm reg2-reg4
( 1) reg2 = 0
( 2) reg3 = 0
( 3) reg4 = 0
   F(  3,  44) =  8.85
   Prob > F =  0.0001

   testparm has another advantage. We have five variables in our dataset that start with the characters reg: region, reg1, reg2, reg3, and reg4. reg* thus means those five variables:

. describe reg*
storage  display  value
  variable name  type  format  label  variable label
region     int  %8.0g  region  Census Region
reg1       byte  %9.0g  region==NE
reg2       byte  %9.0g  region==N Cntrl
reg3       byte  %9.0g  region==South
reg4       byte  %9.0g  region==West

We cannot type test reg* because, in an expression, ‘*’ means multiplication, but here is what would happen if we attempted to test all the variables that begin with reg:

. test region reg1 reg2 reg3 reg4
   region not found
   r(111);

The variable region was not included in our model, so it was not found. However, with testparm,

. testparm reg*
( 1)  reg2 = 0
( 2)  reg3 = 0
( 3)  reg4 = 0
   F(  3,  44) =  8.85
   Prob > F =  0.0001

That is, testparm took reg* to mean all variables that start with reg that were in our model.

Technical note

Actually, reg* means what it always does—all variables in our dataset that begin with reg—in this case, region reg1 reg2 reg3 reg4. testparm just ignores any variables you specify that are not in the model.
Example 8: Replaying the previous test

We just used `test` (`.testparm`, actually, but it does not matter) to test the hypothesis that `reg2`, `reg3`, and `reg4` are jointly zero. We can review the results of our last test by typing `test` without arguments:

```
    . test
     ( 1)  reg2 = 0
     ( 2)  reg3 = 0
     ( 3)  reg4 = 0
         F(  3,  44) =  8.85
              Prob > F =  0.0001
```

Technical note

`test` does not care how we build joint hypotheses; we may freely mix different forms of syntax. (We can even start with `.testparm`, but we cannot use it thereafter because it does not have an `accumulate` option.)

Say that we type `test reg2 reg3 reg4` to test that the coefficients on our region dummies are jointly zero. We could then add a fourth constraint, say, that `medage = 100`, by typing `test medage=100, accumulate`. Or, if we had introduced the `medage` constraint first (our first `test` command had been `test medage=100`), we could then add the region dummy test by typing `test reg2 reg3 reg4, accumulate` or `test (reg2=0) (reg3=0) (reg4=0), accumulate`.

Remember that all previous tests are cleared when we do not specify the `accumulate` option. No matter what tests we performed in the past, if we type `test medage c.medage#c.medage`, omitting the `accumulate` option, we would test that `medage` and `c.medage#c.medage` are jointly zero.

Example 9: Testing the equality of multiple coefficients

Let’s return to our `census3.dta` dataset and test the hypothesis that all the included regions have the same coefficient—that the Northeast is significantly different from the rest of the nation:

```
    . use https://www.stata-press.com/data/r16/census3
       (1980 Census data by state)
    . regress brate medage c.medage#c.medage i.region
       (output omitted)
    . test 2.region=3.region=4.region
       ( 1)  2.region - 3.region  =  0
       ( 2)  2.region - 4.region  =  0
          F(  2,  44) =    8.23
              Prob > F =  0.0009
```

We find that they are not all the same. The syntax `2.region=3.region=4.region` with multiple `=` operators is just a convenient shorthand for typing that the first expression equals the second expression and that the first expression equals the third expression.

```
    . test (2.region=3.region) (2.region=4.region)
```

We performed the test for equality of the three regions by imposing two constraints: region 2 has the same coefficient as region 3, and region 2 has the same coefficient as region 4. Alternatively, we could have tested that the coefficients on regions 2 and 3 are the same and that the coefficients on regions 3 and 4 are the same. We would obtain the same results in either case.

To test for equality of the three regions, we might, likely by mistake, type equality constraints for all pairs of regions:
. test (2.region=3.region) (2.region=4.region) (3.region=4.region)
( 1) 2.region - 3.region = 0
( 2) 2.region - 4.region = 0
( 3) 3.region - 4.region = 0
Constraint 3 dropped
F( 2, 44) = 8.23
Prob > F = 0.0009

Equality of regions 2 and 3 and of regions 2 and 4, however, implies equality of regions 3 and 4. test recognized that the last constraint is implied by the other constraints and hence dropped it.

Technical note

Generally, Stata uses = for assignment, as in gen newvar = exp, and == as the operator for testing equality in expressions. For your convenience, test allows both = and == to be used.

Example 10

The test for the equality of the regions is also possible with the testparm command. When we include the equal option, testparm tests that the coefficients of all the variables specified are equal:

. testparm i(2/4).region, equal
( 1) - 2.region + 3.region = 0
( 2) - 2.region + 4.region = 0
F( 2, 44) = 8.23
Prob > F = 0.0009

We can also obtain the equality test by accumulating single equality tests.

. test 2.region=3.region, notest
( 1) 2.region - 3.region = 0
. test 2.region=4.region, accum
( 1) 2.region - 3.region = 0
( 2) 2.region - 4.region = 0
F( 2, 44) = 8.23
Prob > F = 0.0009

Technical note

If we specify a set of inconsistent constraints, test will tell us by dropping the constraint or constraints that led to the inconsistency. For instance, let’s test that the coefficients on region 2 and region 4 are the same, add the test that the coefficient on region 2 is 20, and finally add the test that the coefficient on region 4 is 21:

. test (2.region=4.region) (2.region=20) (4.region=21)
( 1) 2.region - 4.region = 0
( 2) 2.region = 20
( 3) 4.region = 21
Constraint 2 dropped
F( 2, 44) = 1.82
Prob > F = 0.1737

test informed us that it was dropping constraint 2. All three equations cannot be simultaneously true, so test drops whatever it takes to get back to something that makes sense.
Special syntaxes after multiple-equation estimation

Everything said above about tests after single-equation estimation applies to tests after multiple-equation estimation, as long as you remember to specify the equation name. To demonstrate, let’s estimate a seemingly unrelated regression by using `sureg`; see `[R] sureg`.

```
. use https://www.stata-press.com/data/r16/auto
(1978 Automobile Data)
. sureg (price foreign mpg displ) (weight foreign length)
```

Seemingly unrelated regression

```
<table>

```

To test the significance of `foreign` in the `price` equation, we could type

```
. test [price]foreign
( 1) [price]foreign = 0
   chi2(  1) =  19.89
   Prob > chi2 = 0.0000
```

which is the same result reported by `sureg`: $4.46^2 \approx 19.89$. To test `foreign` in both equations, we could type

```
. test [price]foreign [weight]foreign
( 1) [price]foreign = 0
( 2) [weight]foreign = 0
   chi2(  2) =  31.61
   Prob > chi2 = 0.0000
```

or

```
. test foreign
( 1) [price]foreign = 0
( 2) [weight]foreign = 0
   chi2(  2) =  31.61
   Prob > chi2 = 0.0000
```

This last syntax—typing the variable name by itself—tests the coefficients in all equations in which they appear. The variable `length` appears in only the `weight` equation, so typing

```
. test [weight]length
( 1) [weight]length = 0
   chi2(  1) =  20.10
   Prob > chi2 = 0.0000
```

which is the same result reported by `sureg`: $20.10$. To test `length` in both equations, we could type

```
. test [weight]length [price]length
( 1) [weight]length = 0
( 2) [price]length = 0
   chi2(  2) =  40.21
   Prob > chi2 = 0.0000
```

which is the same result reported by `sureg`: $40.21$. To test `length` in both equations, we could type

```
. test [weight]length [price]length
( 1) [weight]length = 0
( 2) [price]length = 0
   chi2(  2) =  40.21
   Prob > chi2 = 0.0000
```

which is the same result reported by `sureg`: $40.21$. To test `length` in both equations, we could type

```
. test [weight]length [price]length
( 1) [weight]length = 0
( 2) [price]length = 0
   chi2(  2) =  40.21
   Prob > chi2 = 0.0000
```
. test length
   ( 1) [weight]length = 0
       chisq( 1) = 403.94
       Prob > chisq = 0.0000

yields the same result as typing `test [weight]length`. We may also specify a linear expression
rather than a list of coefficients:

. test mpg=displ
   ( 1) [price]mpg - [price]displacement = 0
       chisq( 1) = 4.85
       Prob > chisq = 0.0277

or

. test [price]mpg = [price]displ
   ( 1) [price]mpg - [price]displacement = 0
       chisq( 1) = 4.85
       Prob > chisq = 0.0277

A variation on this syntax can be used to test cross-equation constraints:

. test [price]foreign = [weight]foreign
   ( 1) [price]foreign - [weight]foreign = 0
       chisq( 1) = 23.07
       Prob > chisq = 0.0000

Typing an equation name in square brackets by itself tests all the coefficients except the intercept
in that equation:

. test [price]
   ( 1) [price]foreign = 0
   ( 2) [price]mpg = 0
   ( 3) [price]displacement = 0
       chisq( 3) = 49.64
       Prob > chisq = 0.0000

Typing an equation name in square brackets, a colon, and a list of variable names tests those variables
in the specified equation:

. test [price]: foreign displ
   ( 1) [price]foreign = 0
   ( 2) [price]displacement = 0
       chisq( 2) = 25.19
       Prob > chisq = 0.0000

`test [eqname1=eqname2]` tests that all the coefficients in the two equations are equal. We cannot
use that syntax here because there are different variables in the model:

. test [price=weight]
variables differ between equations
(to test equality of coefficients in common, specify option `common`)
r(111);

The `common` option specifies a test of the equality coefficients common to the equations `price`
and `weight`. 
. test [price=weight], common
  (1)  [price]foreign - [weight]foreign = 0
    chi2( 1) = 23.07
    Prob > chi2 = 0.0000

By default, test does not include the constant, the coefficient of the constant variable _cons, in the test. The cons option specifies that the constant be included.

. test [price=weight], common cons
  (1)  [price]foreign - [weight]foreign = 0
  (2)  [price]_cons - [weight]_cons = 0
    chi2( 2) = 51.23
    Prob > chi2 = 0.0000

We can also use a modification of this syntax with the model if we also type a colon and the names of the variables we want to test:

. test [price=weight]: foreign
  (1)  [price]foreign - [weight]foreign = 0
    chi2( 1) = 23.07
    Prob > chi2 = 0.0000

We have only one variable in common between the two equations, but if there had been more, we could have listed them.

Finally, a simultaneous test of multiple constraints may be specified just as after single-equation estimation.

. test ([price]: foreign) ([weight]: foreign)
  (1)  [price]foreign = 0
  (2)  [weight]foreign = 0
    chi2( 2) = 31.61
    Prob > chi2 = 0.0000

test can also test for equality of coefficients across more than two equations. For instance, test [eq1=eq2=eq3] specifies a test that the coefficients in the three equations eq1, eq2, and eq3 are equal. This requires that the same variables be included in the three equations. If some variables are entered only in some of the equations, you can type test [eq1=eq2=eq3], common to test that the coefficients of the variables common to all three equations are equal. Alternatively, you can explicitly list the variables for which equality of coefficients across the equations is to be tested. For instance, test [eq1=eq2=eq3]: time money tests that the coefficients of the variables time and money do not differ between the equations.

Technical note

test [eq1=eq2=eq3], common tests the equality of the coefficients common to all equations, but it does not test the equality of all common coefficients. Consider the case where

```
eq1 contains the variables var1 var2 var3
eq2 contains the variables var1 var2 var4
eq3 contains the variables var1 var3 var4
```

Obviously, only var1 is common to all three equations. Thus test [eq1=eq2=eq3], common tests that the coefficients of var1 do not vary across the equations, so it is equivalent to test [eq1=eq2=eq3]: var1. To perform a test of the coefficients of variables common to two equations, you could explicitly list the constraints to be tested,

. test ([eq1=eq2=eq3]:var1) ([eq1=eq2]:var2) ([eq1=eq3]:var3) ([eq2=eq3]:var4)
Constrained coefficients

If the test indicates that the data do not allow you to conclude that the constraints are not satisfied, you may want to inspect the constrained coefficients. The `coef` option specified that the constrained results, estimated by GLS, are shown.

```
. test [price=weight], common coef
   ( 1) [price]foreign - [weight]foreign = 0
   chi2(  1) =  23.07
   Prob > chi2 = 0.0000
```

The constrained coefficient of `foreign` is \(-216.40\) with standard error 74.06 in equations `price` and `weight`. The other coefficients and their standard errors are affected by imposing the equality constraint of the two coefficients of `foreign` because the unconstrained estimates of these two coefficients were correlated with the estimates of the other coefficients.

Technical note

The two-step constrained coefficients \(b_c\) displayed by `test, coef` are asymptotically equivalent to the one-stage constrained estimates that are computed by specifying the constraints during estimation using the `constraint()` option of estimation commands (Gourieroux and Monfort 1995, chap. 10). Generally, one-step constrained estimates have better small-sample properties. For inspection and interpretation, however, two-step constrained estimates are a convenient alternative. Moreover, some estimation commands (for example, `stcox`, many `xt` estimators) do not have a `constraint()` option.
Multiple testing

When performing the test of a joint hypothesis, you might want to inspect the underlying 1-degree-of-freedom hypotheses. Which constraint “is to blame”? `test` displays the univariate as well as the simultaneous test if the `mtest` option is specified. For example,

```
. test [price=weight], common cons mtest
    ( 1) [price]foreign - [weight]foreign = 0
    ( 2) [price]_cons - [weight]_cons = 0

          | chi2    df  p
----------|---------|-------|------
(1)      | 23.07   1   0.0000 #
(2)      | 11.17   1   0.0008 #
all      | 51.23   2   0.0000 # unadjusted p-values
```

Both coefficients seem to contribute to the highly significant result. The 1-degree-of-freedom test shown here is identical to those if `test` had been invoked to test just this simple hypotheses. There is, of course, a real risk in inspecting these simple hypotheses. Especially in high-dimensional hypotheses, you may easily find one hypothesis that happens to be significant. Multiple testing procedures are designed to provide some safeguard against this risk. *p*-values of the univariate hypotheses are modified so that the probability of falsely rejecting one of the null hypotheses is bounded. `test` provides the methods based on Bonferroni, Šidák, and Holm.

```
. test [price=weight], common cons mtest(b)
    ( 1) [price]foreign - [weight]foreign = 0
    ( 2) [price]_cons - [weight]_cons = 0

          | chi2    df  p
----------|---------|-------|------
(1)      | 23.07   1   0.0000 #
(2)      | 11.17   1   0.0017 #
all      | 51.23   2   0.0000 # Bonferroni-adjusted p-values
```

Stored results

`test` and `testparm` store the following in `r()`:

Scalars

- `r(p)` two-sided *p*-value
- `r(F)` *F* statistic
- `r(df)` test constraints degrees of freedom
- `r(df_r)` residual degrees of freedom
- `r(dropped_i)` index of *i*th constraint dropped
- `r(p)` two-sided *p*-value
- `r(chi2)` \( \chi^2 \) sum of squares (test)
- `r(ss)` residual sum of squares
- `r(rss)` sum of squares (test)
- `r(drop)` 1 if constraints were dropped, 0 otherwise

Macros

- `r(mtmeth)` method of adjustment for multiple testing
- `r(mtest)` multiple test results

* `r(ss)` and `r(rss)` are defined only when `test` is used for testing effects after `anova`. 
Methods and formulas

test and testparm perform Wald tests. Let the estimated coefficient vector be \( \mathbf{b} \) and the estimated variance–covariance matrix be \( \mathbf{V} \). Let \( \mathbf{Rb} = \mathbf{r} \) denote the set of \( q \) linear hypotheses to be tested jointly.

The Wald test statistic is (Judge et al. 1985, 20–28)

\[
W = (\mathbf{Rb} - \mathbf{r})' \mathbf{(RVR')}^{-1} (\mathbf{Rb} - \mathbf{r})
\]

If the estimation command reports its significance levels using \( Z \) statistics, a chi-squared distribution with \( q \) degrees of freedom, \( W \sim \chi^2_q \) is used for computation of the significance level of the hypothesis test.

If the estimation command reports its significance levels using \( t \) statistics with \( d \) degrees of freedom, an \( F \) statistic, \( F = \frac{1}{q} W \) is computed, and an \( F \) distribution with \( q \) numerator degrees of freedom and \( d \) denominator degrees of freedom computes the significance level of the hypothesis test.

The two-step constrained estimates \( \mathbf{b}_c \) displayed by test with the coef option are the GLS estimates of the unconstrained estimates \( \mathbf{b} \) subject to the specified constraints \( \mathbf{Rb} = \mathbf{c} \) (Gourieroux and Monfort 1995, chap. 10),

\[
\mathbf{b}_c = \mathbf{b} - \mathbf{VR'}(\mathbf{RVR'})^{-1}(\mathbf{Rb} - \mathbf{r})
\]

with variance–covariance matrix

\[
\mathbf{V}_c = \mathbf{V} - \mathbf{VR'}(\mathbf{RVR'})^{-1}\mathbf{RV}
\]

If test displays a Wald test for joint (simultaneous) hypotheses, it can also display all 1-degree-of-freedom tests, with \( p \)-values adjusted for multiple testing. Let \( p_1, p_2, \ldots, p_k \) be the unadjusted \( p \)-values of these 1-degree-of-freedom tests. The Bonferroni-adjusted \( p \)-values are defined as \( p^b_i = \min(1, kp_i) \). The Šidák-adjusted \( p \)-values are \( p^s_i = 1 - (1 - p_i)^k \). Holm’s method for adjusting \( p \)-values is defined as \( p^h_i = \min(1, k_i p_i) \), where \( k_i \) is the number of \( p \)-values at least as large as \( p_i \). Note that \( p^h_i < p^b_i \), reflecting that Holm’s method is strictly less conservative than the widely used Bonferroni method.

If test is used after a svy command, it carries out an adjusted Wald test—this adjustment should not be confused with the adjustment for multiple testing. Both adjustments may actually be combined. Specifically, the survey adjustment uses an approximate \( F \) statistic \( (d-k+1)W/(kd) \), where \( W \) is the Wald test statistic, \( k \) is the dimension of the hypothesis test, and \( d = \) the total number of sampled PSUs minus the total number of strata. Under the null hypothesis, \( (d-k+1)F/(kd) \sim F(k, d-k+1) \), where \( F(k, d-k+1) \) is an \( F \) distribution with \( k \) numerator degrees of freedom and \( d-k+1 \) denominator degrees of freedom. If nosvyadjust is specified, the \( p \)-value is computed using \( W/k \sim F(k, d) \).

See Korn and Graubard (1990) for a detailed description of the Bonferroni adjustment technique and for a discussion of the relative merits of it and of the adjusted and unadjusted Wald tests.
Acknowledgment

The svy adjustment code was adopted from another command developed in collaboration with John L. Eltinge of the United States Census Bureau.

## Description

testnl tests (linear or nonlinear) hypotheses about the estimated parameters from the most recently fit model.

testnl produces Wald-type tests of smooth nonlinear (or linear) hypotheses about the estimated parameters from the most recently fit model. The p-values are based on the delta method, an approximation appropriate in large samples.

testnl can be used with `svy` estimation results; see [SVY] svy postestimation.

The format \( (exp_1=exp_2=exp_3\ldots) \) for a simultaneous-equality hypothesis is just a convenient shorthand for a list \( (exp_1=exp_2) (exp_1=exp_3) \), etc.

testnl may also be used to test linear hypotheses. test is faster if you want to test only linear hypotheses; see [R] test. testnl is the only option for testing linear and nonlinear hypotheses simultaneously.

## Quick start

After single-equation models

Test that the product of the coefficients for \( x_1 \) and \( x_2 \) is equal to 4

\[
\text{testnl } _b[x_1]*_b[x_2] = 4
\]

Test that the ratio of the indicators for the factor variable \( a = 2 \) and \( a = 3 \) is 1

\[
\text{testnl } _b[2.a]/_b[3.a] = 1
\]

Test that an expression involving continuous factor variable syntax is equal to 16

\[
\text{testnl } -_b[x_1]/(2*_b[c.x_1#c.x_1]) = 16
\]

Test the equality of two expressions

\[
\text{testnl } _b[x_1]*_b[x_2] = _b[x_1]*_b[x_3]
\]

Joint test that two products are both equal to 2

\[
\text{testnl } (_b[x_1]*_b[x_2] = 2) (_b[x_1]*_b[x_3] = 2)
\]

Same as above

\[
\text{testnl } _b[x_1]*_b[x_2] = _b[x_1]*_b[x_3] = 2
\]

As above, but add separate tests for each expression

\[
\text{testnl } _b[x_1]*_b[x_2] = _b[x_1]*_b[x_3] = 2, \text{ mtest}
\]

As above, but adjust p-values for multiple comparisons using Holm’s method

\[
\text{testnl } _b[x_1]*_b[x_2] = _b[x_1]*_b[x_3] = 2, \text{ mtest(holm)}
\]
Test a linear hypothesis and a nonlinear hypothesis together
\[ \text{testnl \ (}_b[x1] =_b[x2]) \ (}_b[x2] ^ 2 =_b[x3]) \]

\textit{After multiple-equation models}

Test that the product of the coefficients for \( x1 \) and \( x2 \) in the equation for \( y1 \) is equal to 1
\[ \text{testnl \ } _b[y1:x1]*_b[y1:x2] = 1 \]

Test that the product of the coefficients for \( x1 \) and \( x2 \) in the equation for \( y2 \) is equal to 1
\[ \text{testnl \ } _b[y2:x1]*_b[y2:x2] = 1 \]

Test the equality of expressions involving coefficients from the equations for \( y1 \) and \( y4 \)
\[ \text{testnl \ } _b[y1:x1]*_b[y1:x2] = _b[y4:x1]*_b[y4:x2] \]
Syntax

testnl  exp  =  exp  [  =  exp  ...  ]  [ ,  options ]

testnl  (exp  =  exp  [  =  exp  ...  ] )  [ (exp  =  exp  [  =  exp  ...  ] )  ...  ]  [ ,  options ]

<table>
<thead>
<tr>
<th>options</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>mtest[(opt)]</td>
<td>test each condition separately</td>
</tr>
<tr>
<td>iterate(#)</td>
<td>use maximum # of iterations to find the optimal step size</td>
</tr>
<tr>
<td>df(#)</td>
<td>use $F$ distribution with # denominator degrees of freedom for the reference</td>
</tr>
<tr>
<td>nosvyadjust</td>
<td>carry out the Wald test as $W/k \sim F(k, d)$; for use with svy estimation</td>
</tr>
<tr>
<td></td>
<td>commands when the df() option is also specified</td>
</tr>
</tbody>
</table>

The second syntax means that if more than one expression is specified, each must be surrounded by parentheses.

exp is a possibly nonlinear expression containing:

- `_b[coef]`
- `_b[eqno:coef]`
- `[eqno]coef`
- `[eqno]_b[coef]`

`eqno` is

```
##
name
```

`coef` identifies a coefficient in the model. `coef` is typically a variable name, a level indicator, an interaction indicator, or an interaction involving continuous variables. Level indicators identify one level of a factor variable and interaction indicators identify one combination of levels of an interaction; see [U] 11.4.3 Factor variables. `coef` may contain time-series operators; see [U] 11.4.4 Time-series varlists.

Distinguish between [], which are to be typed, and [ ], which indicate optional arguments.

Options

mtest[(opt)] specifies that tests be performed for each condition separately. `opt` specifies the method for adjusting $p$-values for multiple testing. Valid values for `opt` are

```
bonferroni     Bonferroni’s method
holm           Holm’s method
sidak          Šidák’s method
noadjust       no adjustment is to be made
```

Specifying `mtest` without an argument is equivalent to specifying `mtest(noadjust)`. 
iterate(#) specifies the maximum number of iterations used to find the optimal step size in the calculation of numerical derivatives of the test expressions. By default, the maximum number of iterations is 100, but convergence is usually achieved after only a few iterations. You should rarely have to use this option.

The following options are available with `testnl` but are not shown in the dialog box:

df(#) specifies that the $F$ distribution with # denominator degrees of freedom be used for the reference distribution of the test statistic. With survey data, # is the design degrees of freedom unless `nosvyadjust` is specified.

`nosvyadjust` is for use with `svy` estimation commands when the `df()` option is also specified; see `SVY: svy estimation`. It specifies that the Wald test be carried out without the default adjustment for the design degrees of freedom. That is, the test is carried out as $W/k \sim F(k,d)$ rather than as $(d-k+1)W/(kd) \sim F(k,d-k+1)$, where $k$ is the dimension of the test and $d$ is the design degrees of freedom specified in the `df()` option.

### Remarks and examples

Remarks are presented under the following headings:

- Introduction
- Using testnl to perform linear tests
- Specifying constraints
- Dropped constraints
- Multiple constraints
- Manipulability

#### Introduction

**Example 1**

We have just estimated the parameters of an earnings model on cross-sectional time-series data using one of Stata’s more sophisticated estimators:

```stata
use https://www.stata-press.com/data/r16/earnings
(NLS Women 14-24 in 1968)
.xtgee ln_w grade age c.age#c.age, corr(exchangeable) nolog
```

GEE population-averaged model

| Variable       | Coef.  | Std. Err. | z     | P>|z| | [95% Conf. Interval] |
|----------------|--------|-----------|-------|------|---------------------|
| ln_w           | 0.0749686 | 0.0066111 | 11.34 | 0.000 | 0.062011 - 0.0879261 |
| grade          | 0.1080806 | 0.0235861 | 4.58  | 0.000 | 0.0618526 - 0.1543086 |
| age            |        |           |       |      |                     |
| c.age#c.age    | -0.0016253 | 0.0004739 | -3.43 | 0.001 | -0.0025541 - -0.0006966 |
| _cons          | -0.8788933 | 0.2830899 | -3.10 | 0.002 | -1.433739 - -0.3240473 |
An implication of this model is that peak earnings occur at age $-\frac{\_b[\text{age}]}{(2*\_b[c.\text{age}\#c.\text{age}])}$, which here is equal to 33.2. Say that we have a theory that peak earnings should occur at age $16 + \frac{1}{\_b[\text{grade}]}$.

```
. testnl -\_b[\text{age}]/(2*\_b[c.\text{age}\#c.\text{age}]) = 16 + 1/\_b[\text{grade}]
Equation (1) contains reference to X rather than _b[X]
_r(198);
```

These data do not reject our theory.

**Using testnl to perform linear tests**

`testnl` may be used to test linear constraints, but `test` is faster; see [R] `test`. You could type

```
. testnl _\_b[x4] = _\_b[x1]
```

but it would take less computer time if you typed

```
. test _\_b[x4] = _\_b[x1]
```

**Specifying constraints**

The constraints to be tested can be formulated in many different ways. You could type

```
. testnl _\_b[\text{mpg}]*_\_b[\text{weight}] = 1
```

or

```
. testnl _\_b[\text{mpg}] = 1/_\_b[\text{weight}]
```

or you could express the constraint any other way you wished. (To say that `testnl` allows constraints to be specified in different ways does not mean that the test itself does not depend on the formulation. This point is briefly discussed later.) In formulating the constraints, you must, however, exercise one caution: users of `test` often refer to the coefficient on a variable by specifying the variable name. For example,

```
. test \_\_b[\text{mpg}]=0
```

More formally, they should type

```
. test \_\_b[\text{mpg}]=0
```

but `test` allows the `\_\_b[]` surrounding the variable name to be omitted. `testnl` does not allow this shorthand. Typing

```
. testnl mpg=0
```

specifies the constraint that the value of variable `mpg` in the first observation is zero. If you make this mistake, sometimes `testnl` will catch it:
In other cases, `testnl` may not catch the mistake; then the constraint will be dropped because it does not make sense:

```
. testnl mpg=0
  Constraint (1) dropped
```

(There are reasons other than this for constraints being dropped.) The worst case, however, is

```
. testnl _b[weight]*mpg = 1
```

when what you mean is not that `_b[weight]` equals the reciprocal of the value of `mpg` in the first observation, but rather that

```
. testnl _b[weight]*_b[mpg] = 1
```

Sometimes this mistake will be caught by the “contains reference to X rather than `_b[X]” error, and sometimes it will not. Be careful.

`testnl`, like `test`, can be used after any Stata estimation command, including the survey estimators. When you use it after a multiple-equation command, such as `mlogit` or `heckman`, you refer to coefficients by using Stata’s standard syntax: `[eqname]_b[varname].`

Stata’s single-equation estimation output looks like this:

<table>
<thead>
<tr>
<th>Coef</th>
<th>...</th>
</tr>
</thead>
<tbody>
<tr>
<td>weight</td>
<td>12.27 ... &lt;- coefficient is _b[weight]</td>
</tr>
<tr>
<td>mpg</td>
<td>3.21 ...</td>
</tr>
</tbody>
</table>

Stata’s multiple-equation output looks like this:

<table>
<thead>
<tr>
<th>Coef</th>
<th>...</th>
</tr>
</thead>
<tbody>
<tr>
<td>cat1</td>
<td>...</td>
</tr>
<tr>
<td>weight</td>
<td>12.27 ... &lt;- coefficient is [cat1]_b[weight]</td>
</tr>
<tr>
<td>mpg</td>
<td>3.21 ...</td>
</tr>
<tr>
<td>8</td>
<td>...</td>
</tr>
<tr>
<td>weight</td>
<td>5.83 ... &lt;- coefficient is [8]_b[weight]</td>
</tr>
<tr>
<td>mpg</td>
<td>7.43 ...</td>
</tr>
</tbody>
</table>

**Dropped constraints**

`testnl` automatically drops constraints when

- They are nonbinding, for example, `_b[mpg]=_b[mpg]`. More subtle cases include
  
  \[
  _b[mpg]*_b[weight] = 4 \\
  _b[weight] = 2 \\
  _b[mpg] = 2
  \]

  In this example, the third constraint is nonbinding because it is implied by the first two.

- They are contradictory, for example, `_b[mpg]=2` and `_b[mpg]=3`. More subtle cases include
  
  \[
  _b[mpg]*_b[weight] = 4 \\
  _b[weight] = 2 \\
  _b[mpg] = 3
  \]

  The third constraint contradicts the first two.
Multiple constraints

Example 2

We illustrate the simultaneous test of a series of constraints using simulated data on labor-market promotion in a given year. We fit a probit model with separate effects for education, experience, and experience-squared for men and women.

```
use https://www.stata-press.com/data/r16/promotion
probit promo male male#c.(yedu yexp yexp2), nolog
```

```
+-----------------------------+----------------------------------+

</table>
```

The effects of human capital seem to differ between men and women. A formal test confirms this.

```
. test (yedu#0.male = yedu#1.male) (yexp#0.male = yexp#1.male) > (yexp2#0.male = yexp2#1.male)
( 1) [promo]0b.male#c.yedu - [promo]1.male#c.yedu = 0
( 2) [promo]0b.male#c.yexp - [promo]1.male#c.yexp = 0
( 3) [promo]0b.male#c.yexp2 - [promo]1.male#c.yexp2 = 0
    chi2(  3) =  35.43
    Prob > chi2 = 0.0000
```

How do we interpret this gender difference? It has repeatedly been stressed (see, for example, Long [1997, 47–50]; Allison [1999]) that comparison of groups in binary response models, and similarly in other latent-variable models, is hampered by an identification problem: with $\beta$ the regression coefficients for the latent variable and $\sigma$ the standard deviation of the latent residual, only the $\beta/\sigma$ are identified. In fact, in terms of the latent regression, the probit coefficients should be interpreted as $\beta/\sigma$, not as the $\beta$. If we cannot claim convincingly that the residual standard deviation $\sigma$ does not vary between the sexes, equality of the regression coefficients $\beta$ implies that the coefficients of the probit model for men and women are proportional but not necessarily equal. This is a nonlinear hypothesis in terms of the probit coefficients, not a linear one.
. testnl _b[yedu#1.male]/_b[yedu#0.male] = _b[yexp#1.male]/_b[yexp#0.male]
> _b[yedu#1.male]/_b[yedu#0.male] = _b[yexp2#1.male]/_b[yexp2#0.male]
(1)  _b[yedu#1.male]/_b[yedu#0.male] = _b[yexp#1.male]/_b[yexp#0.male]
(2)  _b[yedu#1.male]/_b[yedu#0.male] = _b[yexp2#1.male]/_b[yexp2#0.male]

\[ \chi^2(2) = 9.21 \]
\[ \text{Prob} > \chi^2 = 0.0100 \]

We conclude that we find fairly strong evidence against the proportionality of the coefficients, and hence we have to conclude that success in the labor market is produced in different ways by men and women. (But remember, these were simulated data.)

> Example 3

The syntax for specifying the equality of multiple expressions is just a convenient shorthand for specifying a series of constraints, namely, that the first expression equals the second expression, the first expression also equals the third expression, etc. The Wald test performed and the output of \texttt{testnl} are the same whether we use the shorthand or we specify the series of constraints. The lengthy specification as a series of constraints can be simplified using the continuation symbols ///.

. testnl (_b[yedu#1.male]/_b[yedu#0.male] =
> _b[yexp#1.male]/_b[yexp#0.male])
> (_b[yedu#1.male]/_b[yedu#0.male] =
> _b[yexp2#1.male]/_b[yexp2#0.male])

\[ \chi^2(2) = 9.21 \]
\[ \text{Prob} > \chi^2 = 0.0100 \]

Having established differences between men and women, we would like to do multiple testing between the ratios. Because we did not specify hypotheses in advance, we prefer to adjust the p-values of tests using, here, Bonferroni’s method.

. testnl _b[yedu#1.male]/_b[yedu#0.male] =
> _b[yexp#1.male]/_b[yexp#0.male] =
> _b[yexp2#1.male]/_b[yexp2#0.male], mtest(b)

\# Bonferroni-adjusted p-values
Manipulability

Although testnl allows you to specify constraints in different ways that are mathematically equivalent, as noted above, this does not mean that the tests are the same. This difference is known as the manipulability of the Wald test for nonlinear hypotheses; also see [R] boxcox. The test might even be significant for one formulation but not significant for another formulation that is mathematically equivalent. Trying out different specifications to find a formulation with the desired $p$-value is totally inappropriate, though it may actually be fun to try. There is no variance under representation because the nonlinear Wald test is actually a standard Wald test for a linearization of the constraint, which depends on the particular specification. We note that the likelihood-ratio test is not manipulable in this sense.

From a statistical point of view, it is best to choose a specification of the constraints that is as linear is possible. Doing so usually improves the accuracy of the approximation of the null-distribution of the test by a $\chi^2$ or an $F$ distribution. The example above used the nonlinear Wald test to test whether the coefficients of human capital variables for men were proportional to those of women. A specification of proportionality of coefficients in terms of ratios of coefficients is fairly nonlinear if the coefficients in the denominator are close to 0. A more linear version of the test results from a bilinear formulation. Thus instead of

```
. testnl _b[yedu#1.male]/_b[yedu#0.male] = _b[yexp#1.male]/_b[yexp#0.male]
(1) _b[yedu#1.male]/_b[yedu#0.male] = _b[yexp#1.male]/_b[yexp#0.male]
    chi2(1) =    6.89
    Prob > chi2 =  0.0087
```

perhaps

```
. testnl _b[yedu#1.male]*_b[yexp#0.male] = _b[yedu#0.male]*_b[yexp#1.male]
(1) _b[yedu#1.male]*_b[yexp#0.male] = _b[yedu#0.male]*_b[yexp#1.male]
    chi2(1) =   13.95
    Prob > chi2 =  0.0002
```

is better, and in fact it has been suggested that the latter version of the test is more reliable. This assertion is confirmed by performing simulations and is in line with theoretical results of Phillips and Park (1988). There is strong evidence against the proportionality of human capital effects between men and women, implying for this example that differences in the residual variances between the sexes can be ruled out as the explanation of the sex differences in the analysis of labor market participation.

Stored results

testnl stores the following in r():

Scalars

- $r(df)$: degrees of freedom
- $r(df_r)$: residual degrees of freedom
- $r(chi2)$: $\chi^2$
- $r(p)$: $p$-value for Wald test
- $r(F)$: $F$ statistic

Macros

- $r(mtmethod)$: method specified in mtest()

Matrices

- $r(G)$: derivatives of $R(b)$ with respect to $b$; see Methods and formulas below
- $r(R)$: $R(b) - q$; see Methods and formulas below
- $r(mtest)$: multiple test results
Methods and formulas

After fitting a model, define \( b \) as the resulting \( 1 \times k \) parameter vector and \( V \) as the \( k \times k \) covariance matrix. The (linear or nonlinear) hypothesis is given by \( R(b) = q \), where \( R \) is a function returning a \( j \times 1 \) vector. The Wald test formula is (Greene 2018, 512–513)

\[
W = \left\{ R(b) - q \right\}' \left( GVG' \right)^{-1} \left\{ R(b) - q \right\}
\]

where \( G \) is the derivative matrix of \( R(b) \) with respect to \( b \). \( W \) is distributed as \( \chi^2 \) if \( V \) is an asymptotic covariance matrix. \( F = W/j \) is distributed as \( F \) for linear regression.

The adjustment methods for multiple testing are described in \( \texttt{[R] test} \). The adjustment for survey design effects is described in \( \texttt{[SVY] svy postestimation} \).

Tetrachoric correlations for binary variables

**Description**

`tetrachoric` computes estimates of the tetrachoric correlation coefficients of the binary variables in `varlist`. All of these variables should be 0, 1, or missing values.

Tetrachoric correlations assume a latent bivariate normal distribution \((X_1, X_2)\) for each pair of variables \((v_1, v_2)\), with a threshold model for the manifest variables, \(v_i = 1\) if and only if \(X_i > 0\). The means and variances of the latent variables are not identified, but the correlation, \(r\), of \(X_1\) and \(X_2\) can be estimated from the joint distribution of \(v_1\) and \(v_2\) and is called the tetrachoric correlation coefficient.

`tetrachoric` computes pairwise estimates of the tetrachoric correlations by the (iterative) maximum likelihood estimator obtained from bivariate probit without explanatory variables (see [R] `biprobit`) by using the Edwards and Edwards (1984) noniterative estimator as the initial value.

The pairwise correlation matrix is returned as \(r(Rho)\) and can be used to perform a factor analysis or a principal component analysis of binary variables by using the `factormat` or `pcamat` commands; see [MV] `factor` and [MV] `pca`.

**Quick start**

Tetrachoric correlation of \(v1\) and \(v2\) with standard error and test of independence

```
tetrachoric v1 v2
```

Matrix of pairwise tetrachoric correlations for \(v1\), \(v2\), and \(v3\)

```
tetrachoric v1 v2 v3
```

Add standard errors and \(p\)-values

```
tetrachoric v1 v2 v3, stats(rho se p)
```

As above, but adjust \(p\)-values for multiple comparisons using Bonferroni’s method

```
tetrachoric v1 v2 v3, stats(rho se p) bonferroni
```

Add star to correlations significant at the 5% level

```
tetrachoric v1 v2 v3, star(.05)
```

Use all available data for each pair of variables and report number of observations used

```
tetrachoric v1 v2 v3, pw stats(rho obs)
```

Adjust correlation matrix to be positive semidefinite

```
tetrachoric v1 v2 v3, posdef
```
Syntax

tetrachoric varlist [ if ] [ in ] [ weight ] [ , options ]

options  Description

Main

stats(statlist)  list of statistics; select up to 4 statistics; default is stats(rho)
edwards  use the noniterative Edwards and Edwards estimator; default is the maximum likelihood estimator
print(#)  significance level for displaying coefficients
star(#)  significance level for displaying with a star
bonferroni  use Bonferroni-adjusted significance level
sidak  use Šidák-adjusted significance level
pw  calculate all the pairwise correlation coefficients by using all available data (pairwise deletion)
zeroadjust  adjust frequencies when one cell has a zero count
matrix  display output in matrix form
notable  suppress display of correlations
posdef  modify correlation matrix to be positive semidefinite

statlist  Description

rho  tetrachoric correlation coefficient
se  standard error of rho
obs  number of observations
p  exact two-sided significance level

by is allowed; see [D] by.
fweights are allowed; see [U] 11.1.6 weight.

Options

stats(statlist) specifies the statistics to be displayed in the matrix of output. stats(rho) is the default. Up to four statistics may be specified. stats(rho se p obs) would display the tetrachoric correlation coefficient, its standard error, the significance level, and the number of observations. If varlist contains only two variables, all statistics are shown in tabular form. stats(), print(), and star() have no effect unless the matrix option is also specified.

edwards specifies that the noniterative Edwards and Edwards estimator be used. The default is the maximum likelihood estimator. If you analyze many binary variables, you may want to use the fast noniterative estimator proposed by Edwards and Edwards (1984). However, if you have skewed variables, the approximation does not perform well.
print(#) specifies the maximum significance level of correlation coefficients to be printed. Correlation coefficients with larger significance levels are left blank in the matrix. Typing \texttt{tetrachoric ... print(.10)} would list only those correlation coefficients that are significant at the 10\% level or lower.

\texttt{star(#)} specifies the maximum significance level of correlation coefficients to be marked with a star. Typing \texttt{tetrachoric ... star(.05)} would “star” all correlation coefficients significant at the 5\% level or lower.

\texttt{bonferroni} makes the Bonferroni adjustment to calculated significance levels. This option affects printed significance levels and the \texttt{print() and star()} options. Thus \texttt{tetrachoric ... print(.05) bonferroni} prints coefficients with Bonferroni-adjusted significance levels of 0.05 or less.

\texttt{sidak} makes the Šidák adjustment to calculated significance levels. This option affects printed significance levels and the \texttt{print()} and \texttt{star()} options. Thus \texttt{tetrachoric ... print(.05) sidak} prints coefficients with Šidák-adjusted significance levels of 0.05 or less.

\texttt{pw} specifies that the tetrachoric correlation be calculated by using all available data. By default, \texttt{tetrachoric} uses casewise deletion, where observations are ignored if any of the specified variables in \texttt{varlist} are missing.

\texttt{zeroadjust} specifies that when one of the cells has a zero count, a frequency adjustment be applied in such a way as to increase the zero to one-half and maintain row and column totals.

\texttt{matrix} forces \texttt{tetrachoric} to display the statistics as a matrix, even if \texttt{varlist} contains only two variables. \texttt{matrix} is implied if more than two variables are specified.

\texttt{notable} suppresses the output.

\texttt{posdef} modifies the correlation matrix so that it is positive semidefinite, that is, a proper correlation matrix. The modified result is the correlation matrix associated with the least-squares approximation of the tetrachoric correlation matrix by a positive-semidefinite matrix. If the correlation matrix is modified, the standard errors and significance levels are not displayed and are returned in \texttt{r()}. 

## Remarks and examples

Remarks are presented under the following headings:

- Association in 2-by-2 tables
- Factor analysis of dichotomous variables
- Tetrachoric correlations with simulated data

### Association in 2-by-2 tables

Although a wide variety of measures of association in cross tabulations have been proposed, such measures are essentially equivalent (monotonically related) in the special case of $2 \times 2$ tables—there is only 1 degree of freedom for nonindependence. Still, some measures have more desirable properties than others. Here we compare two measures: the standard Pearson correlation coefficient and the tetrachoric correlation coefficient. Given asymmetric row or column margins, Pearson correlations are limited to a range smaller than $-1$ to $1$, although tetrachoric correlations can still span the range from $-1$ to $1$. To illustrate, consider the following set of tables for two binary variables, X and Z:
For $a$ equal to 0, 1, 2, 5, 8, 9, and 10, the Pearson and tetrachoric correlations for the above table are

<table>
<thead>
<tr>
<th>$a$</th>
<th>0</th>
<th>1</th>
<th>2</th>
<th>5</th>
<th>8</th>
<th>9</th>
<th>10</th>
</tr>
</thead>
<tbody>
<tr>
<td>Pearson</td>
<td>0.577</td>
<td>0.462</td>
<td>0.346</td>
<td>0</td>
<td>-0.346</td>
<td>-0.462</td>
<td>-0.577</td>
</tr>
<tr>
<td>Tetrachoric</td>
<td>1.000</td>
<td>0.792</td>
<td>0.607</td>
<td>0</td>
<td>-0.607</td>
<td>-0.792</td>
<td>-1.000</td>
</tr>
</tbody>
</table>

The restricted range for the Pearson correlation is especially unfortunate when you try to analyze the association between binary variables by using models developed for continuous data, such as factor analysis and principal component analysis.

The tetrachoric correlation of two variables $(Y_1, Y_2)$ can be thought of as the Pearson correlation of two latent bivariate normal distributed variables $(Y_1^*, Y_2^*)$ with threshold measurement models $Y_i = (Y_i^* > c_i)$ for unknown cutpoints $c_i$. Or equivalently, $Y_i = (Y_i^{**} > 0)$ where the latent bivariate normal $(Y_1^{**}, Y_2^{**})$ are shifted versions of $(Y_1^*, Y_2^*)$ so that the cutpoints are zero. Obviously, you must judge whether assuming underlying latent variables is meaningful for the data. If this assumption is justified, tetrachoric correlations have two advantages. First, you have an intuitive understanding of the size of correlations that are substantively interesting in your field of research, and this intuition is based on correlations that range from $-1$ to 1. Second, because the tetrachoric correlation for binary variables estimates the Pearson correlation of the latent continuous variables (assumed multivariate normal distributed), you can use the tetrachoric correlations to analyze multivariate relationships between the dichotomous variables. When doing so, remember that you must interpret the model in terms of the underlying continuous variables.

Example 1

To illustrate tetrachoric correlations, we examine three binary variables from the familyvalues dataset (described in example 2).

```
. use https://www.stata-press.com/data/r16/familyvalues
    (Attitudes on gender, relationships and family)
. tabulate RS075 RS076
    fam att: trad
    women in division of labor charge bad
    | 0   | 1   | Total |
    |-----|-----|-------|
    0   | 1,564 | 979 | 2,543 |
    1   | 119  | 632 | 751  |
    Total | 1,683 | 1,611 | 3,294 |
. correlate RS074 RS075 RS076
    (obs=3,291)
    RS074 RS075 RS076
    |-----|-----|-----|
    RS074 | 1.000 |   |   |
    RS075 | 0.0396 | 1.000 |   |
    RS076 | 0.1595 | 0.3830 | 1.000 |
```
As usual, the tetrachoric correlation coefficients are larger (in absolute value) and more dispersed than the Pearson correlations.

Factor analysis of dichotomous variables

Example 2

Factor analysis is a popular model for measuring latent continuous traits. The standard estimators are appropriate only for continuous unimodal data. Because of the skewness implied by Bernoulli-distributed variables (especially when the probability is distributed unevenly), a factor analysis of a Pearson correlation matrix can be rather misleading when used in this context. A factor analysis of a matrix of tetrachoric correlations is more appropriate under these conditions (Uebersax 2000). We illustrate this with data on gender, relationship, and family attitudes of spouses using the Households in The Netherlands survey 1995 (Weesie et al. 1995). For attitude variables, it seems reasonable to assume that agreement or disagreement is just a coarse measurement of more nuanced underlying attitudes.
To demonstrate, we examine a few of the variables from the *familyvalues* dataset.

```
. use https://www.stata-press.com/data/r16/familyvalues
(Attitudes on gender, relationships and family)
. describe RS056-RS063

</table>

Again we see that the tetrachoric correlations are generally larger in absolute value than the Pearson correlations. The bivariate probit and Edwards and Edwards estimators (the `edwards` option) implemented in `tetrachoric` may return a correlation matrix that is not positive semidefinite—a mathematical property of any real correlation matrix. Positive definiteness is required by commands for analyses of correlation matrices, such as `factormat` and `pcamat`; see [MV] `factor` and [MV] `pca`. The `posdef` option of `tetrachoric` tests for positive definiteness and projects the estimated correlation matrix to a positive-semidefinite matrix if needed.

```
. matrix C = r(corr)
```

This time, we suppressed the display of the correlations with the `notable` option and requested that the correlation matrix be positive semidefinite with the `posdef` option. Had the correlation matrix not been positive definite, `tetrachoric` would have displayed a warning message and then adjusted the matrix to be positive semidefinite. We placed the resulting tetrachoric correlation matrix into a matrix, C, so that we can perform a factor analysis upon it.

`tetrachoric` with the `posdef` option asserted that C was positive definite because no warning message was displayed. We can verify this by using a familiar characterization of symmetric positive-definite matrices: all eigenvalues are real and positive.

```
. matrix symeigen eigenvectors eigenvalues = C
. matrix list eigenvalues
```

We can proceed with a factor analysis on the matrix C. We use `factormat` and select iterated principal factors as the estimation method; see [MV] `factor`.

Example 3

We noted in example 2 that the matrix of estimates of the tetrachoric correlation coefficients need not be positive definite. Here is an example:

. use https://www.stata-press.com/data/r16/familyvalues
    (Attitudes on gender, relationships and family)
. tetrachoric RS056-RS063 in 1/20, posdef
    (obs=18)

matrix with tetrachoric correlations is not positive semidefinite;
it has 2 negative eigenvalues
maxdiff(corr,adj-corr) = 0.2346
(adj-corr: tetrachoric correlations adjusted to be positive semidefinite)

</table>
The estimated tetrachoric correlation matrix is rank-2 deficient. With this \( C_2 \) matrix, we can only use models of correlation that allow for singular cases.

#### Tetrachoric correlations with simulated data

**Example 4**

We use `drawnorm` (see [D] `drawnorm`) to generate a sample of 1,000 observations from a bivariate normal distribution with means \(-1\) and 1, unit variances, and correlation 0.4.

```plaintext
. clear
. set seed 11000
. matrix m = (1, -1)
. matrix V = (1, .4 \ .4, 1)
. drawnorm c1 c2, n(1000) means(m) cov(V)
```

Now consider the measurement model assumed by the tetrachoric correlations. We observe only whether \( c_1 \) and \( c_2 \) are greater than zero,

```plaintext
. generate d1 = (c1 > 0)
. generate d2 = (c2 > 0)
. tabulate d1 d2

<table>
<thead>
<tr>
<th></th>
<th>d2</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>0</td>
</tr>
<tr>
<td>0</td>
<td>141</td>
</tr>
<tr>
<td>1</td>
<td>706</td>
</tr>
</tbody>
</table>
```

We want to estimate the correlation of \( c_1 \) and \( c_2 \) from the binary variables \( d_1 \) and \( d_2 \). Pearson’s correlation of the binary variables \( d_1 \) and \( d_2 \) is 0.129—a seriously biased estimate of the underlying correlation \( \rho = 0.4 \).
The tetrachoric correlation coefficient of \(d_1\) and \(d_2\) estimates the Pearson correlation of the latent continuous variables, \(c_1\) and \(c_2\).

```
. tetrachoric d1 d2
Number of obs = 1,000
Tetrachoric rho = 0.3875
Std error = 0.0787
Test of Ho: d1 and d2 are independent
2-sided exact P = 0.0000
```

The estimate of the tetrachoric correlation of \(d_1\) and \(d_2\), 0.3875, is much closer to the underlying correlation, 0.4, between \(c_1\) and \(c_2\).

**Stored results**

`tetrachoric` stores the following in `r()`:

- Scalars:
  - `r(rho)`: tetrachoric correlation coefficient between variables 1 and 2
  - `r(N)`: number of observations
  - `r(nneg)`: number of negative eigenvalues (posdef only)
  - `r(se_rho)`: standard error of `r(rho)`
  - `r(p)`: \(p\)-value for two-sided Fisher’s exact test (for the first two variables)

- Macros:
  - `r(method)`: estimator used

- Matrices:
  - `r(Rho)`: tetrachoric correlation matrix
  - `r(Se_Rho)`: standard errors of `r(Rho)`
  - `r(Nobs)`: number of observations used in computing correlation
  - `r(P)`: matrix of \(p\)-values for two-sided Fisher’s exact test

**Methods and formulas**

`tetrachoric` provides two estimators for the tetrachoric correlation \(\rho\) of two binary variables with the frequencies \(n_{ij}, i,j = 0,1\). `tetrachoric` defaults to the slower (iterative) maximum likelihood estimator obtained from bivariate probit without explanatory variables (see \([R]\) `biprobit`) by using the Edwards and Edwards noniterative estimator as the initial value. A fast (noniterative) estimator is also available by specifying the `edwards` option (Edwards and Edwards 1984; Digby 1983)

\[
\hat{\rho} = \frac{\alpha - 1}{\alpha + 1}
\]
where

\[ \alpha = \left( \frac{n_{00}n_{11}}{n_{01}n_{10}} \right)^{\pi/4} (\pi = 3.14 \ldots) \]

if all \( n_{ij} > 0 \). If \( n_{00} = 0 \) or \( n_{11} = 0 \), \( \hat{\rho} = -1 \); if \( n_{01} = 0 \) or \( n_{10} = 0 \), \( \hat{\rho} = 1 \).

The asymptotic variance of the Edwards and Edwards estimator of the tetrachoric correlation is easily obtained by the delta method,

\[ \text{avar}(\hat{\rho}) = \left\{ \frac{\pi \alpha}{2(1 + \alpha)^2} \right\}^2 \left( \frac{1}{n_{00}} + \frac{1}{n_{01}} + \frac{1}{n_{10}} + \frac{1}{n_{11}} \right) \]

provided all \( n_{ij} > 0 \), otherwise it is left undefined (missing). The Edwards and Edwards estimator is fast, but may be inaccurate if the margins are very skewed.

tetrachoric reports exact \( p \)-values for statistical independence, computed by the exact option of [R] tabulate twoway.

tnbreg estimates the parameters of a truncated negative binomial model by maximum likelihood. The dependent variable depvar is regressed on indepvars, where depvar is a positive count variable whose values are all above the truncation point.

Quick start

Truncated negative binomial regression of y on x with truncation at 0
   tnbreg y x

Report incidence-rate ratios
   tnbreg y x, irr

Add categorical variable a using factor variable syntax
   tnbreg y x i.a

As above, but specify a constant truncation point of 2
   tnbreg y x i.a, ll(2)

With exposure variable exp
   tnbreg y x i.a, exposure(exp)

As above, but specifying a variable truncation point stored in variable min
   tnbreg y x i.a, exposure(exp) ll(min)

With cluster–robust standard errors clustering by the levels of cvar
   tnbreg y x i.a, exposure(exp) ll(min) vce(cluster cvar)
Syntax

```
tnbreg `depvar' [ `indepvars'] [ `if'] [ `in'] [ `weight'] [ , `options']
```

**options**

**Options**

`indepvars' may contain factor variables; see [U] 11.4.3 Factor variables. `depvar' and `indepvars' may contain time-series operators; see [U] 11.4.4 Time-series varlists. bayes, bootstrap, by, fp, jackknife, rolling, statsby, and svy are allowed; see [U] 11.1.10 Prefix commands. For more details, see [BAYES] bayes: tnbreg. Weights are not allowed with the bootstrap prefix; see [R] bootstrap. vce() and weights are not allowed with the svy prefix; see [SVY] svy. fweights, iweights, and pweights are allowed; see [U] 11.1.6 weight. collinear and coeflegend do not appear in the dialog box. See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

**noconstant**; see [R] Estimation options.

ll(# | varname) specifies the truncation point, which is a nonnegative integer. The default is zero truncation, ll(0).
dispersion(mean | constant) specifies the parameterization of the model. dispersion(mean), the default, yields a model with dispersion equal to \(1 + \alpha \exp(x_j\beta + \text{offset}_j)\); that is, the dispersion is a function of the expected mean: \(\exp(x_j\beta + \text{offset}_j)\). dispersion(constant) has dispersion equal to \(1 + \delta\); that is, it is a constant for all observations.

exposure(varname_e), offset(varname_o), constraints(constraints); see [R] Estimation options.

vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim, opg), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.

level(#); see [R] Estimation options.
	nolrtest suppresses fitting the Poisson model. Without this option, a comparison Poisson model is fit, and the likelihood is used in a likelihood-ratio test of the null hypothesis that the dispersion parameter is zero.

irr reports estimated coefficients transformed to incidence-rate ratios, that is, \(e^{\beta_i}\) rather than \(\beta_i\). Standard errors and confidence intervals are similarly transformed. This option affects how results are displayed, not how they are estimated or stored. irr may be specified at estimation or when replaying previously estimated results.

nocnsreport; see [R] Estimation options.

display_options: noci, nopvalues, noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(#), fvwrapping(style), cformat(%,fmt), pformat(%,fmt), sformat(%,fmt), and nolstretch; see [R] Estimation options.

maximize_options: difficult, technique(algorithm_spec), iterate(#) [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), itolerance(#), nrtolerance(#), nonrtolerance, and from(init_specs); see [R] Maximize. These options are seldom used.

Setting the optimization type to technique(bhhh) resets the default vcetype to vce(opg).

The following options are available with tnbreg but are not shown in the dialog box: collinear, coeflegend; see [R] Estimation options.

Remarks and examples

Grogger and Carson (1991) showed that overdispersion causes inconsistent estimation of the mean in the truncated Poisson model. To solve this problem, they proposed using the truncated negative binomial model as an alternative. If data are truncated but do not exhibit overdispersion, the truncated Poisson model is more appropriate; see [R] tpoisson. For an introduction to negative binomial regression, see Cameron and Trivedi (2005, 2010) and Long and Freese (2014). For an introduction to truncated negative binomial models, see Cameron and Trivedi (2013) and Long (1997, chap. 8).
tnbreg fits the mean-dispersion and the constant-dispersion parameterizations of truncated negative binomial models. These parameterizations extend those implemented in \texttt{nbreg}; see \cite{Rnbreg}.

\section*{Example 1}

We illustrate the truncated negative binomial model using the 1997 MedPar dataset \citep{Hilbe1999}. The data are from 1,495 patients in Arizona who were assigned to a diagnostic-related group (DRG) of patients having a ventilator. Length of stay (los), the dependent variable, is a positive integer; it cannot have zero values. The data are truncated because there are no observations on individuals who stayed for zero days.

The objective of this example is to determine whether the length of stay was related to the binary variables: \texttt{died}, \texttt{hmo}, \texttt{type1}, \texttt{type2}, and \texttt{type3}.

The \texttt{died} variable was recorded as a 0 unless the patient died, in which case, it was recorded as a 1. The other variables also adopted this encoding. The \texttt{hmo} variable was set to 1 if the patient belonged to a health maintenance organization (HMO).

The \texttt{type1}–\texttt{type3} variables indicated the type of admission used for the patient. The \texttt{type1} variable indicated an emergency admit. The \texttt{type2} variable indicated an urgent admit—that is, the first available bed. The \texttt{type3} variable indicated an elective admission. Because \texttt{type1}–\texttt{type3} were mutually exclusive, only two of the three could be used in the truncated negative binomial regression shown below.

\begin{verbatim}
use https://www.stata-press.com/data/r16/medpar
.tnbreg los died hmo type2-type3, vce(cluster provnum) nolog
\end{verbatim}

\textit{Truncated negative binomial regression}

\begin{verbatim}
Number of obs = 1,495
Truncation point: 0
\end{verbatim}

\begin{verbatim}
Wald chi2(4) = 36.01
Dispersion = mean
Prob > chi2 = 0.0000
Log pseudolikelihood = -4737.535 Pseudo R2 = 0.0139
\end{verbatim}

\begin{verbatim}
(Std. Err. adjusted for 54 clusters in provnum)
\end{verbatim}

\begin{verbatim}
Robust

los coef. Std. Err. z P>|z| [95% Conf. Interval]
\end{verbatim}

\begin{verbatim}
died -.2521884 .061533 -4.10 0.000 -.3727908 -.1315859
hmo -.0754173 .0533132 -1.41 0.157 -.1799091 .0290746
type2  .2685095 .0666474 4.03 0.000 .137883 .3991359
type3  .7668101 .2183505 3.51 0.000 .338851 1.194769
_cons  2.224028 .034727 64.04 0.000 2.155964 2.292091
\end{verbatim}

\begin{verbatim}
/_lnalpha -.630108 .0764019  -7.79853 -.480363
alpha  .5325343 .0406866  .4584734 .6185588
\end{verbatim}

Because observations within the same hospital (\texttt{provnum}) are likely to be correlated, we specified the \texttt{vce(cluster provnum)} option. The results show that whether the patient died in the hospital and the type of admission have significant effects on the patient’s length of stay.

\section*{Example 2}

To illustrate truncated negative binomial regression with more complex data than the previous example, similar data were created from 100 hospitals. Each hospital had its own way of tracking patient data. In particular, hospitals only recorded data from patients with a minimum length of stay, denoted by the variable \texttt{minstay}.
Definitions for minimum length of stay varied among hospitals, typically, from 5 to 18 days. The objective of this example is the same as before: to determine whether the length of stay, recorded in los, was related to the binary variables: died, hmo, type1, type2, and type3.

The binary variables encode the same information as in example 1 above. The minstay variable was used to allow for varying truncation points.

```
. use https://www.stata-press.com/data/r16/medproviders
. tnbgreg los died hmo type2-type3, ll(minstay) vce(cluster hospital) nolog
```

Truncated negative binomial regression                  Number of obs   =        2,144
Truncation points: minstay                             Wald chi2(4)   =      15.22
Dispersion = mean                                 Prob > chi2     =     0.0043
Log pseudolikelihood = -7864.0928                    Pseudo R2       =     0.0007

(Std. Err. adjusted for 100 clusters in hospital)

| los     | Coef. | Std. Err. | z   | P>|z|     | [95% Conf. Interval] |
|---------|-------|-----------|-----|---------|---------------------|

| _cons   | 3.014964 | .0290895  | 103.64 | 0.000   | 2.95795 - 3.071978 |
| /lnalpha| -.996512 | .0828691  | -1.158932 | 0.251 | -.8340916 |
| alpha   | .3691649 | .0305923  | .313821 | 0.756   | .4342688 |

In this analysis, two variables have a statistically significant relationship with length of stay. On average, patients who died in the hospital had longer lengths of stay ($p = 0.01$). Because the coefficient for HMO is negative, that is, $b_{HMO} = -0.073$, on average, patients who were insured by an HMO had shorter lengths of stay ($p = 0.047$). The type of admission was not statistically significant ($p > 0.05$).
tnbreg stores the following in e()::

Scalars
- e(N): number of observations
- e(k): number of parameters
- e(k_aux): number of auxiliary parameters
- e(k_eq): number of equations in e(b)
- e(k_eq_model): number of equations in overall model test

Functions
- e(sample): marks estimation sample
Methods and formulas

Methods and formulas are presented under the following headings:

Mean-dispersion model
Constant-dispersion model

Mean-dispersion model

A negative binomial distribution can be regarded as a gamma mixture of Poisson random variables. The number of times an event occurs, \( y_j \), is distributed as Poisson\((\nu_j \mu_j)\). That is, its conditional likelihood is

\[
 f(y_j | \nu_j) = \frac{(\nu_j \mu_j)^{y_j} e^{-\nu_j \mu_j}}{\Gamma(y_j + 1)}
\]

where \( \mu_j = \exp(x_j \beta + \text{offset}_j) \) and \( \nu_j \) is an unobserved parameter with a Gamma\((1/\alpha, \alpha)\) density:

\[
 g(\nu) = \frac{\nu^{(1-\alpha)/\alpha} e^{-\nu/\alpha}}{\alpha^{1/\alpha} \Gamma(1/\alpha)}
\]

This gamma distribution has a mean of 1 and a variance of \( \alpha \), where \( \alpha \) is our ancillary parameter.

The unconditional likelihood for the \( j \)th observation is therefore

\[
 f(y_j) = \int_0^\infty f(y_j | \nu) g(\nu) d\nu = \frac{\Gamma(m + y_j) \Gamma(m)}{\Gamma(y_j + 1) \Gamma(m)} p_j^m (1 - p_j)^{y_j}
\]

where \( p_j = 1/(1 + \alpha \mu_j) \) and \( m = 1/\alpha \). Solutions for \( \alpha \) are handled by searching for \( \ln \alpha \) because \( \alpha \) must be greater than zero. The conditional probability of observing \( y_j \) events given that \( y_j \) is greater than the truncation point \( \tau_j \) is

\[
 \Pr(Y = y_j | y_j > \tau_j, x_j) = \frac{f(y_j)}{\Pr(Y > \tau_j | x_j)}
\]

The log likelihood (with weights \( w_j \) and offsets) is given by

\[
 \ln L = \sum_{j=1}^n w_j \left[ \ln\{\Gamma(m + y_j)\} - \ln\{\Gamma(y_j + 1)\} \\
 - \ln\{\Gamma(m)\} + m \ln(p_j) + y_j \ln(1 - p_j) - \ln\{\Pr(Y > \tau_j | p_j, m)\} \right]
\]
**Constant-dispersion model**

The constant-dispersion model assumes that $y_j$ is conditionally distributed as $\text{Poisson}(\mu^*_j)$, where $\mu^*_j \sim \text{Gamma}(\mu_j/\delta, \delta)$ for some dispersion parameter $\delta$ [by contrast, the mean-dispersion model assumes that $\mu^*_j \sim \text{Gamma}(1/\alpha, \alpha \mu_j)$]. The log likelihood is given by

$$m_j = \mu_j/\delta \quad p = 1/(1 + \delta)$$

$$\ln L = \sum_{j=1}^{n} w_j \left[ \ln \{\Gamma(m_j + y_j)\} - \ln \{\Gamma(y_j + 1)\} - \ln \{\Gamma(m_j)\} + m_j \ln(p) + y_j \ln(1 - p) - \ln \{\Pr(Y > \tau_j | p, m_j)\} \right]$$

with everything else defined as shown above in the calculations for the mean-dispersion model.

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using `vce(robust)` and `vce(cluster clustvar)`, respectively. See [P] _robust, particularly Maximum likelihood estimators and Methods and formulas.

`tnbreg` also supports estimation with survey data. For details on VCEs with survey data, see [SVY] Variance estimation.

* `forecast`, `hausman`, and `lrtest` are not appropriate with `svy` estimation results.
predict

Description for predict

`predict` creates a new variable containing predictions such as numbers of events, incidence rates, conditional means, probabilities, conditional probabilities, linear predictions, and standard errors.

Menu for predict

Statistics > Postestimation

Syntax for predict

```
predict [type] newvar [if] [in] [, statistic nooffset]
predict [type] { stub* | newvar reg newvar disp } [if] [in] , scores
```

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>

<td>standard error of the linear prediction</td>
</tr>
</tbody>
</table>

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

Options for predict

- `n`, the default, calculates the predicted number of events, which is $\exp(x_j \beta)$ if neither `offset()` nor `exposure()` was specified when the model was fit; $\exp(x_j \beta + \text{offset}_j)$ if `offset()` was specified; or $\exp(x_j \beta) \times \text{exposure}_j$ if `exposure()` was specified.
- `ir` calculates the incidence rate $\exp(x_j \beta)$, which is the predicted number of events when exposure is 1. This is equivalent to specifying both the `n` and the `nooffset` options.
- `cm` calculates the conditional mean,

$$E(y_j \mid y_j > \tau_j) = \frac{E(y_j, y_j > \tau_j)}{Pr(y_j > \tau_j)}$$

where $\tau_j$ is the truncation point found in `e(llopt)`.
\texttt{pr(n)} calculates the probability $Pr(y_j = n)$, where $n$ is a nonnegative integer that may be specified as a number or a variable.

\texttt{pr(a,b)} calculates the probability $Pr(a \leq y_j \leq b)$, where $a$ and $b$ are nonnegative integers that may be specified as numbers or variables;

\begin{itemize}
  \item $b$ missing ($b \geq .$) means $+\infty$;
  \item \texttt{pr(20,.)} calculates $Pr(y_j \geq 20)$;
  \item \texttt{pr(20,b)} calculates $Pr(y_j \geq 20)$ in observations for which $b \geq .$ and calculates $Pr(20 \leq y_j \leq b)$ elsewhere.
\end{itemize}

\texttt{pr(.,b)} produces a syntax error. A missing value in an observation of the variable $a$ causes a missing value in that observation for \texttt{pr(a,b)}.

\texttt{cpr(n)} calculates the conditional probability $Pr(y_j = n \mid y_j > \tau_j)$, where $\tau_j$ is the truncation point found in \texttt{e(llopt)}. $n$ is an integer greater than the truncation point that may be specified as a number or a variable.

\texttt{cpr(a,b)} calculates the conditional probability $Pr(a \leq y_j \leq b \mid y_j > \tau_j)$, where $\tau_j$ is the truncation point found in \texttt{e(llopt)}. The syntax for this option is analogous to that used for \texttt{pr(a,b)} except that $a$ must be greater than the truncation point.

\texttt{xb} calculates the linear prediction, which is $x_j\beta$ if neither \texttt{offset()} nor \texttt{exposure()} was specified when the model was fit; $x_j\beta + \text{offset}_j$ if \texttt{offset()} was specified; or $x_j\beta + \ln(\text{exposure}_j)$ if \texttt{exposure()} was specified; see \texttt{nooffset} below.

\texttt{stdp} calculates the standard error of the linear prediction.

\texttt{nooffset} is relevant only if you specified \texttt{offset()} or \texttt{exposure()} when you fit the model. It modifies the calculations made by \texttt{predict} so that they ignore the offset or exposure variable; the linear prediction is treated as $x_j\beta$ rather than as $x_j\beta + \text{offset}_j$ or $x_j\beta + \ln(\text{exposure}_j)$. Specifying \texttt{predict ...}, \texttt{nooffset} is equivalent to specifying \texttt{predict ...}, \texttt{ir}.

\texttt{scores} calculates equation-level score variables.

The first new variable will contain $\partial \ln L / \partial (x_j \beta)$.

The second new variable will contain $\partial \ln L / \partial (\ln \alpha)$ for \texttt{dispersion(mean)}.

The second new variable will contain $\partial \ln L / \partial (\ln \delta)$ for \texttt{dispersion(constant)}.
margins

Description for margins

margins estimates margins of response for numbers of events, incidence rates, conditional means, probabilities, conditional probabilities, and linear predictions.

Menu for margins

Statistics > Postestimation

Syntax for margins

```
margins [marginlist] [ , options ]
margins [marginlist], predict(statistic ...) [predict(statistic ...) ] [options]
```

<table>

Statistics not allowed with margins are functions of stochastic quantities other than $e(b)$.

For the full syntax, see [R] margins.

Methods and formulas

In the following formulas, we use the same notation as in [R] tnbreg.

Methods and formulas are presented under the following headings:

Mean-dispersion model
Constant-dispersion model
Mean-dispersion model

The equation-level scores are given by

\[
\text{score}(x\beta)_j = p_j(y_j - \mu_j) - \frac{p_j^{(m+1)} \mu_j}{\Pr(Y > \tau_j | p_j, m)} \\
\text{score}(\omega)_j = -m \left\{ \frac{\alpha(\mu_j - y_j)}{1 + \alpha \mu_j} - \ln(1 + \alpha \mu_j) + \psi(y_j + m) - \psi(m) \right\} \\
\]

\[
- \frac{p_j^m}{\Pr(Y > \tau_j | p_j, m)} \{ m \ln(p_j) + \mu_j p_j \}
\]

where \( \omega_j = \ln \alpha_j \), \( \psi(z) \) is the digamma function, and \( \tau_j \) is the truncation point found in e(llopt).

Constant-dispersion model

The equation-level scores are given by

\[
\text{score}(x\beta)_j = m_j \left\{ \psi(y_j + m_j) - \psi(m_j) + \ln(p) + \frac{p_j^{m_j} \ln(p)}{\Pr(Y > \tau_j | p, m_j)} \right\} \\
\text{score}(\omega)_j = y_j - (y_j + m_j)(1 - p) - \text{score}(x\beta)_j - \frac{\mu_j p}{\Pr(Y > \tau_j | p, m_j)} \\
\]

where \( \omega_j = \ln \delta_j \) and \( \tau_j \) is the truncation point found in e(llopt).

tobit — Tobit regression

Description

tobit fits models for continuous responses where the outcome variable is censored. Censoring limits may be fixed for all observations or vary across observations.

Quick start

Tobit regression of y on x1 and x2, specifying that y is censored at the minimum of y
\[ \text{tobit } y \ x1 \ x2, \ ll \]
As above, but where the lower-censoring limit is zero
\[ \text{tobit } y \ x1 \ x2, \ ll(0) \]
As above, but specify the lower- and upper-censoring limits
\[ \text{tobit } y \ x1 \ x2, \ ll(17) \ ul(34) \]
As above, but where lower and upper are variables containing the censoring limits
\[ \text{tobit } y \ x1 \ x2, \ ll(\text{lower}) \ ul(\text{upper}) \]

</table>

- `indepvars` may contain factor variables; see [U] 11.4.3 Factor variables.
- `depvar` and `indepvars` may contain time-series operators; see [U] 11.4.4 Time-series varlists.
- `bayes`, `bootstrap`, `by`, `fmm`, `fp`, `jackknife`, `nestreg`, `rolling`, `statsby`, `stepwise`, and `svy` are allowed; see [U] 11.1.10 Prefix commands. For more details, see [BAYES] bayes: tobit and [FMM] fmm: tobit.
- Weights are not allowed with the bootstrap prefix; see [R] bootstrap.
- `aweights` are not allowed with the jackknife prefix; see [R] jackknife.
- `vce()` and weights are not allowed with the svy prefix; see [SVY] svy.
- `aweights`, `fweights`, `iweights`, and `pweights` are allowed; see [U] 11.1.6 weight.
- `collinear` and `coeflegend` do not appear in the dialog box.
- See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

**Options**

- `noconstant`; see [R] Estimation options.

- `ll(varname | #)` and `ul(varname | #)` indicate the lower and upper limits for censoring, respectively. Observations with `depvar ≤ ll()` are left-censored; observations with `depvar ≥ ul()` are right-censored; and remaining observations are not censored. You do not have to specify the censoring values. If you specify `ll`, the lower limit is the minimum of `depvar`. If you specify `ul`, the upper limit is the maximum of `depvar`.`
offset(varname), constraints(constraints); see [R] Estimation options.

vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.

level(#), nocnsreport; see [R] Estimation options.

display_options: noci, nopvalues, noomitted, vsquish, noemptycells, baselevels,
allbaselevels, nolabel, fvwrap(#), fvwrapon(style), cformat(%,fmt), pformat(%,fmt),
sformat(%,fmt), and nolstretch; see [R] Estimation options.

maximize_options: difficult, technique(algorithm_spec), iterate(#), [no]log, trace,
gradient, showstep, hessian, showtolerance, tolerance(#), lltolerance(#),
ntolerance(#), nonrtolerance, and from(init_specs); see [R] Maximize. These options are seldom used.

The following options are available with tobit but are not shown in the dialog box:
collinear, coeflegend; see [R] Estimation options.

Remarks and examples

tobit fits a linear regression model for a censored continuous outcome. Censoring occurs when the dependent variable is observed only within a certain range of values. When it is not, we know only that it is either above (right-censoring) or below (left-censoring) the censoring value. Censoring differs from truncation. When the data are truncated, we do not observe either the dependent variable or the covariates; see [R] truncreg.

Censoring may result from study design or may be a result of how the outcome is measured. Right-censoring of data may occur, for example, in income surveys that top code the highest income category. Any respondent that earns the censoring limit or more reports only the value at the limit, and we do not know the respondent’s true income. Left-censoring arises naturally when measurements are obtained from an instrument or a laboratory procedure that has a limit of detection. If we observe a value at the measurement limit, we know the true value is at the limit or below it. tobit allows the censoring limits to be the same for all observations or to vary from observation to observation.

Tobin (1958) originally conceived the tobit model as one of consumption of consumer durables where purchases were left-censored at zero. Contemporary literature treats this and similar cases as a corner solution model. See Wooldridge (2020, sec. 17.2), Long (1997, 196–210), and Maddala and Lahiri (2006, 333–336) for an introduction to the tobit model. Wooldridge (2010, chap. 17 and 19) provides an advanced treatment of censored regression models. Cameron and Trivedi (2010, chap. 16) discuss the tobit model using Stata examples.

The tobit model can be written as the latent regression model $y = x\beta + \epsilon$ with a continuousoutcome that is either observed or unobserved. Following Cong (2000), the observed outcome for observation $i$ is defined as
where \( a \) is the lower-censoring limit and \( b \) is the upper-censoring limit. The tobit model assumes that the error term is normally distributed; \( \epsilon \sim N(0, \sigma^2I) \). Depending on the problem at hand, the quantity of interest in a tobit model may be the censored outcome, \( y_i^* \), or the uncensored outcome, \( y_i \). In the measurement instrument scenario above, we may wish to predict the values that fall below the measurement threshold. By contrast, in the consumption of consumer durables scenario above, the latent variable is an artificial construct and the variable of interest is the observed consumer expenditure.

Example 1: Constant-censoring limit

University administrators want to know the relationship between high school grade point average (GPA) and students’ performance in college. \texttt{gpa.dta} contains fictional data on a cohort of 4,000 college students. College GPA (\texttt{gpa2}) and high school GPA (\texttt{hsgpa}) are measured on a continuous scale between zero and four. The outcome of interest is the student’s college GPA. But, for reasons of confidentiality, GPAs below 2.0 are reported as 2.0. In other words, the outcome is censored on the left.

We believe that GPA is also a function of the logarithm of income of the student’s parents (\texttt{pincome}) and whether or not the student participated in a study-skills program while in college (\texttt{program}).

```

```
tobit reports the coefficients for the latent regression model. Thus, we can interpret the coefficients just as we would the coefficients from OLS. For example, participation in a study-skills program increases the expected uncensored GPA by 0.56 points.
Example 2: Tobit model for a corner solution

Suppose that we are interested in the number of hours married women spend working for wages, and we treat observations recording zero hours as observed, per the corner-solution approach discussed in Wooldridge (2010, chap. 16). We use the labor supply data extracted by Mroz (1987) from the 1975 PSID for 753 married women. The variable `whrs75` records the annual number of hours worked. Forty-three percent of the surveyed women worked zero hours, and the remaining women worked on average 1,303 hours a year.

We regress hours worked on household income excluding wife’s income (`nwinc`), years of schooling (`wedyrs`), years of labor market experience (`wexper`) and its square, age (`wifeage`), an indicator for the presence of children under 6 years of age at home (`kl6`), and an indicator for the presence of children from 6 to 18 years old at home (`k618`).

```

The average marginal effect of years of education on the actual hours worked is 47.47. See [R] tobit postestimation for more examples using margins.

James Tobin (1918–2002) was an American economist who after education and research at Harvard moved to Yale, where he was on the faculty from 1950 to 1988. He made many outstanding contributions to economics and was awarded the Nobel Prize in 1981 “for his analysis of financial markets and their relations to expenditure decisions, employment, production and prices”. He trained in the U.S. Navy with the writer, Herman Wouk, who later fashioned a character after Tobin in the novel The Caine Mutiny (1951): “A mandarin-like midshipman named Tobit, with a domed forehead, measured quiet speech, and a mind like a sponge, was ahead of the field by a spacious percentage.”

Stored results
tobit stores the following in e():

Scalars
- e(N) number of observations
- e(N_unc) number of uncensored observations
- e(N_lc) number of left-censored observations
- e(N_rc) number of right-censored observations
- e(k) number of parameters
- e(k_eq) number of equations in e(b)
- e(k_aux) number of auxiliary parameters
- e(k_dv) number of dependent variables
- e(df_m) model degrees of freedom
- e(df_r) residual degrees of freedom
- e(r2_p) pseudo-$R$-squared
- e(ll) log likelihood
- e(ll_0) log likelihood, constant-only model
- e(N_clust) number of clusters
- e(chi2) $\chi^2$ statistic
- e(F) $F$ statistic
- e(p) $p$-value for model test
- e(rank) rank of e(V)
- e(ic) number of iterations
- e(rc) return code
- e(converged) 1 if converged, 0 otherwise
Macros

- `e(cmd)` tobit
- `e(cmdline)` command as typed
- `e(depvar)` name of dependent variable
- `e(llopt)` minimum of `depvar` or contents of `ll()`
- `e(ulopt)` minimum of `depvar` or contents of `ul()`
- `e(wtype)` weight type
- `e(wexp)` weight expression
- `e(covariates)` list of covariates
- `e(title)` title in estimation output
- `e(clustvar)` name of cluster variable
- `e(offset)` linear offset variable
- `e(chi2type)` type of model $\chi^2$ test
- `e(vce)` vcetype specified in `vce()`
- `e(vcetype)` title used to label Std. Err.
- `e(opt)` type of optimization
- `e(which)` max or min; whether optimizer is to perform maximization or minimization
- `e(method)` estimation method: `ml`
- `e(ml_method)` type of `ml` method
- `e(user)` name of likelihood-evaluator program
- `e(technique)` maximization technique
- `e(properties)` b V
- `e(predict)` program used to implement `predict`
- `e(marginsok)` predictions allowed by `margins`
- `e(asbalanced)` factor variables `fvset` as `asbalanced`
- `e(asobserved)` factor variables `fvset` as `asobserved`

Matrices

- `e(b)` coefficient vector
- `e(Cns)` constraints matrix
- `e(ilog)` iteration log (up to 20 iterations)
- `e(gradient)` gradient vector
- `e(V)` variance–covariance matrix of the estimators
- `e(V_modelbased)` model-based variance

Functions

- `e(sample)` marks estimation sample

Methods and formulas

See Methods and formulas in [R] intreg.

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using `vce(robust)` and `vce(cluster clustvar)`, respectively. See [P] _robust, particularly Maximum likelihood estimators and Methods and formulas.

tobit also supports estimation with survey data. For details on VCEs with survey data, see [SVY] Variance estimation.

</table>

* `forecast`, `hausman`, and `lrtest` are not appropriate with `svy` estimation results.
predict

Description for predict

predict creates a new variable containing predictions such as linear predictions, standard errors, probabilities, and expected values.

Menu for predict

Statistics > Postestimation

Syntax for predict

```
predict [ type ] newvar [ if ] [ in ] [ , statistic nooffset ]
predict [ type ] { stub* | newvar,reg newvar,sigma } [ if ] [ in ] , scores
```

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>xb</strong></td>
<td>linear prediction; the default</td>
</tr>
<tr>
<td><strong>stdp</strong></td>
<td>standard error of the linear prediction</td>
</tr>
<tr>
<td><strong>stdf</strong></td>
<td>standard error of the forecast</td>
</tr>
<tr>
<td><strong>pr(a,b)</strong></td>
<td>Pr(a &lt; y_j &lt; b)</td>
</tr>
<tr>
<td><strong>e(a,b)</strong></td>
<td>E(y_j</td>
</tr>
<tr>
<td><strong>ystar(a,b)</strong></td>
<td>E(y_j^<em>, y_j^</em> = max{a, min(y_j,b)})</td>
</tr>
</tbody>
</table>

These statistics are available both in and out of sample; type `predict ... if e(sample) ... if wanted only for the estimation sample.

`stdf` is not allowed with `svy` estimation results.

where `a` and `b` may be numbers or variables; `a` missing (`a ≥ .`) means $-\infty$, and `b` missing (`b ≥ .`) means $+\infty$; see [U] 12.2.1 Missing values.

Options for predict

```
xb, the default, calculates the linear prediction.
```

`stdp` calculates the standard error of the prediction, which can be thought of as the standard error of the predicted expected value or mean for the observation’s covariate pattern. The standard error of the prediction is also referred to as the standard error of the fitted value.

`stdf` calculates the standard error of the forecast, which is the standard error of the point prediction for 1 observation. It is commonly referred to as the standard error of the future or forecast value. By construction, the standard errors produced by `stdf` are always larger than those produced by `stdp`; see Methods and formulas in [R] regress postestimation.
\texttt{pr}(a,b)\) calculates \(\Pr(a < x_j \beta + \epsilon_j < b)\), the probability that \(y_j|x_j\) would be observed in the interval \((a,b)\).

\(a\) and \(b\) may be specified as numbers or variable names; \(lb\) and \(ub\) are variable names;
\(\texttt{pr}(20,30)\) calculates \(\Pr(20 < x_j \beta + \epsilon_j < 30)\);
\(\texttt{pr}(lb,ub)\) calculates \(\Pr(lb < x_j \beta + \epsilon_j < ub)\); and
\(\texttt{pr}(20,ub)\) calculates \(\Pr(20 < x_j \beta + \epsilon_j < ub)\).

\(a\) missing \((a \geq .)\) means \(-\infty\); \(\texttt{pr}(.,30)\) calculates \(\Pr(-\infty < x_j \beta + \epsilon_j < 30)\);
\(\texttt{pr}(lb,30)\) calculates \(\Pr(-\infty < x_j \beta + \epsilon_j < 30)\) in observations for which \(lb \geq .\)
and calculates \(\Pr(lb < x_j \beta + \epsilon_j < 30)\) elsewhere.

\(b\) missing \((b \geq .)\) means \(+\infty\); \(\texttt{pr}(20,.)\) calculates \(\Pr(+\infty > x_j \beta + \epsilon_j > 20)\);
\(\texttt{pr}(20,ub)\) calculates \(\Pr(+\infty > x_j \beta + \epsilon_j > 20)\) in observations for which \(ub \geq .\)
and calculates \(\Pr(20 < x_j \beta + \epsilon_j < ub)\) elsewhere.

\(e(a,b)\) calculates \(E(x_j \beta + \epsilon_j \mid a < x_j \beta + \epsilon_j < b)\), the expected value of \(y_j|x_j\) conditional on \(y_j|x_j\) being in the interval \((a,b)\), meaning that \(y_j|x_j\) is truncated.
\(a\) and \(b\) are specified as they are for \(\texttt{pr}()\).

\(\texttt{ystar}(a,b)\) calculates \(E(y_j^*), \) where \(y_j^* = a\) if \(x_j \beta + \epsilon_j \leq a,\)
y\(y_j^* = b\) if \(x_j \beta + \epsilon_j \geq b,\) and \(y_j^* = x_j \beta + \epsilon_j\) otherwise, meaning that \(y_j^*\) is censored. \(a\) and \(b\) are specified as they are for \(\texttt{pr}()\).

\(\texttt{nooffset}\) is relevant only if you specified \(\texttt{offset(varname)}\). It modifies the calculations made by \(\texttt{predict}\) so that they ignore the offset variable; the linear prediction is treated as \(x_j \beta\) rather than as \(x_j \beta + \text{offset}_j\).

\(\texttt{scores}\) calculates equation-level score variables.

The first new variable will contain \(\partial \ln L / \partial (x_j \beta)\).

The second new variable will contain \(\partial \ln L / \partial \sigma\).
margins

Description for margins

margins estimates margins of response for linear predictions, probabilities, and expected values.

Menu for margins

Statistics > Postestimation

Syntax for margins

```
margins [marginlist] [, options]
margins [marginlist], predict(statistic ...) [predict(statistic ...) ...] [options]
```

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>xb</td>
<td>linear prediction; the default</td>
</tr>
<tr>
<td>pr(a,b)</td>
<td>Pr(a &lt; y_j &lt; b)</td>
</tr>
<tr>
<td>e(a,b)</td>
<td>E(y_j</td>
</tr>
<tr>
<td>ystar(a,b)</td>
<td>E(y^<em>_j), y^</em>_j = max{a, min(y_j,b)}</td>
</tr>
<tr>
<td>stdp</td>
<td>not allowed with margins</td>
</tr>
<tr>
<td>stdf</td>
<td>not allowed with margins</td>
</tr>
</tbody>
</table>

Statistics not allowed with margins are functions of stochastic quantities other than e(b).

For the full syntax, see [R] margins.

Remarks and examples

Example 1: Marginal predictions

In example 2 of [R] tobit, we fit a tobit model of annual number of hours that married women spend working and then obtained estimated average marginal effect of 47.47 for years of education on observed hours worked.

```
. use https://www.stata-press.com/data/r16/mroz87
   (1975 PSID data from Mroz, 1987)
. tobit whrs75 nwinc wedyrs wexper c.wexper#c.wexper wifeage kl6 k618, ll(0)
   (output omitted)
. margins, dydx(wedyrs) predict(ystar(0,..))
   (output omitted)
```

However, we may not want this overall effect. To obtain marginal effects for specific alternative scenarios, we use margins with the at() option. For example, continuing with example 2 of [R] tobit to estimate the means of the marginal effects on the expected value of the censored outcome conditional on education ranging from 8 years to 17 years, we type
. margins, dydx(wedyrs) predict(ystar(0,.)) at(wedyrs=(8(1)17))

Average marginal effects  Number of obs = 753
Model VCE : OIM
Expression : E(whrs75*|whrs75>0), predict(ystar(0,.))
  dy/dx w.r.t. : wedyrs
   1._at : wedyrs = 8
   2._at : wedyrs = 9
   3._at : wedyrs = 10
   4._at : wedyrs = 11
   5._at : wedyrs = 12
   6._at : wedyrs = 13
   7._at : wedyrs = 14
   8._at : wedyrs = 15
   9._at : wedyrs = 16
  10._at : wedyrs = 17

|        | dy/dx | Std. Err. |      z | P>|z| | [95% Conf. Interval] |
|--------|-------|-----------|-------|------|----------------------|
| wedyrs |       |           |       |      |                      |
| 1      | 39.59 | 8.43      | 4.69  | 0.00 | 23.06                |
| 2      | 41.45 | 9.42      | 4.40  | 0.00 | 22.98                |
| 3      | 43.31 | 10.41     | 4.16  | 0.00 | 22.89                |
| 4      | 45.15 | 11.39     | 3.96  | 0.00 | 22.81                |
| 5      | 46.97 | 12.38     | 3.80  | 0.00 | 22.72                |
| 6      | 48.78 | 13.33     | 3.65  | 0.00 | 22.65                |
| 7      | 50.55 | 14.26     | 3.56  | 0.00 | 22.59                |
| 8      | 52.28 | 15.16     | 3.45  | 0.00 | 22.56                |
| 9      | 53.98 | 16.03     | 3.37  | 0.00 | 22.56                |
| 10     | 55.64 | 16.86     | 3.30  | 0.00 | 22.56                |

The estimated mean of the marginal effects is about 39.59 hours for 8 years of schooling, about 41.45 hours for 9 years of schooling, and so on.

Total

**total — Estimate totals**

<table>
<thead>
<tr>
<th>Description</th>
<th>Quick start</th>
<th>Menu</th>
<th>Syntax</th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

**Description**

total produces estimates of totals, along with standard errors.

**Quick start**

Total of continuous variable v1

```
total v1
```

As above, but restrict estimation to observations where catvar = 1

```
total v1 if catvar==1
```

As above, but using `svyset` data

```
svy, subpop(if catvar==1): total v1
```

Total of v1 for each level of catvar

```
total v1, over(catvar)
```

With jackknife standard errors

```
total v1, vce(jackknife)
```

**Menu**

Statistics > Summaries, tables, and tests > Summary and descriptive statistics > Totals
Syntax

```
total varlist [if] [in] [weight] [, options]
```

<table>
<thead>
<tr>
<th>options</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>if/in/over</td>
<td></td>
</tr>
<tr>
<td><code>over(varlist_o)</code></td>
<td>group over subpopulations defined by varlist_o</td>
</tr>
<tr>
<td>SE/Cluster</td>
<td></td>
</tr>
<tr>
<td><code>vce(vcetype)</code></td>
<td><code>vcetype</code> may be analytic, <code>cluster clustvar</code>, bootstrap, or jackknife</td>
</tr>
<tr>
<td>Reporting</td>
<td></td>
</tr>
<tr>
<td><code>level(#)</code></td>
<td>set confidence level; default is level(95)</td>
</tr>
<tr>
<td><code>noheader</code></td>

</tr>
<tr>
<td><code>display_options</code></td>
<td>control column formats, line width, display of omitted variables and base and empty cells, and factor-variable labeling</td>
</tr>
<tr>
<td><code>coeflegend</code></td>
<td>display legend instead of statistics</td>
</tr>
</tbody>
</table>

`varlist` may contain factor variables; see [U] 11.4.3 Factor variables.
`bootstrap`, `jackknife`, `mi estimate`, `rolling`, `statsby`, and `svy` are allowed; see [U] 11.1.10 Prefix commands.
`vce(bootstrap)` and `vce(jackknife)` are not allowed with the `mi estimate` prefix.
Weights are not allowed with the bootstrap prefix; see [R] bootstrap.
`vce()` and weights are not allowed with the `svy` prefix; see [SVY] svy.
`fweights`, `iweights`, and `pweights` are allowed; see [U] 11.1.6 weight.
`coeflegend` does not appear in the dialog box.
See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

Options

**if/in/over**

`over(varlist_o)` specifies that estimates be computed for multiple subpopulations, which are identified by the different values of the variables in varlist_o. Only numeric, nonnegative, integer-valued variables are allowed in over(varlist_o).

**SE/Cluster**

`vce(vcetype)` specifies the type of standard error reported, which includes types that are derived from asymptotic theory (analytic), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.
`vce(bootstrap)` the default, uses the analytically derived variance estimator associated with the sample total.

**Reporting**

`level(#)`; see [R] Estimation options.
`noheader` prevents the table header from being displayed.
`display_options`: `noomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fwrap(#)`, `fwrapon(style)`, `cformat(%fmt)`, and `nolstretch`; see [R] Estimation options.
The following option is available with total but is not shown in the dialog box:coeflegend; see [R] Estimation options.

Remarks and examples

Example 1

Suppose that we collected data on incidence of heart attacks. The variable heartatk indicates whether a person ever had a heart attack (1 means yes; 0 means no). We can then estimate the total number of persons who have had heart attacks for each sex in the population represented by the data we collected.

```stata
. use https://www.stata-press.com/data/r16/total
. total heartatk [pw=swgt], over(sex)
Total estimation
Number of obs = 4,946

<table>
<thead>
<tr>
<th></th>
<th>Total</th>
<th>Std. Err.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>heartatk@sex</td>
<td></td>
<td></td>
<td></td>
</tr>
<tr>
<td>Male</td>
<td>944559</td>
<td>104372.3</td>
<td>739943</td>
</tr>
<tr>
<td>Female</td>
<td>581590</td>
<td>82855.59</td>
<td>419156.3</td>
</tr>
</tbody>
</table>
```

Stored results

total stores the following in e():

Scalars

e(N)  number of observations
N_over number of subpopulations
N_clust number of clusters
k_eq number of equations in e(b)
df_r sample degrees of freedom
rank rank of e(V)

Macros

cmd total
cmdline command as typed
varlist
wtype weight type
wexp weight expression
title title in estimation output
clustvar name of cluster variable
over varlist from over()
vce vcetype specified in vce()
vctype title used to label Std. Err.
(properties) b V
estat_cmd program used to implement estat
marginsnotok predictions disallowed by margins

Matrices

b vector of total estimates
V (co)variance estimates
N vector of numbers of nonmissing observations
error error code corresponding to e(b)

Functions

e(sample) marks estimation sample
Methods and formulas

Methods and formulas are presented under the following headings:

- The total estimator
- Survey data
- The survey total estimator
- The poststratified total estimator
- Subpopulation estimation

The total estimator

Let $y$ denote the variable on which to calculate the total and $y_j, j = 1, \ldots, n$, denote an individual observation on $y$. Let $w_j$ be the frequency weight (or `iweight` or `pweight`), and if no weight is specified, define $w_j = 1$ for all $j$. The sum of the weights is an estimate of the population size:

$$\hat{N} = \sum_{j=1}^{n} w_j$$

If the population values of $y$ are denoted by $Y_j, j = 1, \ldots, N$, the associated population total is

$$Y = \sum_{j=1}^{N} Y_j = N\bar{y}$$

where $\bar{y}$ is the population mean. The total is estimated as

$$\hat{Y} = \hat{N}\bar{y}$$

The variance estimator for the total is

$$\hat{V}(\hat{Y}) = \hat{N}^2\hat{V}(\bar{y})$$

where $\hat{V}(\bar{y})$ is the variance estimator for the mean; see [R] mean. The standard error of the total is the square root of the variance.

If $x, x_j, \bar{x}$, and $\hat{X}$ are similarly defined for another variable (observed jointly with $y$), the covariance estimator between $\hat{X}$ and $\hat{Y}$ is

$$\hat{\text{Cov}}(\hat{X}, \hat{Y}) = \hat{N}^2\hat{\text{Cov}}(\bar{x}, \bar{y})$$

where $\hat{\text{Cov}}(\bar{x}, \bar{y})$ is the covariance estimator between two means; see [R] mean.

Survey data

See [SVY] Variance estimation and [SVY] Poststratification for discussions that provide background information for the following formulas.
The survey total estimator

Let $Y_j$ be a survey item for the $j$th individual in the population, where $j = 1, \ldots, M$ and $M$ is the size of the population. The associated population total for the item of interest is

$$Y = \sum_{j=1}^{M} Y_j$$

Let $y_j$ be the survey item for the $j$th sampled individual from the population, where $j = 1, \ldots, m$ and $m$ is the number of observations in the sample.

The estimator $\hat{Y}$ for the population total $Y$ is

$$\hat{Y} = \sum_{j=1}^{m} w_j y_j$$

where $w_j$ is a sampling weight. The estimator for the number of individuals in the population is

$$\hat{M} = \sum_{j=1}^{m} w_j$$

The score variable for the total estimator is the variable itself,

$$z_j(\hat{Y}) = y_j$$

The poststratified total estimator

Let $P_k$ denote the set of sampled observations that belong to poststratum $k$, and define $I_{P_k}(j)$ to indicate if the $j$th observation is a member of poststratum $k$, where $k = 1, \ldots, L_P$ and $L_P$ is the number of poststrata. Also, let $M_k$ denote the population size for poststratum $k$. $P_k$ and $M_k$ are identified by specifying the `poststrata()` and `postweight()` options on `svyset`; see [SVY] svyset.

The estimator for the poststratified total is

$$\hat{Y}_P = \sum_{k=1}^{L_P} \frac{M_k}{\hat{M}_k} \hat{Y}_k = \sum_{k=1}^{L_P} \frac{M_k}{\hat{M}_k} \sum_{j=1}^{m} I_{P_k}(j) w_j y_j$$

where

$$\hat{M}_k = \sum_{j=1}^{m} I_{P_k}(j) w_j$$

The score variable for the poststratified total is

$$z_j(\hat{Y}_P) = \sum_{k=1}^{L_P} I_{P_k}(j) \frac{M_k}{\hat{M}_k} \left( y_j - \frac{\hat{Y}_k}{\hat{M}_k} \right)$$
Subpopulation estimation

Let $S$ denote the set of sampled observations that belong to the subpopulation of interest, and define $I_S(j)$ to indicate if the $j$th observation falls within the subpopulation.

The estimator for the subpopulation total is

$$\hat{Y}^S = \sum_{j=1}^{m} I_S(j) \ w_j y_j$$

and its score variable is

$$z_j(\hat{Y}^S) = I_S(j) \ y_j$$

The estimator for the poststratified subpopulation total is

$$\hat{Y}^{PS} = \sum_{k=1}^{L_P} \frac{M_k}{M} \hat{Y}^S_k = \sum_{k=1}^{L_P} \frac{M_k}{M} \sum_{j=1}^{m} I_{P_k}(j) I_S(j) \ w_j y_j$$

and its score variable is

$$z_j(\hat{Y}^{PS}) = \sum_{k=1}^{L_P} I_{P_k}(j) \ \frac{M_k}{M} \left\{ I_S(j) \ y_j - \frac{\hat{Y}^S_k}{M_k} \right\}$$

</tr>
<tr>
<td>nlcom</td>
<td>point estimates, standard errors, testing, and inference for nonlinear combinations of coefficients</td>
</tr>
<tr>
<td>pwcompare</td>
<td>pairwise comparisons of estimates</td>
</tr>
<tr>
<td>test</td>
<td>Wald tests of simple and composite linear hypotheses</td>
</tr>
<tr>
<td>testnl</td>
<td>Wald tests of nonlinear hypotheses</td>
</tr>
</tbody>
</table>

Remarks and examples

Example 1

Continuing with our data on incidence of heart attacks from example 1 in [R] `total`, we want to test whether there are twice as many heart attacks among men than women in the population.

```
  . use https://www.stata-press.com/data/r16/total
  . total heartatk [pw=swgt], over(sex)
    (output omitted)
  . test heartatk@1.sex = 2 * heartatk@2.sex
     ( 1) c.heartatk@1bn.sex - 2*c.heartatk@2.sex = 0
    F( 1, 4945) = 1.25
    Prob > F = 0.2643
```

Thus we do not reject our hypothesis that the total number of heart attacks for men is twice that for women in the population.

[U] 20 Estimation and postestimation commands
tpoisson — Truncated Poisson regression

Description

tpoisson fits a truncated Poisson regression model when the number of occurrences of an event is restricted to be above a truncation point, below a truncation point, or between two truncation points. Truncated Poisson models are appropriate when neither the dependent variable nor the covariates are observed in the truncated part of the distribution. By default, \texttt{tpoisson} assumes left-truncation occurs at zero, but truncation may be specified at other fixed points or at values that vary across observations.

Quick start

Truncated Poisson regression of $y$ on $x_1$ and $x_2$ with left-truncation at 0

\begin{verbatim}
   tpoisson y x1 x2
\end{verbatim}

Add categorical variable $a$ using factor-variable syntax

\begin{verbatim}
   tpoisson y x1 x2 i.a
\end{verbatim}

As above, but report incidence-rate ratios and use a constant truncation point of 4

\begin{verbatim}
   tpoisson y x1 x2 i.a, irr ll(4)
\end{verbatim}

With offset variable \texttt{lnexp}

\begin{verbatim}
   tpoisson y x1 x2 i.a, offset(lnexp)
\end{verbatim}

As above, but with a variable truncation point stored in variable $\text{min}$

\begin{verbatim}
   tpoisson y x1 x2 i.a, offset(lnexp) ll(min)
\end{verbatim}

With variable left- and right-truncation points

\begin{verbatim}
   tpoisson y x1 x2, ll(min) ul(max)
\end{verbatim}

With variable right-truncation points

\begin{verbatim}
   tpoisson y x1 x2, ul(max)
\end{verbatim}

Constrain the coefficients for $2.a$ and $3.a$ to equality

\begin{verbatim}
   constraint define 1 2.a = 3.a
   tpoisson y x1 x2 i.a, constraints(1)
\end{verbatim}

Menu

Statistics > Count outcomes > Truncated Poisson regression
Syntax

`tpoisson depvar [ indepvars ] [ if ] [ in ] [ weight ] [, options ]`

**options**

**Model**

- `noconstant` suppress constant term
- `ll(# | varname)` lower limit for truncation; default is `ll(0)` when neither `ll()` nor `ul()` is specified
- `ul(# | varname)` upper limit for truncation
- `exposure(varname_o)` include \( \ln(varname_o) \) in model with coefficient constrained to 1
- `offset(varname_o)` include \( varname_o \) in model with coefficient constrained to 1
- `constraints(constraints)` apply specified linear constraints

**SE/Robust**

- `vce(vcetype)` `vcetype` may be `oim`, `robust`, `cluster clustvar`, `opg`, `bootstrap`, or `jackknife`

**Reporting**

- `level(#)` set confidence level; default is `level(95)`
- `irr` report incidence-rate ratios
- `noconsreport` do not display constraints
- `display_options` control columns and column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling

**Maximization**

- `maximize_options` control the maximization process; seldom used
- `collinear` keep collinear variables
- `coeflegend` display legend instead of statistics

**dependencies**

- `indepvars` may contain factor variables; see [U] 11.4.3 Factor variables.
- `depvar` and `indepvars` may contain time-series operators; see [U] 11.4.4 Time-series varlists.
- `bayes`, `bootstrap`, `by`, `fmm`, `fp`, `jackknife`, `rolling`, `statsby`, and `svy` are allowed; see [U] 11.1.10 Prefix commands. For more details, see [BAYES] bayes: `tpoisson` and [FMM] fmm: `tpoisson`.
- Weights are not allowed with the `bootstrap` prefix; see [R] bootstrap.
- `vce()` and weights are not allowed with the `svy` prefix; see [SVY] svy.
- `fweight()`, `iweight()`, and `pweight()` are allowed; see [U] 11.1.6 weight.
- `collinear` and `coeflegend` do not appear in the dialog box.
- See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

**Options**

- `noconstant`; see [R] Estimation options.

- `ll(# | varname)` and `ul(#|varname)` specify the lower and upper limits for truncation, respectively.
  - You may specify nonnegative integer values for one or both.
  - When neither `ll()` nor `ul()` is specified, the default is zero truncation, `ll(0)`, equivalent to left-truncation at zero.
exposure(varname_e), offset(varname_o), constraints(constraints); see [R] Estimation options.

`vce(vcetype)` specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim, opg), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] `vce_option`.

`level(#)`; see [R] Estimation options.

`irr` reports estimated coefficients transformed to incidence-rate ratios, that is, $e^{\beta_i}$ rather than $\beta_i$. Standard errors and confidence intervals are similarly transformed. This option affects how results are displayed, not how they are estimated. `irr` may be specified at estimation or when replaying previously estimated results.

`nocnsreport`; see [R] Estimation options.

display_options: noci, nopvalues, noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(#), fvwrapon(style), cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch; see [R] Estimation options.

`maximize_options: difficult, technique(algorithm_spec), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(init_specs); see [R] Maximize`. These options are seldom used.

Setting the optimization type to `technique(bhhh)` resets the default `vcetype` to `vce(opg)`.

The following options are available with `tpoisson` but are not shown in the dialog box:

collinear, coeflegend; see [R] Estimation options.

Remarks and examples

tpoisson fits a truncated Poisson regression model by maximum likelihood estimation when the number of occurrences of an event is restricted to be above a truncation point, below a truncation point, or between two truncation points. If the dependent variable is not truncated, standard Poisson regression may be more appropriate; see [R] `poisson`.

When the data are truncated, we do not observe either the dependent variable or the covariates. For example, consider a study about the number of days that individuals with hyperglycemia are hospitalized after presenting to the hospital. If we select our sample only from admission records, then the sample is truncated at zero because we have data only on individuals who stayed at least one day. Now assume that we are relying on billing data and that hospitals may submit either a final bill when a patient is discharged or an interim bill every 30 days. In this case, we have no information about patients who are hospitalized fewer than 1 day or more than 30 days. Our data are left-truncated at 0 and right-truncated at 30.

A related phenomenon is censoring. For censored observations, we observe complete covariate information but only a censored value of the dependent variable. Different research designs can give rise to censored data or truncated data. See [R] `cpoisson` for information about censored Poisson regression.

Example 1: Left-truncation at zero

Consider the Simonoff (2003) dataset of running shoes for a sample of runners who registered an online running log. A running-shoe marketing executive is interested in knowing how the number of pairs of running shoes purchased relates to other factors such as gender, marital status, age, education, income, typical number of runs per week, average miles run per week, and the preferred type of running. These data are naturally truncated at zero. A truncated Poisson model is fit to the number of pairs of shoes owned on runs per week, miles run per week, gender, age, and marital status.

No options are needed because zero truncation is the default for tpoisson.

```
. use https://www.stata-press.com/data/r16/runshoes
. tpoisson shoes rpweek mpweek male age married
```

|                      | Coef. | Std. Err. | z    | P>|z| | [95% Conf. Interval] |
|----------------------|-------|-----------|------|------|----------------------|
| rpweek               | 0.1576| 0.1098    | 1.44 | 0.151| (0.0576, 0.3727)      |
| mpweek               | 0.0211| 0.0091    | 2.31 | 0.021| (0.0032, 0.0389)      |
| male                 | 0.0446| 0.0091    | 2.31 | 0.021| (0.0032, 0.0389)      |
| age                  | 0.0185| 0.0037    | 0.51 | 0.521| (0.0017, 0.0456)      |
| married              | -0.1283| 0.0275| -4.74| 0.000| (-0.2750, 0.0200)     |
| _cons                | -1.2058| 0.6619| -1.82| 0.069| (-2.5033, 0.0916)     |

Using the zero-truncated Poisson regression with these data, only the coefficient on average miles per week is statistically significant at the 5% level.

Example 2: Left-truncation with a fixed-truncation point

Semiconductor manufacturing requires that silicon wafers be coated with a layer of metal oxide. The depth of this layer is strictly controlled. In this example, a critical oxide layer is designed for 300 ± 20 angstroms (Å).

After the oxide layer is coated onto a wafer, the wafer enters a photolithography step in which the lines representing the electrical connections are printed on the oxide and later etched and filled with metal. The widths of these lines are measured. In this example, they are controlled to 90 ± 5 micrometers (µm).

After these and other steps, each wafer is electrically tested at probe. If too many failures are discovered, the wafer is rejected and sent for engineering analysis. In this example, the maximum number of probe failures tolerated for this product is 10.
A major failure at probe has been encountered—88 wafers had more than 10 failures each. The 88 wafers that failed were tested using 4 probe machines. The engineer suspects that the failures were a result of faulty probe machines, poor depth control, or poor line widths. The line widths and depths in these data are the actual measurement minus its specification target, 300 Å for the oxide depths and 90 µm for the line widths.

The following table tabulates the average failure rate for each probe using Stata’s mean command; see [R] mean.

```stata
.use https://www.stata-press.com/data/r16/probe
.mean failures, over(probe)
```

<table>
<thead>
<tr>
<th>probe</th>
<th>mean failures</th>
</tr>
</thead>
<tbody>
<tr>
<td>1</td>
<td>15.875</td>
</tr>
<tr>
<td>2</td>
<td>14.95833</td>
</tr>
<tr>
<td>3</td>
<td>16.47059</td>
</tr>
<tr>
<td>4</td>
<td>23.09677</td>
</tr>
</tbody>
</table>

The 95% confidence intervals in this table suggest that there are about 5–11 additional failures per wafer on probe 4. These are unadjusted for varying line widths and oxide depths. Possibly, probe 4 received the wafers with larger line widths or extreme oxide depths.

Truncated Poisson regression more clearly identifies the root causes for the increased failures by estimating the differences between probes adjusted for the line widths and oxide depths. It also allows us to determine whether the deviations from specifications in line widths or oxide depths might be contributing to the problem.

```stata
tpoisson failures i.probe depth width, ll(10) nolog
```

| probe | Coef. | Std. Err. | z   | P>|z| | [95% Conf. Interval] |
|-------|-------|-----------|-----|------|----------------------|
| 1     | -1.1113037 | .1019786 | -1.09 | 0.275 | -.3111781 -.0885707 |
| 2     | .0114339    | .1036032 | 0.11 | 0.912 | -.1916245 .2144924 |
| 3     | .4254115    | .0841277 | 5.06 | 0.000 | .2605242 .5902989 |
| 4     | -.0005034   | .0033375 | -0.15 | 0.880 | -.0107647 .000638 |

The coefficients listed for the probes are testing the null hypothesis: \( H_0: \) probe_\(i\) = probe_\(1\), where \(i\) equals 2, 3, and 4. Because the only coefficient that is statistically significant is the one for testing for \( H_0: \) probe_\(4\) = probe_\(1\), \(p < 0.001\), and because the \(p\)-values for the other probes are not statistically significant, that is, \(p \geq 0.275\), the implication is that there is a difference between probe 4 and the other machines. Because the coefficient for this test is positive, 0.425, the conclusion is that the average failure rate for probe 4, after adjusting for line widths and oxide depths, is higher than the other probes. Possibly, probe 4 needs calibration or the head used with this machine is defective.

Line-width control is statistically significant, \(p = 0.034\), but variation in oxide depths is not causing the increased failure rate. The engineer concluded that the sudden increase in failures is the result of
two problems. First, probe 4 is malfunctioning, and second, there is a possible lithography or etching problem.

Stored results

tpoisson stores the following in e():

Scalars

- e(N): number of observations
- e(k): number of parameters
- e(k_eq): number of equations in e(b)
- e(k_eq_model): number of equations in overall model test
- e(k_dv): number of dependent variables
- e(df_m): model degrees of freedom
- e(r2_p): pseudo-$R^2$-squared
- e(ll): log likelihood
- e(ll_0): log likelihood, constant-only model
- e(N_clust): number of clusters
- e(chi2): $\chi^2$
- e(p): $p$-value for model test
- e(rank): rank of e(V)
- e(ic): number of iterations
- e(rc): return code
- e(converged): 1 if converged, 0 otherwise

Macros

- e(cmd): tpoisson
- e(cmdline): command as typed
- e(depvar): name of dependent variable
- e(llopt): contents of ll(), or 0 if neither ll() nor ul() is specified
- e(ulopt): contents of ul(), if specified
- e(wtype): weight type
- e(wexp): weight expression
- e(title): title in estimation output
- e(clustvar): name of cluster variable
- e(offset): linear offset variable
- e(chi2type): Wald or LR; type of model $\chi^2$ test
- e(vce): vcetype specified in vce()
- e(vcetype): title used to label Std. Err.
- e(opt): type of optimization
- e(which): max or min; whether optimizer is to perform maximization or minimization
- e(ml_method): type of ml method
- e(user): name of likelihood-evaluator program
- e(technique): maximization technique
- e(properties): b V
- e(predict): program used to implement predict
- e(asbalanced): factor variables fvset as asbalanced
- e(asobserved): factor variables fvset as asobserved

Matrices

- e(b): coefficient vector
- e(Cns): constraints matrix
- e(llog): iteration log (up to 20 iterations)
- e(gradient): gradient vector
- e(V): variance–covariance matrix of the estimators
- e(V_modelbased): model-based variance

Functions

- e(sample): marks estimation sample
Methods and formulas

For a nonnegative count outcome $Y$ with left-truncation point $ll_j$ and right-truncation point $ul_j$, we can write the truncated Poisson model as

$$f(y_j) = \frac{\exp(-\lambda_j)\lambda_j^{y_j}}{y_j! \Pr(ll_j < Y < ul_j | \xi_j)}$$

where

$$\xi_j = x_j\beta + \text{offset}_j$$
$$\lambda_j = \exp(\xi_j)$$

and $x_j$ is a vector of observed covariates. The conditional probability of observing $y_j$ events, therefore given by $ll_j < y_j < ul_j$, is

$$\Pr(Y = y_j \mid ll_j < y_j < ul_j, x_j) = \frac{\exp(-\lambda_j)\lambda_j^{y_j}}{y_j! \Pr(ll_j < Y < ul_j | x_j)}$$

The log likelihood is given by

$$\ln L = \sum_{j=1}^{n} w_j [-\lambda_j + \xi_j y_j - \ln(y_j!) - \ln \{ \Pr(ll_j < Y < ul_j | \xi_j) \}]$$

If no weights are specified, $w_j = 1$.

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using vce(robust) and vce(cluster clustvar), respectively. See [P] _robust, particularly Maximum likelihood estimators and Methods and formulas.

tpoisson also supports estimation with survey data. For details on VCEs with survey data, see [SVY] Variance estimation.

Acknowledgment

We gratefully acknowledge the previous work by Joseph Hilbe (1944–2017) (1999), a former editor of the Stata Technical Bulletin and coauthor of the Stata Press book Generalized Linear Models and Extensions.

* `forecast`, `hausman`, and `lrtest` are not appropriate with `svy` estimation results.
predict

**Description for predict**

`predict` creates a new variable containing predictions such as numbers of events, incidence rates, conditional means, probabilities, conditional probabilities, linear predictions, standard errors, and equation-level scores.

**Menu for predict**

Statistics > Postestimation

**Syntax for predict**

```
predict [ `type` ] newvar [ `if` ] [ `in` ] [ `, statistic | nooffset` ]
```

<table>
<thead>
<tr>

</tr>
</tbody>
</table>

These statistics are available both in and out of sample; type `predict ... if e(sample) ... if wanted` only for the estimation sample.

**Options for predict**

- `n`, the default, calculates the predicted number of events, which is $\exp(x_j \beta)$ if neither `offset()` nor `exposure()` was specified when the model was fit; $\exp(x_j \beta + \text{offset})$ if `offset()` was specified; or $\exp(x_j \beta) \times \text{exposure}$ if `exposure()` was specified.

- `ir` calculates the incidence rate $\exp(x_j \beta)$, which is the predicted number of events when exposure is 1. This is equivalent to specifying both the `n` and the `nooffset` options.

- `cm` calculates the conditional mean,

$$E(y_j | ll_j < y_j < ul_j) = \frac{E(y_j, ll_j < y_j < ul_j)}{Pr(ll_j < y_j < ul_j)}$$

where $ll_j$ is the left-truncation point specified at estimation and $ul_j$ is the right-truncation point specified at estimation.
pr(\(n\)) calculates the probability \(\Pr(y_j = n)\), where \(n\) is a nonnegative integer that may be specified as a number or a variable.

pr(\((a, b)\)) calculates the probability \(\Pr(a \leq y_j \leq b)\), where \(a\) and \(b\) are nonnegative integers that may be specified as numbers or variables;

\(b\) missing \((b \geq .)\) means \(+\infty\);

pr\((20, .)\) calculates \(\Pr(y_j \geq 20)\);

pr\((20, b)\) calculates \(\Pr(y_j \geq 20)\) in observations for which \(b \geq .\) and calculates \(\Pr(20 \leq y_j \leq b)\) elsewhere.

pr\((., b)\) produces a syntax error. A missing value in an observation of the variable \(a\) causes a missing value in that observation for pr\((a, b)\).

cpr(\(n\)) calculates the conditional probability \(\Pr(y_j = n \mid ll_j < y_j < ul_j)\), where \(n\) is a nonnegative integer that may be specified as a number or a variable. \(ll_j\) and \(ul_j\) are as defined in cm.

cpr\((a, b)\) calculates the conditional probability \(\Pr(a \leq y_j \leq b \mid ll_j < y_j < ul_j)\), where \(a\) and \(b\) are as defined in pr\((a, b)\) with the additional restrictions that \(a > ll_j\) and \(b < ul_j\). \(ll_j\) and \(ul_j\) are as defined in cm.

\(\text{xb}\) calculates the linear prediction, which is \(x_j \beta\) if neither offset() nor exposure() was specified when the model was fit; \(x_j \beta + \text{offset}_j\) if offset() was specified; or \(x_j \beta + \ln(\text{exposure}_j)\) if exposure() was specified; see nooffset below.

\(\text{stdp}\) calculates the standard error of the linear prediction.

\(\text{score}\) calculates the equation-level score, \(\partial \ln L / \partial (x_j \beta)\).

nooffset is relevant only if you specified offset() or exposure() when you fit the model. It modifies the calculations made by predict so that they ignore the offset or exposure variable; the linear prediction is treated as \(x_j \beta\) rather than as \(x_j \beta + \text{offset}_j\) or \(x_j \beta + \ln(\text{exposure}_j)\). Specifying predict ..., nooffset is equivalent to specifying predict ..., ir.
margins

Description for margins

margins estimates margins of response for numbers of events, incidence rates, conditional means, probabilities, conditional probabilities, and linear predictions.

Menu for margins

Statistics > Postestimation

Syntax for margins

```
margins [marginlist] [, options]  
margins [marginlist], predict(statistic ...) [predict(statistic ...) ...] [options]
```

<table>

</tr>
</tbody>
</table>

Statistics not allowed with margins are functions of stochastic quantities other than $e(b)$.

For the full syntax, see [R] margins.

Remarks and examples

Example 1: Obtaining margins of the conditional mean

In example 1 of [R] tpoisson, a truncated Poisson model is fit to the number of pairs of shoes owned on runs per week, miles run per week, gender, age, and marital status. We continue that example to determine the effect of miles run per week on the average number of pairs of shoes owned.

After reading in the data, we use summarize to obtain the 25th, 50th, and 75th percentiles for miles run per week.
. use https://www.stata-press.com/data/r16/runshoes
. summarize mpweek, detail

<table>
<thead>

</tr>
<tr>
<td>99%</td>
<td>57.5</td>
</tr>
</tbody>
</table>

Obs       = 60
Sum of Wgt. = 60
Mean       = 24.71167
Variance   = 205.9034
Skewness   = .1948568
Kurtosis   = 2.065304

We fit the model from example 1 of [R] tpoisson again. We next specify these values for the percentiles to margins to estimate the conditional mean of the number of pairs of shoes at different quantiles of miles run per week. To do this, we use the at() option of margins.

. quietly tpoisson shoes rpweek mpweek male age married
. margins, at(mpweek=(12.5 27.5 32.5)) predict(cm)

Predictive margins Number of obs = 60
Model VCE : OIM
Expression : Conditional mean of n > ll(0), predict(cm)
1._at : mpweek = 12.5
2._at : mpweek = 27.5
3._at : mpweek = 32.5

|   | Margin | Std. Err. | z   | P>|z| | [95% Conf. Interval] |
|---|--------|-----------|-----|-----|----------------------|
| 1 | 1.942149 | .2111564 | 9.20 | 0.000 | 1.52829 | 2.356008 |
| 2 | 2.376253 | .1714522 | 13.86 | 0.000 | 2.040213 | 2.712293 |
| 3 | 2.564339 | .1948129 | 13.16 | 0.000 | 2.182513 | 2.946165 |

We see that people who run 12.5 miles per week are expected to own 1.94 pairs of shoes. The expected number of pairs of shoes owned increases as the average miles per week increases. We expect people who run 27.5 miles per week have 2.38 pairs of shoes and those who run 32.5 miles per week have 2.56 pairs of shoes.

Methods and formulas

Continuing from Methods and formulas in [R] tpoisson, the equation-level scores are given by

\[
\text{score}(x\beta)_j = y_j - \lambda_j - \frac{\{ \exp(-\lambda_j)\lambda_j^{ll_j}/ll_j! - \exp(-\lambda_j)\lambda_j^{(ul_j-1)}/(ul_j - 1)!\}}{\Pr(ll_j < Y < ul_j | \xi_j)} \lambda_j
\]

</tr>
<tr>
<td></td>
<td></td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

**Quick start**

Translate SMCL-format log `mylog.smcl` to a text log file `mylog.log`

```
translate mylog.smcl mylog.log
```

As above, but translate `mylog.smcl` to PostScript file `mylog.ps`

```
translate mylog.smcl mylog.ps
```

Send output from the Results window to new `mylog.txt` when no log was started

```
translate @Results mylog.txt
```
Syntax

Print log and SMCL files

\texttt{print \ filename \ [\ , \ like(ext) \ name(windowname) \ override\_options]} \ 

Translate log files to SMCL files and vice versa

\texttt{translate \ filename\_in \ filename\_out \ [\ , \ translator(tname) \ name(windowname) \ override\_options \ replace]} \ 

View translator parameter settings

\texttt{translator \ query \ [tname]} \ 

Change translator parameter settings

\texttt{translator \ set \ [tname \ setopt \ setval]} \ 

Return translator parameter settings to default values

\texttt{translator \ reset \ tname} \ 

List current mappings from one extension to another

\texttt{transmap \ query \ [\.ext]} \ 

Specify that files with one extension be treated the same as files with another extension

\texttt{transmap \ define \ .ext\new \ .ext\old} \ 

\texttt{filename} in print, in addition to being a filename to be printed, may be specified as @Results to mean the Results window and @Viewer to mean the Viewer window.

\texttt{filename\_in} in translate may be specified just as \texttt{filename} in print.

\texttt{tname} in translator specifies the name of a translator; see the \texttt{translator()} option under Options for translate.

Options for print

\texttt{like(ext)} specifies how the file should be translated to a form suitable for printing. The default is to determine the translation method from the extension of \texttt{filename}. Thus \texttt{mylog.smcl} is translated according to the rule for translating \texttt{smcl} files, \texttt{myfile.txt} is translated according to the rule for translating \texttt{txt} files, and so on. (These rules are, in fact, translate’s \texttt{smcl2prn} and \texttt{txt2prn} translators, but put that aside for the moment.)

Rules for the following extensions are predefined:

\texttt{.txt} \hspace{1cm} \texttt{assume input file contains plain text} \\
\texttt{.log} \hspace{1cm} \texttt{assume input file contains Stata log text} \\
\texttt{.smcl} \hspace{1cm} \texttt{assume input file contains SMCL}
To print a file that has an extension different from those listed above, you can define a new extension, but you do not have to do that. Assume that you wish to print the file read.me, which you know to contain plain text. If you were just to type `print read.me`, you would be told that Stata cannot translate .me files. (You would actually be told that the translator for me2prn was not found.) You could type `print read.me, like(txt)` to tell `print` to print `read.me` like a .txt file.

On the other hand, you could type

```
.transmap define .me .txt
```

to tell Stata that .me files are always to be treated like .txt files. If you did that, Stata would remember the new rule, even in future sessions.

When you specify the `like()` option, you override the recorded rules. So, if you were to type `print mylog.smcl, like(txt)`, the file would be printed as plain text (meaning that all the SMCL commands would show).

`name(windowname)` specifies which window to print when printing a Viewer. The default is for Stata to print the topmost Viewer [Unix(GUI) users: See the second technical note in Printing files, Unix]. The `name()` option is ignored when printing the Results window.

The window name is located inside the parentheses in the window title. For example, if the title for a Viewer window is `Viewer (#1) [help print]`, the name for the window is `#1`.

`override_options` refers to `translate`’s options for overriding default values. `print` uses `translate` to translate the file into a format suitable for sending to the printer, and thus `translate`’s `override_options` may also be used with `print`. The settings available vary between each translator (for example, `smcl2ps` will have different settings than `smcl2txt`) and may also differ across operating systems (for example, Windows may have different printing options than macOS). To find out what you can override when printing .smcl files, type

```
.translator query smcl2prn
(output omitted)
```

In the omitted output, you might learn that there is an `rmargin #` tunable value, which specifies the right margin in inches. You could specify the `override_option rmargin(#)` to temporarily override the default value, or you could type `translator set smcl2prn rmargin #` beforehand to permanently reset the value.

Alternatively, on some computers with some translators, you might discover that nothing can be set.
Options for translate

`translator(tname)` specifies the name of the translator to be used to translate the file. The available translators are

<table>

</tr>
</tbody>
</table>

If `translator()` is not specified, `translate` determines which translator to use from extensions of the filenames specified. Typing `translate myfile.smcl myfile.ps` would use the `smcl2ps` translator. Typing `translate myfile.smcl myfile.ps, translate(smcl2prn)` would override the default and use the `smcl2prn` translator.

Actually, when you type `translate a.b c.d`, `translate` looks up `.b` in the `transmap` extension-synonym table. If `.b` is not found, the translator `b2d` is used. If `.b` is found in the table, the mapped extension is used (call it `b'`), and then the translator `b'2d` is used. For example,

<table>
<thead>
<tr>
<th>Command</th>
<th>Translator used</th>
</tr>
</thead>
<tbody>
<tr>
<td>. translate myfile.smcl myfile.ps</td>
<td>smcl2ps</td>
</tr>
<tr>
<td>. translate myfile.odd myfile.ps</td>
<td>odd2ps, which does not exist, so error</td>
</tr>
<tr>
<td>. transmap define .odd .txt</td>
<td></td>
</tr>
<tr>
<td>. translate myfile.odd myfile.ps</td>
<td>txt2ps</td>
</tr>
</tbody>
</table>

You can list the mappings that `translate` uses by typing `transmap query`.

`name(windowname)` specifies which window to translate when translating a Viewer. The default is for Stata to translate the topmost Viewer. The `name()` option is ignored when translating the Results window.

The window name is located inside the parentheses in the window title. For example, if the title for a Viewer window is `Viewer (#1) [help print]`, the name for the window is #1.
override_options override any of the default options of the specified or implied translator. To find out what you can override for, say, $\text{log2ps}$, type

```
   . translator query log2ps
```

In the omitted output, you might learn that there is an $\text{rmargin}$ # tunable value, which, for $\text{log2ps}$, specifies the right margin in inches. You could specify the `override_option rmargin(#)` to temporarily override the default value or type `translator set log2ps rmargin #` beforehand to permanently reset the value.

`replace` specifies that `filename_out` be replaced if it already exists.

### Remarks and examples

Remarks are presented under the following headings:

- **Overview**
- **Printing files**
- **Printing files, Mac and Windows**
- **Printing files, Unix**
- **Translating files from one format to another**

### Overview

`print` prints log, SMCL, and text files. Although there is considerable flexibility in how `print` (and `translate`, which `print` uses) can be set to work, they have already been set up and should just work:

```
   . print mylog.smcl
   . print mylog.log
```

Unix users may discover that they need to do a bit of setup before `print` works; see **Printing files, Unix** below. International Unix users may also wish to modify the default paper size. All users can tailor `print` and `translate` to their needs.

`print` may also be used to print the current contents of the Results window or the Viewer. For instance, the current contents of the Results window could be printed by typing

```
   . print @Results
```

`translate` translates log and SMCL files from one format to another, the other typically being suitable for printing. `translate` can also translate SMCL logs (logs created by typing, say, `log using mylog`) to plain text:

```
   . translate mylog.smcl mylog.log
```

You can use `translate` to recover a log when you have forgotten to start one. You may type

```
   . translate @Results mylog.txt
```

to capture as plain text what is currently shown in the Results window.

This entry provides a general overview of `print` and `translate` and covers in detail the printing and translation of text (nongraphic) files.

`translator query`, `translator set`, and `translator reset` show, change, and restore the default values of the settings for each translator.

`transmap define` and `transmap query` create and show mappings from one file extension to another for use with `print` and `translate`. 
For example, print myfile.txt knows to use a translator appropriate for printing text files because of the .txt extension. However, it does not know what to do with .xyz files. If you have .xyz files and always wish to treat them as .txt files, you can type transmap define .xyz .txt.

**Printing files**

Printing should be easy; just type

```
. print mylog.smcl
. print mylog.log
```

You can use print to print SMCL files, plain text files, and even the contents of the Results and Viewer windows:

```
. print @Results
. print @Viewer
. print @Viewer, name(#2)
```

For information about printing and translating graph files, see [G-2] graph print and see [G-2] graph export.

**Printing files, Mac and Windows**

When you type print, you are using the same facility that you would be using if you had selected Print from the File menu. If you try to print a file that Stata does not know about, Stata will complain:

```
. print read.me
translator me2prn not found
(perhaps you need to specify the like() option)
r(111);
```

Then you could type

```
. print read.me, like(txt)
```

To indicate that you wanted read.me sent to the printer in the same fashion as if the file were named readme.txt, or you could type

```
. transmap define .me .txt
. print read.me
```

Here you are telling Stata once and for all that you want files ending in .me to be treated in the same way as files ending in .txt. Stata will remember this mapping, even across sessions. To clear the .me mapping, type

```
. transmap define .me
```

To see all the mappings, type

```
. transmap query
```

To print to a file, use the translate command, not print:

```
. translate mylog.smcl mylog.prn
```

translate prints to a file by using the Windows print driver when the new filename ends in .prn. Under Mac, the .prn translators are the same as the .pdf translators. We suggest that you simply use the .pdf file extension when printing to a file.
Printing files, Unix

Stata assumes that you have a PostScript printer attached to your Unix computer and that the Unix command `lpr(1)` can be used to send PostScript files to it, but you can change this. On your Unix system, typing

```
mycomputer$ lpr < filename
```

may not be sufficient to print PostScript files. For instance, perhaps on your system you would need to type

```
mycomputer$ lpr -Plexmark < filename
```

or

```
mycomputer$ lpr -Plexmark filename
```

or something else. To set the print command to be `lpr -Plexmark filename` and to state that the printer expects to receive PostScript files, type

```
.p printer define prn ps "lpr -Plexmark @"
```

That is, just type the command necessary to send files to your printer and include an `@` sign where the filename should be substituted. Two file formats are available: `ps` and `txt`. The default setting, as shipped from the factory, is

```
.p printer define prn ps "lpr < @"
```

We will return to the `printer` command in the technical note that follows because it has some other capabilities you should know about.

In any case, after you redefine the default printer, the following should just work:

```
.p print mylog.smcl
.p print mylog.log
```

If you try to print a file that Stata does not know about, it will complain:

```
.p print read.me
translator me2prn not found
r(111);
```

Here you could type

```
.p print read.me, like(txt)
```

to indicate that you wanted `read.me` sent to the printer in the same fashion as if the file were named `readme.txt`, or you could type
Here you are telling Stata once and for all that you want files ending in .me to be treated in the same way as files ending in .txt. Stata will remember this setting for .me, even across sessions.

If you want to clear the .me setting, type

```
.transmap define .me
```

If you want to see all your settings, type

```
.transmap query
```

Technical note

If the text you wish to print contains Unicode characters, those characters may not appear correctly in PostScript files because the PostScript fonts do not support Unicode. Stata will map as many characters as possible to characters supported by Unicode but will print a question mark (?) for any unsupported character. We recommend that you export the text to a PDF file, which has fonts with better support for Unicode characters.

Technical note

The syntax of the `printer` command is

```
printer define prinurname [ { {ps | txt} "Unix command with @" } ]
printer query [ prinurname ]
```

You may define multiple printers. By default, `print` uses the printer named prn, but `print` has the syntax

```
print filename [ , like(ext) printer(printername) override_options ]
```

so, if you define multiple printers, you may route your output to them.

For instance, if you have a second printer on your system, you might type

```
printer define lexmark ps "lpr -Plexmark < @"
```

After doing that, you could type

```
print myfile.smcl, printer(lexmark)
```

Any printers that you set will be remembered even across sessions. You can delete printers:

```
printer define lexmark
```

You can list all the defined printers by typing `printer query`, and you can list the definition of a particular printer, say, prn, by typing `printer query prn`.

The default printer prn we have predefined for you is

```
printer define prn ps "lpr < @"
```

meaning that we assume that it is a PostScript printer and that the Unix command `lpr(1)`, without options, is sufficient to cause files to print. Feel free to change the default definition. If you change it, the change will be remembered across sessions.
Technical note

Unix (GUI) users should note that X-Windows does not have the concept of a window z-order, which prevents Stata from determining which window is the topmost window. Instead, Stata determines which window is topmost based on which window has the focus. However, some window managers will set the focus to a window without bringing the window to the top. What Stata considers the topmost window may not appear topmost visually. For this reason, you should always use the name() option to ensure that the correct window is printed.

Technical note

When you select the Results window to print from the Print menu or toolbar button, the result is the same as if you were to issue the print command. When you select a Viewer window to print from the Print menu or toolbar button, the result is the same as if you were to issue the print command with a name() option.

The translation to PostScript format is done by translate and, in particular, is performed by the translators smcl2ps, log2ps, and txt2ps. There are many tunable parameters in each of these translators. You can display the current values of these tunable parameters for, say, smcl2ps by typing

```
. translator query smcl2ps
(output omitted)
```

and you can set any of the tunable parameters (for instance, setting smcl2ps’s rmargin value to 1) by typing

```
. translator set smcl2ps rmargin 1
(output omitted)
```

Any settings you make will be remembered across sessions. You can reset smcl2ps to be as it was when Stata was shipped by typing

```
. translator reset smcl2ps
```

Translating files from one format to another

If you have a SMCL log, which you might have created by previously typing log using mylog, you can translate it to an text log by typing

```
. translate myfile.smcl myfile.log
```

and you can translate it to a PostScript file by typing

```
. translate myfile.smcl myfile.ps
```

translate translates files from one format to another, and, in fact, print uses translate to produce a file suitable for sending to the printer.

When you type

```
. translate a b c d
```

translate looks for the predefined translator b2d and uses that to perform the translation. If there is a transmap synonym for b, however, the mapped value b’ is used: b’2d.
Only certain translators exist, and they are listed under the description of the `translate()` option in `Options for translate` above, or you can type

```
    . translator query
```

for a complete (and perhaps more up-to-date) list.

Anyway, `translate` forms the name `b2d` or `b′2d`, and if the translator does not exist, `translate` issues an error message. With the `translator()` option, you can specify exactly which translator to use, and then it does not matter how your files are named.

The only other thing to know is that some translators have tunable parameters that affect how they perform their translation. You can type

```
    . translator query translator_name
```

to find out what those parameters are. Some translators have no tunable parameters, and some have many:

```
    . translator query smcl2ps
```

</tbody>
</table>

You can temporarily override any setting by specifying the `setopt(setval)` option on the `translate` (or `print`) command. For instance, you can type

```
    . translate ..., ... cmdnumber(off)
```

or you can reset the value permanently by typing

```
    . translator set smcl2ps setopt setval
```

For instance,

```
    . translator set smcl2ps cmdnumber off
```

If you reset a value, Stata will remember the change, even in future sessions.
Mac and Windows users: The smcl2ps (and the other *2ps translators) are not used by print, even when you have a PostScript printer attached to your computer. Instead, the Mac or Windows print driver is used. Resetting smcl2ps values will not affect printing; instead, you change the defaults in the Printers Control Panel in Windows and by selecting Page Setup... from the File menu in Mac. You can, however, translate files yourself using the smcl2ps translator and the other *2ps translators.

Technical note: Using PDF translators (Windows and Unix)

When using translate to translate a log, SMCL, or text file or a Stata graph into a PDF file, some characters may not display correctly in the resulting PDF file. This happens when translating content that contains Unicode characters from different languages; one font may not be adequate to display every character used. If an appropriate font is not available for a character, that character will not display correctly in the resulting PDF file.

Specific fonts can be used to build a font chain. Those fonts are specified using fontname and are separated by commas. The most preferred font should be listed first, followed by the less preferred fonts. A maximum of 16 fonts can be specified. Stata will inspect each character in the original content, and if a glyph for the corresponding character is not available in the default font, then each font in the font chain will be checked until a font is found to display that character.

You can set fonts in the font chain by specifying addfonts for each PDF translator as follows:

```
    . translator set tname addfonts fontname
```

Here, tname is the name of a PDF translator, which can be smcl2pdf, log2pdf, txt2pdf, Results2pdf, Viewer2pdf, or Graph2pdf. See the translator() option under Options for translate.

Stata has the ability to select a font automatically if the default font and the fonts in the font chain do not contain a glyph for the character. Automatic font selection can be controlled using the following:

```
    . translator set tname autofont on | off
```

By default, autofont is on. Unix (console) users will need to set the font directories so the fonts can be found.

PDF files accept Base14 fonts, Type 1 fonts, and TrueType fonts with an extension of .ttf or .ttc. If fontname refers to a TrueType font or a Type 1 font, the corresponding TrueType or Type 1 font file will be searched for within the default font directory. Unix (console) users can type

```
    . translator set tname fontdir fontdirectory
```

to set the default font directory. fontdirectory can contain multiple font directories separated by semicolons. If the specified TrueType or Type 1 font cannot be found under the current font directory, an error message will be issued.

Stored results

transmap query .ext stores in macro r(suffix) the mapped extension (without the leading period) or stores ext if the ext is not mapped.

translator query translatename stores setval in macro r(setopt) for every setopt, setval pair.

printer query printername (Unix only) stores in macro r(suffix) the “filetype” of the input that the printer expects (currently “ps” or “txt”) and, in macro r(command), the command to send output to the printer.

**truncreg** — Truncated regression

**Description**

`truncreg` fits a regression model of `depvar` on `indepvars` from a sample drawn from a restricted part of the population. Under the normality assumption for the whole population, the error terms in the truncated regression model have a truncated normal distribution, which is a normal distribution that has been scaled upward so that the distribution integrates to one over the restricted range.

**Quick start**

Truncated regression of `y` on `x1` and `x2` truncated below 16

```
truncreg y x1 x2, ll(16)
```

Specify that `y` is truncated above 35

```
truncreg y x1 x2, ul(35)
```

With `y` truncated below 17 and above 35

```
truncreg y x1 x2, ll(17) ul(35)
```

Specify a lower truncation point that varies across observations using the variable `trunc`

```
truncreg y x1 x2, ll(trunc)
```

As above, but with bootstrapped standard errors using 200 replications

```
truncreg y x1 x2, ll(trunc) vce(bootstrap, reps(200))
```

See last estimates with legend of coefficient names instead of statistics

```
truncreg, coeflegend
```

**Menu**

Statistics > Linear models and related > Truncated regression
Syntax

```
truncreg depvar [ indepvars ] [ if ] [ in ] [ weight ] [ , options ]
```

**Options**

**Model**
- `noconstant` suppress constant term
- `ll(varname | #)` left-truncation variable or limit
- `ul(varname | #)` right-truncation variable or limit
- `offset(varname)` include `varname` in model with coefficient constrained to 1
- `constraints(constraints)` apply specified linear constraints

**SE/Robust**
- `vce(vcetype)` `vcetype` may be `oim`, `robust`, `cluster clustvar`, `opg`, `bootstrap`, or `jackknife`

**Reporting**
- `level(#)` set confidence level; default is `level(95)`
- `lrmodel` perform the likelihood-ratio model test instead of the default Wald test
- `nocnsreport` do not display constraints
- `display_options` control columns and column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling

**Maximization**
- `maximize_options` control the maximization process; seldom used
- `collinear` keep collinear variables
- `coeflegend` display legend instead of statistics

**Options**

- `indepvars` may contain factor variables; see [U] 11.4.3 Factor variables.
- `depvar` and `indepvars` may contain time-series operators; see [U] 11.4.4 Time-series varlists.
- `bayes, bootstrap, by, fmm, fp, jackknife, mi estimate, rolling, statsby, and svy` are allowed; see [U] 11.1.10 Prefix commands. For more details, see [BAYES] bayes: truncreg and [FMM] fmm: truncreg. `vce(bootstrap)` and `vce(jackknife)` are not allowed with the `mi estimate` prefix; see [MI] mi estimate.
- Weights are not allowed with the `bootstrap` prefix; see [R] bootstrap.
- `aweights` are not allowed with the `jackknife` prefix; see [R] jackknife.
- `vce()`, `lrmodel`, and weights are not allowed with the `svy` prefix; see [SVY] svy.
- `aweights, fweights, iweights, and pweights` are allowed; see [U] 11.1.6 weight.
- `collinear` and `coeflegend` do not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

**Syntax**

```
truncreg depvar [ indepvars ] [ if ] [ in ] [ weight ] [ , options ]
```

**Options**

**Model**
- `noconstant` suppress constant term
- `ll(varname | #)` left-truncation variable or limit
- `ul(varname | #)` right-truncation variable or limit
- `offset(varname)` include `varname` in model with coefficient constrained to 1
- `constraints(constraints)` apply specified linear constraints

**SE/Robust**
- `vce(vcetype)` `vcetype` may be `oim`, `robust`, `cluster clustvar`, `opg`, `bootstrap`, or `jackknife`

**Reporting**
- `level(#)` set confidence level; default is `level(95)`
- `lrmodel` perform the likelihood-ratio model test instead of the default Wald test
- `nocnsreport` do not display constraints
- `display_options` control columns and column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling

**Maximization**
- `maximize_options` control the maximization process; seldom used
- `collinear` keep collinear variables
- `coeflegend` display legend instead of statistics

**Options**

- `indepvars` may contain factor variables; see [U] 11.4.3 Factor variables.
- `depvar` and `indepvars` may contain time-series operators; see [U] 11.4.4 Time-series varlists.
- `bayes, bootstrap, by, fmm, fp, jackknife, mi estimate, rolling, statsby, and svy` are allowed; see [U] 11.1.10 Prefix commands. For more details, see [BAYES] bayes: truncreg and [FMM] fmm: truncreg. `vce(bootstrap)` and `vce(jackknife)` are not allowed with the `mi estimate` prefix; see [MI] mi estimate.
- Weights are not allowed with the `bootstrap` prefix; see [R] bootstrap.
- `aweights` are not allowed with the `jackknife` prefix; see [R] jackknife.
- `vce()`, `lrmodel`, and weights are not allowed with the `svy` prefix; see [SVY] svy.
- `aweights, fweights, iweights, and pweights` are allowed; see [U] 11.1.6 weight.
- `collinear` and `coeflegend` do not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

**Options**

- `noconstant` suppress constant term
- `ll(varname | #)` and `ul(varname | #)` indicate the lower and upper limits for truncation, respectively.
  You may specify one or both. Observations with `depvar ≤ ll()` are left-truncated, observations with `depvar ≥ ul()` are right-truncated, and the remaining observations are not truncated. See [R] tobit for a more detailed description.
offset(varname), constraints(constants); see [R] Estimation options.

vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim, opg), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.

level(#), lrmodel, nocnsreport; see [R] Estimation options.

display_options: noci, nopvalues, noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fwrap(#), fvwrap(style), cformat(%,fmt), pformat(%,fmt), sformat(%,fmt), and nolstretch; see [R] Estimation options.

maximize_options: difficult, technique(algorithm_spec), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(init_specs); see [R] Maximize. These options are seldom used, but you may use the ltol(#!) option to relax the convergence criterion; the default is 1e-6 during specification searches.

Setting the optimization type to technique(bhhh) resets the default vcetype to vce(opg).

The following options are available with truncreg but are not shown in the dialog box:
collinear, coeflegend; see [R] Estimation options.

Remarks and examples

Truncated regression fits a model of a dependent variable on independent variables from a restricted part of a population. Truncation is essentially a characteristic of the distribution from which the sample data are drawn. If x has a normal distribution with mean $\mu$ and standard deviation $\sigma$, the density of the truncated normal distribution is

$$f(x \mid a < x < b) = \frac{f(x)}{\Phi\left(\frac{b-\mu}{\sigma}\right) - \Phi\left(\frac{a-\mu}{\sigma}\right)} = \frac{\frac{1}{\sigma} \phi\left(\frac{x-\mu}{\sigma}\right)}{\Phi\left(\frac{b-\mu}{\sigma}\right) - \Phi\left(\frac{a-\mu}{\sigma}\right)}$$

where $\phi$ and $\Phi$ are the density and distribution functions of the standard normal distribution.

Compared with the mean of the untruncated variable, the mean of the truncated variable is greater if the truncation is from below, and the mean of the truncated variable is smaller if the truncation is from above. Moreover, truncation reduces the variance compared with the variance in the untruncated distribution.
Example 1

We will demonstrate `truncreg` with part of the Mroz dataset distributed with Berndt (1996). This dataset contains 753 observations on women’s labor supply. Our subsample is of 250 observations, with 150 market laborers and 100 nonmarket laborers.

### Technical note

Whether truncated regression is more appropriate than the ordinary least-squares estimation depends on the purpose of that estimation. If we are interested in the mean of wife’s working hours conditional on the subsample of market laborers, least-squares estimation is appropriate. However if we are interested in the mean of wife’s working hours regardless of market or nonmarket labor status, least-squares estimates could be seriously misleading.

Truncation and censoring are different concepts. A sample has been censored if no observations have been systematically excluded but some of the information contained in them has been suppressed. In a truncated distribution, only the part of the distribution above (or below, or between) the truncation points is relevant to our computations. We need to scale it up by the probability that an observation falls in the range that interests us to make the distribution integrate to one. The censored distribution used by tobit, however, is a mixture of discrete and continuous distributions. Instead of rescaling over the observable range, we simply assign the full probability from the censored regions to the censoring points. The truncated regression model is sometimes less well behaved than the tobit model.
Davidson and MacKinnon (1993) provide an example where truncation results in more inconsistency than censoring.

Stored results

`truncreg` stores the following in `e()`:

Scalars

- `e(N)`: number of observations
- `e(N_bf)`: number of observations before truncation
- `e(chi2)`: model $\chi^2$
- `e(k_eq)`: number of equations in `e(b)`
- `e(k_eq_model)`: number of equations in overall model test
- `e(k_aux)`: number of auxiliary parameters
- `e(df_m)`: model degrees of freedom
- `e(ll)`: log likelihood
- `e(ll_0)`: log likelihood, constant-only model
- `e(N_clust)`: number of clusters
- `e(sigma)`: estimate of sigma
- `e(p)`: $p$-value for model test
- `e(rank)`: rank of `e(V)`
- `e(ic)`: number of iterations
- `e(rc)`: return code
- `e(converged)`: 1 if converged, 0 otherwise

Macros

- `e(cmd)`: `truncreg`
- `e(cmdline)`: command as typed
- `e(llopt)`: contents of `ll()`, if specified
- `e(ulopt)`: contents of `ul()`, if specified
- `e(depvar)`: name of dependent variable
- `e(wtype)`: weight type
- `e(wexp)`: weight expression
- `e(title)`: title in estimation output
- `e(clustvar)`: name of cluster variable
- `e(offset1)`: offset
- `e(chi2type)`: Wald or LR; type of model $\chi^2$ test
- `e(vcetype)`: `vcetype` specified in `vce()`
- `e(title)`: title used to label Std. Err.
- `e(opt)`: type of optimization
- `e(which)`: max or min; whether optimizer is to perform maximization or minimization
- `e(ml_method)`: type of `ml` method
- `e(user)`: name of likelihood-evaluator program
- `e(technique)`: maximization technique
- `e(properties)`: `b` `V`
- `e(predict)`: program used to implement `predict`
- `e(marginsok)`: predictions allowed by `margins`
- `e(asbalanced)`: factor variables fvset as `asbalanced`
- `e(asobserved)`: factor variables fvset as `asobserved`

Matrices

- `e(b)`: coefficient vector
- `e(Cns)`: constraints matrix
- `e(ilog)`: iteration log (up to 20 iterations)
- `e(gradient)`: gradient vector
- `e(V)`: variance–covariance matrix of the estimators
- `e(V_modelbased)`: model-based variance
- `e(means)`: means of independent variables
- `e(dummy)`: indicator for dummy variables

Functions

- `e(sample)`: marks estimation sample
Methods and formulas

Greene (2018, 918–924) and Davidson and MacKinnon (1993, 534–537) provide introductions to the truncated regression model.

Let $y = X\beta + \epsilon$ be the model. $y$ represents continuous outcomes either observed or not observed. Our model assumes that $\epsilon \sim N(0, \sigma^2 I)$.

Let $a$ be the lower limit and $b$ be the upper limit. The log likelihood is

$$\ln L = -\frac{n}{2} \log(2\pi\sigma^2) - \frac{1}{2\sigma^2} \sum_{j=1}^{n} (y_j - x_j\beta)^2 - \sum_{j=1}^{n} \log \left\{ \Phi \left( \frac{b - x_j\beta}{\sigma} \right) - \Phi \left( \frac{a - x_j\beta}{\sigma} \right) \right\}$$

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using `vce(robust)` and `vce(cluster clustvar)`, respectively. See [P] _robust, particularly Maximum likelihood estimators and Methods and formulas.

`truncreg` also supports estimation with survey data. For details on VCEs with survey data, see [SVY] Variance estimation.

predict

Description for predict

predict creates a new variable containing predictions such as linear predictions, standard errors, probabilities, and expected values.

Menu for predict

Statistics > Postestimation

Syntax for predict

```
predict [type] newvar [if] [in] [, statistic nooffset]
predict [type] { stub* | newvar_reg newvar_insigma } [if] [in] , scores
```

statistic | Description
---|---
Main
xb | linear prediction; the default
stdp | standard error of the prediction
stdf | standard error of the forecast
pr(a,b) | $Pr(a < y_j < b)$
e(a,b) | $E(y_j | a < y_j < b)$
ystar(a,b) | $E(y_{j*}^*), y_{j*}^* = \max\{a, \min(y_j, b)\}$

These statistics are available both in and out of sample; type predict ... if e(sample) ... if wanted only for the estimation sample.

stdf is not allowed with svy estimation results.

where $a$ and $b$ may be numbers or variables; $a$ missing $(a \geq .)$ means $-\infty$, and $b$ missing $(b \geq .)$ means $+\infty$; see [U] 12.2.1 Missing values.

Options for predict

- **xb**, the default, calculates the linear prediction.

- **stdp** calculates the standard error of the prediction, which can be thought of as the standard error of the predicted expected value or mean for the observation’s covariate pattern. The standard error of the prediction is also referred to as the standard error of the fitted value.

- **stdf** calculates the standard error of the forecast, which is the standard error of the point prediction for 1 observation. It is commonly referred to as the standard error of the future or forecast value. By construction, the standard errors produced by stdf are always larger than those produced by stdp; see Methods and formulas in [R] regress postestimation.

- **pr(a,b)** calculates $Pr(a < x_j b + u_j < b)$, the probability that $y_j | x_j$ would be observed in the interval $(a, b)$.
a and b may be specified as numbers or variable names; lb and ub are variable names;
pr(20,30) calculates Pr(20 < x_j b + u_j < 30);
pr(lb,ub) calculates Pr(lb < x_j b + u_j < ub); and
pr(20,ub) calculates Pr(20 < x_j b + u_j < ub).

a missing (a ≥ .) means −∞; pr(. ,30) calculates Pr(−∞ < x_j b + u_j < 30);
and calculates Pr(lb < x_j b + u_j < 30) in observations for which lb ≥ .
and calculates Pr(20 < x_j b + u_j < ub) elsewhere.
b missing (b ≥ .) means +∞; pr(20,.) calculates Pr(+∞ > x_j b + u_j > 20);
pr(20,ub) calculates Pr(+∞ > x_j b + u_j > 20) in observations for which ub ≥ .
and calculates Pr(20 < x_j b + u_j < ub) elsewhere.

e(a,b) calculates E(x_j b + u_j | a < x_j b + u_j < b), the expected value of y_j|x_j conditional on
y_j|x_j being in the interval (a, b), meaning that y_j|x_j is truncated.
a and b are specified as they are for pr().
ystar(a,b) calculates E(y_j^*), where y_j^* = a if x_j b + u_j ≤ a, y_j^* = b if x_j b + u_j ≥ b, and
y_j^* = x_j b + u_j otherwise, meaning that y_j^* is censored. a and b are specified as they are for pr().

nooffset is relevant only if you specified offset(varname). It modifies the calculations made by
predict so that they ignore the offset variable; the linear prediction is treated as x_j b rather than
as x_j b + offset_j.

scores calculates equation-level score variables.
The first new variable will contain ∂ln L/∂(x_j β).
The second new variable will contain ∂ln L/∂σ.
margins

Description for margins

margins estimates margins of response for linear predictions, probabilities, and expected values.

Syntax for margins

```
margins [marginlist] [, options]
margins [marginlist], predict(statistic ...) [predict(statistic ...) ...] [options]
```

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>xb</td>
<td>linear prediction; the default</td>
</tr>
<tr>
<td>pr(a,b)</td>
<td>Pr(a &lt; y_j &lt; b)</td>
</tr>
<tr>
<td>e(a,b)</td>
<td>E(y_j</td>
</tr>
<tr>
<td>ystar(a,b)</td>
<td>E(y^<em>_j), y^</em>_j = max{a, min(y_j, b)}</td>
</tr>
<tr>
<td>stdp</td>
<td>not allowed with margins</td>
</tr>
<tr>
<td>stdf</td>
<td>not allowed with margins</td>
</tr>
</tbody>
</table>

Statistics not allowed with margins are functions of stochastic quantities other than e(b).

For the full syntax, see [R] margins.

Also see

[R] truncreg — Truncated regression
[U] 20 Estimation and postestimation commands
ttest — $t$ tests (mean-comparison tests)

**Description**

ttest performs $t$ tests on the equality of means. The test can be performed for one sample against a hypothesized population mean. Two-sample tests can be conducted for paired and unpaired data. The assumption of equal variances can be optionally relaxed in the unpaired two-sample case.

*ttesti* is the immediate form of *ttest*; see [U] 19 Immediate commands.

**Quick start**

Test that the mean of $v1$ is equal between two groups defined by *catvar*

```stata
    ttest v1, by(catvar)
```

As above, but assume unequal variances

```stata
    ttest v1, by(catvar) unequal
```

Paired $t$ test of $v2$ and $v3$

```stata
    ttest v2 == v3
```

As above, but with unpaired data and conduct test separately for each level of *catvar*

```stata
    by catvar: ttest v2 == v3, unpaired
```

Test that the mean of $v4$ is 3 at the 90% confidence level

```stata
    ttest v4 == 3, level(90)
```

Test $\mu_1 = \mu_2$ if $\bar{x}_1 = 3.2$, $sd_1 = 0.1$, $\bar{x}_2 = 3.4$, and $sd_2 = 0.15$ with $n_1 = n_2 = 12$

```stata
    ttesti 12 3.2 .1 12 3.4 .15
```

Syntax

One-sample t test

\[
ttest \text{ varname} == \# \left[ \text{if} \right] \left[ \text{in} \right] \left[ , \text{level(\#)} \right]
\]

Two-sample t test using groups

\[
ttest \text{ varname} \left[ \text{if} \right] \left[ \text{in} \right], \text{by(groupvar)} \left[ \text{options}_1 \right]
\]

Two-sample t test using variables

\[
ttest \text{ varname}_1 == \text{ varname}_2 \left[ \text{if} \right] \left[ \text{in} \right], \text{unpaired} \left[ \text{unequal welch level(\#)} \right]
\]

Paired t test

\[
ttest \text{ varname}_1 == \text{ varname}_2 \left[ \text{if} \right] \left[ \text{in} \right] \left[ , \text{level(\#)} \right]
\]

Immediate form of one-sample t test

\[
ttesti \#\text{obs} \#\text{mean} \#\text{sd} \#\text{val} \left[ , \text{level(\#)} \right]
\]

Immediate form of two-sample t test

\[
ttesti \#\text{obs}_1 \#\text{mean}_1 \#\text{sd}_1 \#\text{obs}_2 \#\text{mean}_2 \#\text{sd}_2 \left[ , \text{options}_2 \right]
\]

<table>

</tr>
</tbody>
</table>

by is allowed with \text{ttest}; see [D] by.
Options

by(groupvar) specifies the groupvar that defines the two groups that ttest will use to test the hypothesis that their means are equal. Specifying by(groupvar) implies an unpaired (two sample) t test. Do not confuse the by() option with the by prefix; you can specify both.

unpaired specifies that the data be treated as unpaired. The unpaired option is used when the two sets of values to be compared are in different variables.

unequal specifies that the unpaired data not be assumed to have equal variances.

welch specifies that the approximate degrees of freedom for the test be obtained from Welch's formula (1947) rather than from Satterthwaite's approximation formula (1946), which is the default when unequal is specified. Specifying welch implies unequal.

level(#) specifies the confidence level, as a percentage, for confidence intervals. The default is level(95) or as set by set level; see [U] 20.8 Specifying the width of confidence intervals.

Remarks and examples

Remarks are presented under the following headings:

One-sample t test
Two-sample t test
Paired t test
Two-sample t test compared with one-way ANOVA
Immediate form
Video examples

One-sample t test

Example 1

In the first form, ttest tests whether the mean of the sample is equal to a known constant under the assumption of unknown variance. Assume that we have a sample of 74 automobiles. We know each automobile's average mileage rating and wish to test whether the overall average for the sample is 20 miles per gallon.

. use https://www.stata-press.com/data/r16/auto
(1978 Automobile Data)
. ttest mpg==20
One-sample t test

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>Std. Dev.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>mpg</td>
<td>74</td>
<td>21.2973</td>
<td>.6725511</td>
<td>5.785503</td>
<td>19.9569</td>
</tr>
</tbody>
</table>

mean = mean(mpg) t = 1.9289
Ho: mean = 20 degrees of freedom = 73
Ha: mean < 20 Ha: mean != 20 Ha: mean > 20
Pr(T < t) = 0.9712 Pr(|T| > |t|) = 0.0576 Pr(T > t) = 0.0288

The test indicates that the underlying mean is not 20 with a significance level of 5.8%.
Two-sample t test

Example 2: Two-sample $t$ test using groups

We are testing the effectiveness of a new fuel additive. We run an experiment in which 12 cars are given the fuel treatment and 12 cars are not. The results of the experiment are as follows:

<table>
<thead>
<tr>
<th>treated</th>
<th>mpg</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>20</td>
</tr>
<tr>
<td>0</td>
<td>23</td>
</tr>
<tr>
<td>0</td>
<td>21</td>
</tr>
<tr>
<td>0</td>
<td>25</td>
</tr>
<tr>
<td>0</td>
<td>18</td>
</tr>
<tr>
<td>0</td>
<td>17</td>
</tr>
<tr>
<td>0</td>
<td>18</td>
</tr>
<tr>
<td>0</td>
<td>24</td>
</tr>
<tr>
<td>0</td>
<td>20</td>
</tr>
<tr>
<td>0</td>
<td>24</td>
</tr>
<tr>
<td>0</td>
<td>23</td>
</tr>
<tr>
<td>0</td>
<td>19</td>
</tr>
<tr>
<td>1</td>
<td>24</td>
</tr>
<tr>
<td>1</td>
<td>25</td>
</tr>
<tr>
<td>1</td>
<td>21</td>
</tr>
<tr>
<td>1</td>
<td>22</td>
</tr>
<tr>
<td>1</td>
<td>23</td>
</tr>
<tr>
<td>1</td>
<td>18</td>
</tr>
<tr>
<td>1</td>
<td>17</td>
</tr>
<tr>
<td>1</td>
<td>28</td>
</tr>
<tr>
<td>1</td>
<td>24</td>
</tr>
<tr>
<td>1</td>
<td>27</td>
</tr>
<tr>
<td>1</td>
<td>21</td>
</tr>
<tr>
<td>1</td>
<td>23</td>
</tr>
</tbody>
</table>

The treated variable is coded as 1 if the car received the fuel treatment and 0 otherwise.

We can test the equality of means of the treated and untreated group by typing

```
. use https://www.stata-press.com/data/r16/fuel3
. ttest mpg, by(treated)
```

Two-sample t test with equal variances

<table>
<thead>
<tr>
<th>Group</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>Std. Dev.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>12</td>
<td>21</td>
<td>.7881701</td>
<td>2.730301</td>
<td>19.26525  22.73475</td>
</tr>
<tr>
<td>1</td>
<td>12</td>
<td>22.75</td>
<td>.9384465</td>
<td>3.250874</td>
<td>20.68449  24.81551</td>
</tr>
<tr>
<td>combined</td>
<td>24</td>
<td>21.875</td>
<td>.6264476</td>
<td>3.068954</td>
<td>20.57909  23.17091</td>
</tr>
<tr>
<td>diff</td>
<td></td>
<td>-1.75</td>
<td>1.225518</td>
<td>-4.291568</td>
<td>.7915684</td>
</tr>
</tbody>
</table>

\[ \text{diff} = \text{mean}(0) - \text{mean}(1) \]
\[ t = -1.4280 \]
\[ \text{degrees of freedom} = 22 \]
\[ \text{Ho: diff} = 0 \]
\[ \text{Ha: diff} < 0 \]
\[ \text{Ha: diff} \neq 0 \]
\[ \text{Ha: diff} > 0 \]
\[ \text{Pr}(T < t) = 0.0837 \]
\[ \text{Pr}(|T| > |t|) = 0.1673 \]
\[ \text{Pr}(T > t) = 0.9163 \]

We do not find a statistically significant difference in the means.
If we were not willing to assume that the variances were equal and wanted to use Welch’s formula, we could type

```
ttest mpg, by(treated) welch
```

Two-sample t test with unequal variances

<table>
<thead>
<tr>
<th>Group</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>Std. Dev.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>12</td>
<td>21</td>
<td>.7881701</td>
<td>2.730301</td>
<td>19.26525 22.73475</td>
</tr>
<tr>
<td>1</td>
<td>12</td>
<td>22.75</td>
<td>.9384465</td>
<td>3.250874</td>
<td>20.68449 24.81551</td>
</tr>
<tr>
<td>combined</td>
<td>24</td>
<td>21.875</td>
<td>.6264476</td>
<td>3.068954</td>
<td>20.57909 23.17091</td>
</tr>
<tr>
<td>diff</td>
<td></td>
<td>-1.75</td>
<td>1.225518</td>
<td>-4.28369</td>
<td>.7836902</td>
</tr>
</tbody>
</table>

diff = mean(0) - mean(1) 
$t = -1.4280$
Ho: diff = 0
Welch’s degrees of freedom = 23.2465

Ha: diff < 0
Ha: diff != 0
Ha: diff > 0
Pr(T < t) = 0.0833
Pr(|T| > |t|) = 0.1666
Pr(T > t) = 0.9167

Technical note

In two-sample randomized designs, subjects will sometimes refuse the assigned treatment but still be measured for an outcome. In this case, take care to specify the group properly. You might be tempted to let `varname` contain missing where the subject refused and thus let `ttest` drop such observations from the analysis. Zelen (1979) argues that it would be better to specify that the subject belongs to the group in which he or she was randomized, even though such inclusion will dilute the measured effect.

Example 3: Two-sample t test using variables

There is a second, inferior way to organize the data in the preceding example. We ran a test on 24 cars, 12 without the additive and 12 with. We now create two new variables, `mpg1` and `mpg2`.

<table>
<thead>
<tr>
<th>mpg1</th>
<th>mpg2</th>
</tr>
</thead>
<tbody>
<tr>
<td>20</td>
<td>24</td>
</tr>
<tr>
<td>23</td>
<td>25</td>
</tr>
<tr>
<td>21</td>
<td>21</td>
</tr>
<tr>
<td>25</td>
<td>22</td>
</tr>
<tr>
<td>18</td>
<td>23</td>
</tr>
<tr>
<td>17</td>
<td>18</td>
</tr>
<tr>
<td>18</td>
<td>17</td>
</tr>
<tr>
<td>24</td>
<td>28</td>
</tr>
<tr>
<td>20</td>
<td>24</td>
</tr>
<tr>
<td>24</td>
<td>27</td>
</tr>
<tr>
<td>23</td>
<td>21</td>
</tr>
<tr>
<td>19</td>
<td>23</td>
</tr>
</tbody>
</table>

This method is inferior because it suggests a connection that is not there. There is no link between the car with 20 mpg and the car with 24 mpg in the first row of the data. Each column of data could be arranged in any order. Nevertheless, if our data are organized like this, `ttest` can accommodate us.
**. ttest mpg1==mpg2, unpaired**

Two-sample t test with equal variances

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>Std. Dev.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>mpg1</td>
<td>12</td>
<td>21</td>
<td>.7881701</td>
<td>2.730301</td>
<td>19.26525 22.73475</td>
</tr>
<tr>
<td>mpg2</td>
<td>12</td>
<td>22.75</td>
<td>.9384465</td>
<td>3.250874</td>
<td>20.68449 24.81551</td>
</tr>
<tr>
<td>combined</td>
<td>24</td>
<td>21.875</td>
<td>.6264476</td>
<td>3.068954</td>
<td>20.57909 23.17091</td>
</tr>
<tr>
<td>diff</td>
<td>12</td>
<td>-1.75</td>
<td>1.225518</td>
<td>-4.291568 .7915684</td>
<td></td>
</tr>
</tbody>
</table>

\[
\text{diff} = \text{mean(mpg1)} - \text{mean(mpg2)}
\]

\[
t = -1.4280
\]

Ho: diff = 0

<table>
<thead>
<tr>
<th>Ha: diff &lt; 0</th>
<th>Ha: diff != 0</th>
<th>Ha: diff &gt; 0</th>
</tr>
</thead>
<tbody>
<tr>
<td>Pr(T &lt; t) = 0.0837</td>
<td>Pr(</td>
<td>T</td>
</tr>
</tbody>
</table>

**Paired t test**

**Example 4**

Suppose that the preceding data were actually collected by running a test on 12 cars. Each car was run once with the fuel additive and once without. Our data are stored in the same manner as in example 3, but this time, there is most certainly a connection between the mpg values that appear in the same row. These come from the same car. The variables mpg1 and mpg2 represent mileage without and with the treatment, respectively.

**. ttest mpg1==mpg2**

Paired t test

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>Std. Dev.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>mpg1</td>
<td>12</td>
<td>21</td>
<td>.7881701</td>
<td>2.730301</td>
<td>19.26525 22.73475</td>
</tr>
<tr>
<td>mpg2</td>
<td>12</td>
<td>22.75</td>
<td>.9384465</td>
<td>3.250874</td>
<td>20.68449 24.81551</td>
</tr>
<tr>
<td>diff</td>
<td>12</td>
<td>-1.75</td>
<td>.7797144</td>
<td>2.70101</td>
<td>-3.46614 -.0338602</td>
</tr>
</tbody>
</table>

\[
\text{mean(diff)} = \text{mean(mpg1) - mpg2)}
\]

\[
t = -2.2444
\]

Ho: mean(diff) = 0

<table>
<thead>
<tr>
<th>Ha: mean(diff) &lt; 0</th>
<th>Ha: mean(diff) != 0</th>
<th>Ha: mean(diff) &gt; 0</th>
</tr>
</thead>
<tbody>
<tr>
<td>Pr(T &lt; t) = 0.0232</td>
<td>Pr(</td>
<td>T</td>
</tr>
</tbody>
</table>

We find that the means are statistically different from each other at any level greater than 4.6%.
Two-sample t test compared with one-way ANOVA

Example 5

In example 2, we saw that ttest can be used to test the equality of a pair of means; see [R] oneway for an extension that allows testing the equality of more than two means.

Suppose that we have data on the 50 states. The dataset contains the median age of the population (medage) and the region of the country (region) for each state. Region 1 refers to the Northeast, region 2 to the North Central, region 3 to the South, and region 4 to the West. Using oneway, we can test the equality of all four means.

```stata
use https://www.stata-press.com/data/r16/census
(1980 Census data by state)
. oneway medage region
```

### Analysis of Variance

<table>
<thead>
<tr>
<th>Source</th>
<th>SS</th>
<th>df</th>
<th>MS</th>
<th>F</th>
<th>Prob &gt; F</th>
</tr>
</thead>
<tbody>
<tr>
<td>Between</td>
<td>46.39619</td>
<td>3</td>
<td>15.465396</td>
<td>7.56</td>
<td>0.0003</td>
</tr>
<tr>
<td>Within</td>
<td>94.12379</td>
<td>46</td>
<td>2.04616945</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Total</td>
<td>140.519985</td>
<td>49</td>
<td>2.8677548</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Bartlett’s test for equal variances: chi2(3) = 10.5757 Prob>chi2 = 0.014

We find that the means are different, but we are interested only in testing whether the means for the Northeast (region==1) and West (region==4) are different. We could use oneway:

```stata
. oneway medage region if region==1 | region==4
```

### Analysis of Variance

<table>
<thead>
<tr>
<th>Source</th>
<th>SS</th>
<th>df</th>
<th>MS</th>
<th>F</th>
<th>Prob &gt; F</th>
</tr>
</thead>
<tbody>
<tr>
<td>Between</td>
<td>46.241247</td>
<td>1</td>
<td>46.241247</td>
<td>20.02</td>
<td>0.0002</td>
</tr>
<tr>
<td>Within</td>
<td>46.1969169</td>
<td>20</td>
<td>2.30984584</td>
<td></td>
<td></td>
</tr>
<tr>
<td>Total</td>
<td>92.4381638</td>
<td>21</td>
<td>4.40181733</td>
<td></td>
<td></td>
</tr>
</tbody>
</table>

Bartlett’s test for equal variances: chi2(1) = 2.4679 Prob>chi2 = 0.116

We could also use ttest:

```stata
. ttest medage if region==1 | region==4, by(region)
```

### Two-sample t test with equal variances

<table>
<thead>
<tr>
<th>Group</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>Std. Dev.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>NE</td>
<td>9</td>
<td>31.23333</td>
<td>.341581</td>
<td>1.023474</td>
<td>30.44662 32.02005</td>
</tr>
<tr>
<td>West</td>
<td>13</td>
<td>28.28462</td>
<td>.4923577</td>
<td>1.775221</td>
<td>27.21186 29.35737</td>
</tr>
<tr>
<td>combined</td>
<td>22</td>
<td>29.49091</td>
<td>.4473059</td>
<td>2.098051</td>
<td>28.56069 30.42113</td>
</tr>
<tr>
<td>diff</td>
<td>2</td>
<td>2.948718</td>
<td>.6590372</td>
<td>1.57399</td>
<td>4.323445</td>
</tr>
</tbody>
</table>

<table>
<thead>
<tr>
<th>diff = mean(NE) - mean(West)</th>
<th>t = 4.4743</th>
<th>degrees of freedom = 20</th>
</tr>
</thead>
<tbody>
<tr>
<td>Ha: diff &lt; 0</td>
<td>Ha: diff != 0</td>
<td>Ha: diff &gt; 0</td>
</tr>
<tr>
<td>Pr(T &lt; t) = 0.9999</td>
<td>Pr(</td>
<td>T</td>
</tr>
</tbody>
</table>

The significance levels of both tests are the same.
Immediate form

Example 6

`ttesti` is like `ttest`, except that we specify summary statistics rather than variables as arguments. For instance, we are reading an article that reports the mean number of sunspots per month as 62.6 with a standard deviation of 15.8. There are 24 months of data. We wish to test whether the mean is 75:

```
. ttesti 24 62.6 15.8 75
```

One-sample t test

<table>
<thead>
<tr>
<th></th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>Std. Dev.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>x</td>
<td>24</td>
<td>62.6</td>
<td>3.225161</td>
<td>15.8</td>
<td>55.92825 69.27175</td>
</tr>
</tbody>
</table>

mean = mean(x)  t = -3.8448
Ho: mean = 75  degrees of freedom = 23
Ha: mean < 75  Ha: mean != 75  Ha: mean > 75
Pr(T < t) = 0.0004  Pr(|T| > |t|) = 0.0008  Pr(T > t) = 0.9996

Example 7

There is no immediate form of `ttest` with paired data because the test is also a function of the covariance, a number unlikely to be reported in any published source. For unpaired data, however, we might type

```
. ttesti 20 20 5 32 15 4
```

Two-sample t test with equal variances

<table>
<thead>
<tr>
<th></th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>Std. Dev.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>x</td>
<td>20</td>
<td>20</td>
<td>1.118034</td>
<td>5</td>
<td>17.65993 22.34007</td>
</tr>
<tr>
<td>y</td>
<td>32</td>
<td>15</td>
<td>.7071068</td>
<td>4</td>
<td>13.55785 16.44215</td>
</tr>
<tr>
<td>combined</td>
<td>52</td>
<td>16.92308</td>
<td>.6943785</td>
<td>5.007235</td>
<td>15.52905 18.3171</td>
</tr>
<tr>
<td>diff</td>
<td>5</td>
<td>1.256135</td>
<td>2.476979</td>
<td>7.523021</td>
<td></td>
</tr>
</tbody>
</table>

diff = mean(x) - mean(y)  t = 3.9805
Ho: diff = 0  degrees of freedom = 50
Ha: diff < 0  Ha: diff != 0  Ha: diff > 0
Pr(T < t) = 0.9999  Pr(|T| > |t|) = 0.0002  Pr(T > t) = 0.0001

If we had typed `ttesti 20 20 5 32 15 4, unequal`, the test would have assumed unequal variances.
ttest — *t* tests (mean-comparison tests) 2815

**Video examples**

- One-sample *t* test in Stata
- *t* test for two independent samples in Stata
- *t* test for two paired samples in Stata
- One-sample *t*-test calculator
- Two-sample *t*-test calculator

**Stored results**

`ttest` and `ttesti` store the following in `r()`:

<table>
<thead>
<tr>
<th>Scalar</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>r(N_1)</code></td>
<td>sample size <code>n_1</code></td>
</tr>
<tr>
<td><code>r(N_2)</code></td>
<td>sample size <code>n_2</code></td>
</tr>

</table>

**Methods and formulas**

See, for instance, Hoel (1984, 140–161) or Dixon and Massey (1983, 121–130) for an introduction and explanation of the calculation of these tests. Acock (2018, 164–178) and Hamilton (2013, 145–150) describe *t* tests using applications in Stata.

The test for \( \mu = \mu_0 \) for unknown \( \sigma \) is given by

\[
t = \frac{\bar{x} - \mu_0}{\sqrt{n}}
\]

The statistic is distributed as Student’s *t* with \( n-1 \) degrees of freedom (Gosset [Student, pseud.] 1908).

The test for \( \mu_x = \mu_y \) when \( \sigma_x \) and \( \sigma_y \) are unknown but \( \sigma_x = \sigma_y \) is given by

\[
t = \frac{\bar{x} - \bar{y}}{\left\{ \frac{(n_x-1)s_x^2 + (n_y-1)s_y^2}{n_x + n_y - 2} \right\}^{1/2} \left( \frac{1}{n_x} + \frac{1}{n_y} \right)^{1/2}}
\]

The result is distributed as Student’s *t* with \( n_x + n_y - 2 \) degrees of freedom.

You could perform `ttest` (without the `unequal` option) in a regression setting given that regression assumes a homoskedastic error model. To compare with the `ttest` command, denote the underlying observations on \( x \) and \( y \) by \( x_j, j = 1, \ldots, n_x \), and \( y_j, j = 1, \ldots, n_y \). In a regression framework, typing `ttest` without the unequal option is equivalent to

1. creating a new variable \( z_j \) that represents the stacked observations on \( x \) and \( y \) (so that \( z_j = x_j \) for \( j = 1, \ldots, n_x \) and \( z_{n_x+j} = y_j \) for \( j = 1, \ldots, n_y \))
2. and then estimating the equation \( z_j = \beta_0 + \beta_1 d_j + \epsilon_j \), where \( d_j = 0 \) for \( j = 1, \ldots, n_x \) and \( d_j = 1 \) for \( j = n_x + 1, \ldots, n_x + n_y \) (that is, \( d_j = 0 \) when the \( z \) observations represent \( x \), and \( d_j = 1 \) when the \( z \) observations represent \( y \)).
The estimated value of $\beta_1$, $b_1$, will equal $\bar{y} - \bar{x}$, and the reported $t$ statistic will be the same $t$ statistic as given by the formula above.

The test for $\mu_x = \mu_y$ when $\sigma_x$ and $\sigma_y$ are unknown and $\sigma_x \neq \sigma_y$ is given by

$$t = \frac{\bar{x} - \bar{y}}{\left(\frac{s_x^2}{n_x} + \frac{s_y^2}{n_y}\right)^{1/2}}$$

The result is distributed as Student’s $t$ with $\nu$ degrees of freedom, where $\nu$ is given by (with Satterthwaite’s [1946] formula)

$$\frac{\left(\frac{s_x^2}{n_x} + \frac{s_y^2}{n_y}\right)^2}{\frac{\left(s_x^2/n_x\right)^2}{n_x-1} + \frac{\left(s_y^2/n_y\right)^2}{n_y-1}}$$

With Welch’s formula (1947), the number of degrees of freedom is given by

$$-2 + \frac{\left(\frac{s_x^2}{n_x} + \frac{s_y^2}{n_y}\right)^2}{\frac{\left(s_x^2/n_x\right)^2}{n_x+1} + \frac{\left(s_y^2/n_y\right)^2}{n_y+1}}$$

The test for $\mu_x = \mu_y$ for matched observations (also known as paired observations, correlated pairs, or permanent components) is given by

$$t = \frac{\bar{d}\sqrt{n}}{s_d}$$

where $\bar{d}$ represents the mean of $x_i - y_i$ and $s_d$ represents the standard deviation. The test statistic $t$ is distributed as Student’s $t$ with $n-1$ degrees of freedom.

You can also use `ttest` without the `unpaired` option in a regression setting because a paired comparison includes the assumption of constant variance. The `ttest` with an unequal variance assumption does not lend itself to an easy representation in regression settings and is not discussed here. $(x_j - y_j) = \beta_0 + \epsilon_j$.

---

**William Sealy Gosset (1876–1937)** was born in Canterbury, England. He studied chemistry and mathematics at Oxford and worked as a chemist with the brewers Guinness in Dublin. Gosset became interested in statistical problems, which he discussed with Karl Pearson and later with Fisher and Neyman. He published several important papers under the pseudonym “Student”, and he lent that name to the $t$ test he invented.
Stella Cunliffe (1917–2012) was an advocate for increased understanding of the role of human nature in experiments and methodological rigor in social statistics. She was born in Battersea, England. She was the first person from her local public girls’ school to attend college, obtaining a bachelor of science from the London School of Economics. Her first job was with the Danish Bacon Company during World War II, where she was in charge of bacon rations for London. After the war, she moved to Germany and again helped to ration food, this time for refugees.

She then spent a long career in quality control at the Guinness Brewing Company. Cunliffe observed that the weights of rejected casks skewed lighter. Noting that workers had to roll casks that were too light or too heavy uphill to be remade, she had the scales moved to the top of the hill. With workers able to roll rejected casks downhill, the weight of these casks began to follow a normal distribution.

After 25 years at Guinness, Cunliffe joined the British Home Office, where she would go on to become the first woman to serve as director of statistics. During her tenure at the Home Office, she emphasized applying principles of experimental design she had learned at Guinness to the study of such topics as birth rates, recidivism, and criminology. In 1975, she became the first woman to serve as president of the Royal Statistical Society.

The `update` command reports on the current update level and installs official updates to Stata. Official updates are updates to Stata as it was originally shipped from StataCorp, not the additions to Stata published in, for instance, the *Stata Journal (SJ)*. Those additions are installed using the `net` command and updated using the `ado update` command; see [R] `net` and [R] `ado update`.

`update` without arguments reports on the update level of the currently installed Stata.

`update from` sets an update source, which may be a directory name or URL. If you are on the Internet, type `update from https://www.stata.com`.

`update query` compares the update level of the currently installed Stata with that available from the update source and displays a report.

`update all` updates all necessary files. This is what you should type to check for and install updates.

`set update_query` determines if `update query` is to be automatically performed when Stata is launched. Only Mac and Windows platforms can be set for automatic updating.

`set update_interval #` sets the number of days to elapse before performing the next automatic `update query`. The default # is 7. The interval starts from the last time an `update query` was performed (automatically or manually). Only Mac and Windows platforms can be set for automatic updating.

`set update_prompt` determines whether a dialog is to be displayed before performing an automatic `update query`. The dialog allows you to perform an `update query` now, perform one the next time Stata is launched, perform one after the next interval has passed, or disable automatic `update query`. Only Mac and Windows platforms can be set for automatic updating.
**Syntax**

*Report on update level of currently installed Stata*

```
update
```

*Set update source*

```
update from location
```

*Compare update level of currently installed Stata with that of source*

```
update query [, from(location)]
```

*Perform update if necessary*

```
update all [, from(location) detail force exit]
```

*Set automatic updates (Mac and Windows only)*

```
set update_query {on|off}
set update_interval #
set update_prompt {on|off}
```

**Options**

*from(location)* specifies the location of the update source. You can specify the *from()* option on the individual *update* commands or use the *update from* command. Which you do makes no difference. You typically do not need to use this option.

*detail* specifies to display verbose output during the update process.

*force* specifies to force downloading of all files even if, based on the date comparison, Stata does not think it is necessary. There is seldom a reason to specify this option.

*exit* instructs Stata to exit when the update has successfully completed. There is seldom a reason to specify this option.

**Remarks and examples**

`update` updates the official components of Stata from the official source: https://www.stata.com. If you are connected to the Internet, the easy thing to do is to type

```
.update all
```

and follow the instructions. If Stata is up to date, *update all* will do nothing. Otherwise, it will download whatever is necessary and install the files. If you just want to know what updates are available, type

```
.update query
```
update query will check if any updates are available and report that information. If updates are available, it will recommend that you type update all.

If you want to report the current update level, type

    . update

update will report the update level of the Stata installation. update will also show you the date that updates were last checked and if any updates were available at that time.

Stored results

update without a subcommand, update from, and update query store the following in r():

Scalars

- r(inst_exe) date of executable installed (*)
- r(avbl_exe) date of executable available over web (*) (**)
- r(inst_ado) date of ado-files installed (*)
- r(avbl_ado) date of ado-files available over web (*) (**)
- r(inst_utilities) date of utilities installed (*)
- r(avbl_utilities) date of utilities available over web (*) (**)
- r(inst_docs) date of documentation installed (*)
- r(avbl_docs) date of documentation available over web (*) (**)

Macros

- r(name_exe) name of the Stata executable
- r(dir_exe) directory in which executable is stored
- r(dir_ado) directory in which ado-files are stored
- r(dir_utilities) directory in which utilities are stored
- r(dir_docs) directory in which PDF documentation is stored

Notes:

* Dates are stored as integers counting the number of days since January 1, 1960; see [D] Datetime.

** These dates are not stored by update without a subcommand because update by itself reports information solely about the local computer and does not check what is available on the web.

This entry describes the `vce()` option, which is common to most estimation commands. `vce()` specifies how to estimate the variance–covariance matrix (VCE) corresponding to the parameter estimates. The standard errors reported in the table of parameter estimates are the square root of the variances (diagonal elements) of the VCE.

**Syntax**

\[
\text{estimation\_cmd} \ldots \left[ , \ vce(\text{vcetype}) \right] \ldots
\]

<table>
<thead>
<tr>
<th>vcetype</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>oim</td>
<td>observed information matrix (OIM)</td>
</tr>
<tr>
<td>opg</td>
<td>outer product of the gradient (OPG) vectors</td>
</tr>
<tr>
<td>robust</td>
<td>Huber/White/sandwich estimator</td>
</tr>
<tr>
<td>cluster clustvar</td>
<td>clustered sandwich estimator</td>
</tr>
</tbody>
</table>

**Options**

- `vce(oim)` is usually the default for models fit using maximum likelihood. `vce(oim)` uses the observed information matrix (OIM); see [R] ml.
- `vce(opg)` uses the sum of the outer product of the gradient (OPG) vectors; see [R] ml. This is the default VCE when the `technique(bhhh)` option is specified; see [R] Maximize.
- `vce(robust)` uses the robust or sandwich estimator of variance. This estimator is robust to some types of misspecification so long as the observations are independent; see [U] 20.22 Obtaining robust variance estimates.
If the command allows `pweights` and you specify them, `vce(robust)` is implied; see [U] 20.24.3 Sampling weights.

`vce(cluster clustvar)` specifies that the standard errors allow for intragroup correlation, relaxing the usual requirement that the observations be independent. That is, the observations are independent across groups (clusters) but not necessarily within groups. `clustvar` specifies to which group each observation belongs, for example, `vce(cluster personid)` in data with repeated observations on individuals. `vce(cluster clustvar)` affects the standard errors and variance–covariance matrix of the estimators but not the estimated coefficients; see [U] 20.22 Obtaining robust variance estimates.

`vce(bootstrap [ , bootstrap_options ] )` uses a bootstrap; see [R] bootstrap. After estimation with `vce(bootstrap)`, see [R] bootstrap postestimation to obtain percentile-based or bias-corrected confidence intervals.

`vce(jackknife [ , jackknife_options ] )` uses the delete-one jackknife; see [R] jackknife.

### Remarks and examples

Remarks are presented under the following headings:

**Prefix commands**

**Passing options in vce()**

### Prefix commands

Specifying `vce(bootstrap)` or `vce(jackknife)` is often equivalent to using the corresponding prefix command. Here is an example using `jackknife` with `regress`.

```
. use https://www.stata-press.com/data/r16/auto
(1978 Automobile Data)
. regress mpg turn trunk, vce(jackknife)
(running regress on estimation sample)
Jackknife replications (74)
.................................................. 50
........................
Linear regression

Number of obs = 74
Replications = 74
F( 2, 73) = 66.26
Prob > F = 0.0000
R-squared = 0.5521
Adj R-squared = 0.5395
Root MSE = 3.9260

|                | Coef.  | Std. Err. | t     | P>|t|   | 95% Conf. Interval |
|----------------|--------|-----------|-------|-------|-------------------|
| mpg turn       | -.7610113 | .150726 | -5.05 | 0.000 | -1.061408 to -.4606147 |
| mpg trunk      | -.3161825 | .1282326 | -2.47 | 0.016 | -.5717498 to -.0606152 |
| mpg _cons      | 55.82001 | 5.031107 | 11.09 | 0.000 | 45.79303 to 65.84699 |
```
Here it does not matter whether we specify the `vce(jackknife)` option or instead use the `jackknife` prefix.

However, `vce(jackknife)` should be used in place of the `jackknife` prefix whenever available because they are not always equivalent. For example, to use the `jackknife` prefix with `clogit` properly, you must tell `jackknife` to omit whole groups rather than individual observations. Specifying `vce(jackknife)` does this automatically.

```
. use https://www.stata-press.com/data/r16/clogitid
. jackknife, cluster(id): clogit y x1 x2, group(id)
```

This extra information is automatically communicated to `jackknife` by `clogit` when the `vce()` option is specified.

```
. clogit y x1 x2, group(id) vce(jackknife)
```

| mpg      | Coef.  | Std. Err. | t     | P>|t|    | [95% Conf. Interval] |
|----------|--------|-----------|-------|--------|----------------------|
| turn     | -.761  | .1507     | -5.05 | 0.000  | -1.061408 -.4606147  |
| trunk    | -.316  | .1282     | -2.47 | 0.016  | -.5717498 -.0606152  |
| _cons    | 55.82  | 5.03      | 11.09 | 0.000  | 45.79303 65.84699    |

| y        | Coef.  | Std. Err. | t     | P>|t|    | [95% Conf. Interval] |
|----------|--------|-----------|-------|--------|----------------------|
| x1       | .65336 | .30106    | 2.17  | 0.034  | .052103 1.254623     |
| x2       | .06591 | .04878    | 1.35  | 0.181  | -.0315151 .1633489   |
Passing options in vce()

If you wish to specify more options to the bootstrap or jackknife estimation, you can include them within the vce() option. Below we request 300 bootstrap replications and save the replications in bsreg.dta:

```
use https://www.stata-press.com/data/r16/auto
(1978 Automobile Data)
regress mpg turn trunk, vce(bootstrap, nodots seed(123) rep(300) saving(bsreg))
```

```
Observed Bootstrap Normal-based
coef. std. err. z p>|z| [95% conf. interval]
--- --- -------- ------- ---------------
 turn -.7610113 .1497877 -5.08 0.000 -1.05459 -.4674329
 trunk -.3161825 .1286802 -2.46 0.014 -.5683909 -.063974
_cons 55.82001 4.9221 11.34 0.000 46.17287 65.46715
```

```
.bstat using bsreg
```

```
Bootstrap results
--- ------- ---------------
number of obs = 74
replications = 300
command:  regress mpg turn trunk

Observed Bootstrap Normal-based
coef. std. err. z p>|z| [95% conf. interval]
--------- -------- ------- ------- ---------------
 turn -.7610113 .1497877 -5.08 0.000 -1.05459 -.4674329
 trunk -.3161825 .1286802 -2.46 0.014 -.5683909 -.063974
_cons 55.82001 4.9221 11.34 0.000 46.17287 65.46715
```

Methods and formulas

By default, Stata’s maximum likelihood estimators display standard errors based on variance estimates given by the inverse of the negative Hessian (second derivative) matrix. If vce(robust), vce(cluster clustvar), or pweights is specified, standard errors are based on the robust variance estimator (see [U] 20.22 Obtaining robust variance estimates); likelihood-ratio tests are not appropriate here (see [SVY] Survey), and the model \( \chi^2 \) is from a Wald test. If vce(opg) is specified, the standard errors are based on the outer product of the gradients; this option has no effect on likelihood-ratio tests, though it does affect Wald tests.

If vce(bootstrap) or vce(jackknife) is specified, the standard errors are based on the chosen replication method; here the model \( \chi^2 \) or \( F \) statistic is from a Wald test using the respective replication-based covariance matrix. The \( t \) distribution is used in the coefficient table when the vce(jackknife) option is specified. vce(bootstrap) and vce(jackknife) are also available with some commands that are not maximum likelihood estimators.

[U] 20 Estimation and postestimation commands
Description

view displays file contents in the Viewer.

view file displays the specified file. file is optional, so if you had a SMCL session log created by typing log using mylog, you could view it by typing view mylog.smcl. view file can properly display .smcl files (logs and the like), .sthlp files, and text files. view file’s asis option specifies that the file be displayed as plain text, regardless of the filename’s extension.

view browse opens your browser pointed to url. Typing view browse https://www.stata.com would bring up your browser pointed to the website https://www.stata.com.

[view] help displays the specified topic in the Viewer. For example, to review the help for Stata’s print command, you could type help print. See [R] help for more details.

[view] search displays the results of the search command in the Viewer. For instance, to search the system help for information on robust regression, you could type search robust regression. See [R] search for more details.

view net does the same as the net command—see [R] net—but displays the result in the Viewer. For instance, typing view net search hausman test would search the Internet for additions to Stata related to the Hausman test. Typing view net from https://www.stata.com would go to the Stata additions download site at https://www.stata.com.

view ado does the same as the ado command—see [R] ado—but displays the result in the Viewer. For instance, typing view ado dir would show a list of files you have installed.

view update does the same as the update command—see [R] update—but displays the result in the Viewer. Typing view update would show the dates of what you have installed, and from there you could click to compare those dates with the latest updates available. Typing view update query would skip the first step and show the comparison.

Menu

File > View...
Syntax

Display file in Viewer

```plaintext
view [file] ["filename"] [, asis adopath]
```

Bring up browser pointed to specified URL

```plaintext
view browse ["url"]
```

Display help results in Viewer

```plaintext
[view] help [topic_or_command_name]
```

Display search results in Viewer

```plaintext
[view] search keywords
```

Display net results in Viewer

```plaintext
view net [netcmd]
```

Display ado-results in Viewer

```plaintext
view ado [adocmd]
```

Display update results in Viewer

```plaintext
view update [updatecmd]
```

Options

asis, allowed with `view file`, specifies that the file be displayed as text, regardless of the `filename`’s extension. `view file`’s default action is to display files ending in `.smcl` and `.sthlp` as SMCL; see `[P] smcl`.

adopath, allowed with `view file`, specifies that Stata search the `S_ADO` path for `filename` and display it, if found.

Remarks and examples

Most users access the Viewer by selecting `File > View...` and proceeding from there. Some commands allow you to skip that step. Some common interactive uses of commands that display their results in the Viewer are the following:
. view mysession.smcl
. view mysession.log
. help print
. help regress
. search hausman test
. view net
. view ado
. view update query

vwls estimates a linear regression using variance-weighted least squares. It differs from ordinary least-squares (OLS) regression in that it does not assume homogeneity of variance, but requires that the conditional variance of `depvar` be estimated prior to the regression. The estimated variance need not be constant across observations. `vwls` treats the estimated variance as if it were the true variance when it computes standard errors of the coefficients.

You must supply an estimate of the conditional standard deviation of `depvar` to `vwls` by using the `sd(varname)` option, or you must have grouped data with the groups defined by the `indepvars` variables. In the latter case, `vwls` treats all `indepvars` as categorical variables, computes the mean and standard deviation of `depvar` separately for each subgroup, and computes the regression of the subgroup means on `indepvars`.

`regress` with analytic weights can be used to produce another kind of “variance-weighted least squares”; see `Remarks and examples` for an explanation of the difference.

**Quick start**

Variance-weighted least-squares regression of `y` on `x1` and `x2`, with the estimated conditional std. dev. of `y` stored in `sd`

```
vwls y1 x1 x2, sd(sd)
```

Add categorical variable `a` using factor-variable syntax

```
vwls y1 x1 x2 i.a, sd(sd)
```

As above, but restrict the sample to cases where `v` is greater than 1

```
vwls y1 x1 x2 i.a if v>1, sd(sd)
```

Variance-weighted least-squares regression for grouped data with subgroups defined by `a2` and `a3`

```
vwls y2 i.a2 i.a3
```

**Menu**

```
Statistics > Linear models and related > Other > Variance-weighted least squares
```
Variance-weighted least squares

**Syntax**

```plaintext
vwls depvar indepvars [if] [in] [weight] [, options]
```

**Options**

<table>
<thead>
<tr>
<th>Model</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>noconstant</code></td>
<td>suppress constant term</td>
</tr>
<tr>
<td><code>sd(varname)</code></td>
<td>variable containing estimate of conditional standard deviation</td>
</tr>
</tbody>
</table>

**Reporting**

<table>
<thead>
<tr>
<th><code>level(#)</code></th>
<th>set confidence level; default is <code>level(95)</code></th>
</tr>
</thead>
<tbody>
<tr>
<td><code>display_options</code></td>
<td>control columns and column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling</td>
</tr>
</tbody>
</table>

**Options**

- `noconstant`; see [R] Estimation options.
- `sd(varname)` is an estimate of the conditional standard deviation of `depvar` (that is, it can vary observation by observation). All values of `varname` must be > 0. If you specify `sd()`, you cannot use fweights.
  
  If `sd()` is not given, the data will be grouped by `indepvars`. Here `indepvars` are treated as categorical variables, and the means and standard deviations of `depvar` for each subgroup are calculated and used for the regression. Any subgroup for which the standard deviation is zero is dropped.

- `level(#)`; see [R] Estimation options.
  
  `display_options`: `noci`, `nopvalues`, `nomitted`, `vsquish`, `noemptycells`, `baselevels`, `allbaselevels`, `nofvlabel`, `fvwrap(#)`, `fvwrapon(style)`, `cformat(\%fmt)`, `pformat(\%fmt)`, `sformat(\%fmt)`, and `nolstretch`; see [R] Estimation options.

The following option is available with `vwls` but is not shown in the dialog box:

- `coeflegend`; see [R] Estimation options.
Remarks and examples

The `vwls` command is intended for use with two special—and different—types of data. The first contains data that consist of measurements from physical science experiments in which all error is due solely to measurement errors and the sizes of the measurement errors are known.

You can also use variance-weighted least-squares linear regression for certain problems in categorical data analysis, such as when all the independent variables are categorical and the outcome variable is either continuous or a quantity that can sensibly be averaged. If each of the subgroups defined by the categorical variables contains a reasonable number of subjects, then the variance of the outcome variable can be estimated independently within each subgroup. For the purposes of estimation, `vwls` treats each subgroup as one observation, with the dependent variable being the subgroup mean of the outcome variable.

The `vwls` command fits the model

\[ y_i = x_i \beta + \varepsilon_i \]

where the errors \( \varepsilon_i \) are independent normal random variables with the distribution \( \varepsilon_i \sim N(0, \nu_i) \). The independent variables \( x_i \) are assumed to be known without error.

As described above, `vwls` assumes that you already have estimates \( s_i^2 \) for the variances \( \nu_i \). The error variance is not estimated in the regression. The estimates \( s_i^2 \) are used to compute the standard errors of the coefficients; see Methods and formulas below.

In contrast, weighted OLS regression assumes that the errors have the distribution \( \varepsilon_i \sim N(0, \sigma^2 / w_i) \), where the \( w_i \) are known weights and \( \sigma^2 \) is an unknown parameter that is estimated in the regression. This is the difference from variance-weighted least squares: in weighted OLS, the magnitude of the error variance is estimated in the regression using all the data.

Example 1

An artificial, but informative, example illustrates the difference between variance-weighted least squares and weighted OLS.

We measure the quantities \( x_i \) and \( y_i \) and estimate that the standard deviation of \( y_i \) is \( s_i \). We enter the data into Stata:

```
. use https://www.stata-press.com/data/r16/vwlsxmpl
. list
```

```
+----+----+----+
<table>
<thead>
<tr>
<th>x</th>
<th>y</th>
<th>s</th>
</tr>
</thead>
</table>
 1.  | 1  | 1.2| .5 |
 2.  | 2  | 1.9| .5 |
 3.  | 3  | 3.2| 1  |
 4.  | 4  | 4.3| 1  |
 5.  | 5  | 4.9| 1  |
 6.  | 6  | 6.0| 2  |
 7.  | 7  | 7.2| 2  |
 8.  | 8  | 7.9| 2  |
  +----+----+----+
```

Because we want observations with smaller variance to carry larger weight in the regression, we compute an OLS regression with analytic weights proportional to the inverse of the squared standard deviations:
If we compute a variance-weighted least-squares regression by using `vwls`, we get the same results for the coefficient estimates but very different standard errors:

```
vwls y x, sd(s)
```

Variance-weighted least-squares regression  Number of obs  =  8
Goodness-of-fit chi2(6)  =  0.28  Model chi2(1)  =  33.24
Prob > chi2  =  0.9996  Prob > chi2  =  0.0000

```
       y |     Coef.  Std. Err.    z  P>|z|     [95% Conf. Interval]
-------------+-------------------------------------------------------------
     x |   .9824683   .170409   5.77  0.000       .6484728   1.316464
_cons |  .1138554    .514841    0.22  0.825      -.8952124   1.122923
-------------+-------------------------------------------------------------
```

Although the values of \( y_i \) were nicely linear with \( x_i \), the `vwls` regression used the large estimates for the standard deviations to compute large standard errors for the coefficients. For weighted OLS regression, however, the scale of the analytic weights has no effect on the standard errors of the coefficients—only the relative proportions of the analytic weights affect the regression.

If we are sure of the sizes of our error estimates for \( y_i \), using `vwls` is valid. However, if we can estimate only the relative proportions of error among the \( y_i \), then `vwls` is not appropriate.

### Example 2

Let’s now consider an example of the use of `vwls` with categorical data. Suppose that we have blood pressure data for \( n = 400 \) subjects, categorized by gender and race (black or white). Here is a description of the data:
Performing a variance-weighted regression using `vwlsls` gives

```
. vwlsls bp gender race
```

|                | Coef.   | Std. Err. | z     | P>|z|     | [95% Conf. Interval] |
|----------------|---------|-----------|-------|---------|----------------------|
| gender         | 5.876522| 1.170241  | 5.02  | 0.000   | 3.582892 – 8.170151  |
| race           | 2.372818| 1.191683  | 1.99  | 0.046   | 0.037163 – 4.708473  |
| _cons          | 116.6486| 0.9296297 | 125.48| 0.000   | 114.8266 – 118.4707  |

By comparison, an OLS regression gives the following result:

```
. regress bp gender race
```

<table>
<thead>
<tr>
<th>Source</th>
<th>SS</th>
<th>df</th>
<th>MS</th>
<th>Number of obs = 400</th>
</tr>
</thead>
<tbody>
<tr>
<td>Model</td>
<td>4485.66639</td>
<td>2</td>
<td>2242.83319</td>
<td>Prob &gt; F = 0.0000</td>
</tr>
<tr>
<td>Residual</td>
<td>58442.7305</td>
<td>397</td>
<td>147.210908</td>
<td>R-squared = 0.0713</td>
</tr>
<tr>
<td>Total</td>
<td>62928.3969</td>
<td>399</td>
<td>157.71528</td>
<td>Root MSE = 12.133</td>
</tr>
</tbody>
</table>

|                | Coef.    | Std. Err. | t      | P>|t|     | [95% Conf. Interval] |
|----------------|----------|-----------|--------|---------|----------------------|
| gender         | 6.1775   | 1.213305  | 5.09   | 0.000   | 3.792194 – 8.562806  |
| race           | 2.5875   | 1.213305  | 2.13   | 0.034   | 0.202193 – 4.972806  |
| _cons          | 116.4862 | 1.050753  | 110.86 | 0.000   | 114.4205 – 118.552   |

Note the larger value for the `race` coefficient (and smaller `p`-value) in the OLS regression. The assumption of homogeneity of variance in OLS means that the mean for black men pulls the regression line higher than in the `vwlsls` regression, which takes into account the larger variance for black men and reduces its effect on the regression.
Stored results

\texttt{vwls} stores the following in \texttt{e()}:  

**Scalars**  
- \texttt{e(N)}: number of observations  
- \texttt{e(df\_m)}: model degrees of freedom  
- \texttt{e(chi2)}: model $\chi^2$  
- \texttt{e(df\_gf)}: goodness-of-fit degrees of freedom  
- \texttt{e(chi2\_gf)}: goodness-of-fit $\chi^2$  
- \texttt{e(rank)}: rank of \texttt{e(V)}

**Macros**  
- \texttt{e(cmd)}: \texttt{vwls}  
- \texttt{e(cmdline)}: command as typed  
- \texttt{e(depvar)}: name of dependent variable  
- \texttt{e(properties)}: \texttt{b V}  
- \texttt{e(predict)}: program used to implement \texttt{predict}  
- \texttt{e(asbalanced)}: factor variables \texttt{fvset} as \texttt{asbalanced}  
- \texttt{e(asobserved)}: factor variables \texttt{fvset} as \texttt{asobserved}

**Matrices**  
- \texttt{e(b)}: coefficient vector  
- \texttt{e(V)}: variance–covariance matrix of the estimators

**Functions**  
- \texttt{e(sample)}: marks estimation sample

Methods and formulas

Let $y = (y_1, y_2, \ldots, y_n)'$ be the vector of observations of the dependent variable, where $n$ is the number of observations. When \texttt{sd()} is specified, let $s_1, s_2, \ldots, s_n$ be the standard deviations supplied by \texttt{sd()}. For categorical data, when \texttt{sd()} is not given, the means and standard deviations of $y$ for each subgroup are computed, and $n$ becomes the number of subgroups, $y$ is the vector of subgroup means, and $s_i$ are the standard deviations for the subgroups.

Let $V = \text{diag}(s_1^2, s_2^2, \ldots, s_n^2)$ denote the estimate of the variance of $y$. Then the estimated regression coefficients are  

$$b = (X'V^{-1}X)^{-1}X'V^{-1}y$$

and their estimated covariance matrix is  

$$\hat{\text{Cov}}(b) = (X'V^{-1}X)^{-1}$$

A statistic for the goodness of fit of the model is  

$$Q = (y - Xb)'V^{-1}(y - Xb)$$

where $Q$ has a $\chi^2$ distribution with $n - k$ degrees of freedom ($k$ is the number of independent variables plus the constant, if any).

2837
predict

Description for predict

predict creates a new variable containing predictions such as linear predictions and standard errors.

Menu for predict

Statistics > Postestimation

Syntax for predict

```
predict [type] newvar [if] [in] [, xb stdp]
```

These statistics are available both in and out of sample; type predict ... if e(sample) ... if wanted only for the estimation sample.

Options for predict

- **xb**, the default, calculates the linear prediction.
- **stdevp** calculates the standard error of the linear prediction.
margins

Description for margins

margins estimates margins of response for linear predictions.

Menu for margins

Statistics > Postestimation

Syntax for margins

\[ \text{margins} \ [ \text{marginlist} ] \ [ , \ \text{options} ] \]
\[ \text{margins} \ [ \text{marginlist} ] \ , \ \text{predict}(statistic \ldots) \ [ \text{options} ] \]

<table>
<thead>

[R] vwls — Variance-weighted least squares
[U] 20 Estimation and postestimation commands
which — Display location and version for an ado-file

Description

which looks for file *filename.ftype* along the S_ADO path. If Stata finds the file, which displays the full path and filename, along with, if the file is text, all lines in the file that begin with “*!” in the first column. If Stata cannot find the file, which issues the message “file not found along ado-path” and sets the return code to 111. *ftype* must be a file type for which Stata usually looks along the ado-path to find. Allowable *ftypes* are

   .ado, .class, .dlg, .idlg, .sthlp, .ihlp, .hlp, .jar, .key, .maint, .mata, .mlib, 
   .mo, .mnu, .plugin, .png, .py, .scheme, .stbcal, and .style

If *ftype* is omitted, which assumes .ado. When searching for .ado files, if Stata cannot find the file, Stata then checks to see if *filename* is a built-in Stata command, allowing for valid abbreviations. If it is, the message “built-in command” is displayed; if not, the message “command not found as either built-in or ado-file” is displayed and the return code is set to 111.

For information about internal version control, see [P] version.

Syntax

which *fname[.ftype] [, all]*

Option

all forces which to report the location of all files matching the *fname.ftype* found along the search path. The default is to report just the first one found.

Remarks and examples

If you write programs, you know that you make changes to the programs over time. If you are like us, you also end up with multiple versions of the program stored on your disk, perhaps in different directories. You may even have given copies of your programs to other Stata users, and you may not remember which version of a program you or your friends are using. The which command helps you solve this problem.

Example 1

The which command displays the path for *filename*.ado and any lines in the code that begin with “*!” . For example, we might want information about the *test* command, described in [R] test, which is an ado-file written by StataCorp. Here is what happens when we type which test:

```
. which test
C:\Program Files\Stata16\ado\base\t\test.ado
*! version 2.4.0 30oct2018
```
which displays the path for the test.ado file and also a line beginning with “*!” that indicates the version of the file. This is how we, at StataCorp, do version control—see [U] 18.11.1 Version for an explanation of our version control numbers.

We do not need to be so formal. which will display anything typed after lines that begin with ‘*!’. For instance, we might write myprog.ado:

```
. which myprog
.
myprog.ado
*! first written 1/03/2019
*! bug fix on 1/05/2019 (no variance case)
*! updated 1/24/2019 to include noconstant option
*! still suspicious if variable takes on only two values
```

It does not matter where in the program the lines beginning with *! are—which will list them (in particular, our “still suspicious” comment was buried about 50 lines down in the code). All that is important is that the *! marker appear in the first two columns of a line.

---

**Example 2**

If we type which command, where command is a built-in command rather than an ado-file, Stata responds with

```
. which summarize
built-in command: summarize
```

If command was neither a built-in command nor an ado-file, Stata would respond with

```
. which junk
command junk not found as either built-in or ado-file
r(111);
```

---

[P] version — Version control

[U] 17 Ado-files

[U] 18.11.1 Version
### Description

`xi` expands terms containing categorical variables into indicator (also called dummy) variable sets by creating new variables and, in the second syntax (`xi: any_stata_command`), executes the specified command with the expanded terms. The dummy variables created are

- `i.varname` creates dummies for categorical variable `varname`
- `i.varname1*i.varname2` creates dummies for categorical variables `varname1` and `varname2`: all interactions and main effects
- `i.varname1*varname3` creates dummies for categorical variable `varname1` and continuous variable `varname3`: all interactions and main effects
- `i.varname1|varname3` creates dummies for categorical variable `varname1` and continuous variable `varname3`: all interactions and main effect of `varname3`, but no main effect of `varname1`

### Menu

Data > Create or change data > Other variable-creation commands > Interaction expansion

Most commands in Stata now allow factor variables; see [U] 11.4.3 Factor variables. To determine if a command allows factor variables, see the information printed below the options table for the command. If the command allows factor variables, it will say something like “`indepvars` may contain factor variables”.

We recommend that you use factor variables instead of `xi` if a command allows factor variables. We include [R] xi in our documentation so that readers can consult it when using a Stata command that does not allow factor variables.
Syntax

```
xi [, prefix(string) noomit] term(s)
xi [, prefix(string) noomit] : any_stata_command varlist_with_terms ...
```

where a *term* has the form

```
i.varname or I.varname
i.varname1*i.varname2 or I.varname1*I.varname2
i.varname1*varname3 or I.varname1*varname3
i.varname1|varname3 or I.varname1|varname3
```

*varname*, *varname1*, and *varname2* denote numeric or string categorical variables. *varname3* denotes a continuous, numeric variable.

Options

```
prefix(string) allows you to choose a prefix other than _I for the newly created interaction variables. The prefix cannot be longer than four characters. By default, *xi* will create interaction variables starting with _I. When you use *xi*, it drops all previously created interaction variables starting with the prefix specified in the *prefix(string)* option or with _I by default. Therefore, if you want to keep the variables with a certain prefix, specify a different prefix in the *prefix(string)* option.
```

```
noomit prevents *xi* from omitting groups. This option provides a way to generate an indicator variable for every category having one or more variables, which is useful when combined with the noconstant option of an estimation command.
```

Remarks and examples

Remarks are presented under the following headings:

```
Background
Indicator variables for simple effects
Controlling the omitted dummy
Categorical variable interactions
Interactions with continuous variables
Using *xi*: Interpreting output
How *xi* names variables
*xi* as a command rather than a command prefix
Warnings
```

*xi* provides a convenient way to include dummy or indicator variables when fitting a model (say, with *regress* or *logistic*). For instance, assume that the categorical variable *agegrp* contains 1 for ages 20–24, 2 for ages 25–39, 3 for ages 40–44, etc. Typing

```
.xi: logistic outcome weight i.agegrp bp
```

estimates a logistic regression of *outcome* on *weight*, dummies for each *agegrp* category, and *bp*. That is, *xi* searches out and expands terms starting with “*i.*” or “*I.*” but ignores the other variables. *xi* will expand both numeric and string categorical variables, so if you had a string variable *race* containing “white”, “black”, and “other”, typing

```
.xi: logistic outcome weight bp i.agegrp i.race
```

would include indicator variables for the race group as well.
The \text{i.} indicator variables \text{xi} expands may appear anywhere in the \text{varlist}, so
\begin{verbatim}
 . xi: logistic outcome i.agegrp weight i.race bp
\end{verbatim}
would fit the same model.

You can also create interactions of categorical variables; typing
\begin{verbatim}
 xi: logistic outcome weight bp i.agegrp*i.race
\end{verbatim}
fits a model with indicator variables for all \text{agegrp} and \text{race} combinations, including the \text{agegrp} and \text{race} main-effect terms (that is, the terms that are created when you just type \text{i.agegrp i.race}).

You can interact dummy variables with continuous variables; typing
\begin{verbatim}
 xi: logistic outcome bp i.agegrp*weight i.race
\end{verbatim}
fits a model with indicator variables for all \text{agegrp} categories interacted with \text{weight}, plus the main-effect terms \text{weight} and \text{i.agegrp}.

You can get the interaction terms without the \text{agegrp} main effect (but with the \text{weight} main effect) by typing
\begin{verbatim}
 xi: logistic outcome bp i.agegrp|weight i.race
\end{verbatim}
You can also include multiple interactions:
\begin{verbatim}
 xi: logistic outcome bp i.agegrp*weight i.agegrp*i.race
\end{verbatim}

We will now back up and describe the construction of dummy variables in more detail.

\section*{Background}

The terms \text{continuous}, \text{categorical}, and \text{indicator} or \text{dummy} variables are used below. Continuous variables measure something—such as height or weight—and at least conceptually can take on any real number over some range. Categorical variables, on the other hand, take on a finite number of values, each denoting membership in a subclass—for example, excellent, good, and poor, which might be coded 0, 1, 2, or 1, 2, 3, or even “Excellent”, “Good”, and “Poor”. An indicator or dummy variable—the terms are used interchangeably—is a special type of two-valued categorical variable that contains values 0, denoting false, and 1, denoting true. The information contained in any \text{k}-valued categorical variable can be equally well represented by \text{k} indicator variables. Instead of one variable recording values representing excellent, good, and poor, you can have three indicator variables, indicating the truth or falseness of “result is excellent”, “result is good”, and “result is poor”.

\text{xi} provides a convenient way to convert categorical variables to dummy or indicator variables when you fit a model (say, with \text{regress} or \text{logistic}).

\section*{Example 1}

For instance, assume that the categorical variable \text{agegrp} contains 1 for ages 20–24, 2 for ages 25–39, and 3 for ages 40–44. (There is no one over 44 in our data.) As it stands, \text{agegrp} would be a poor candidate for inclusion in a model even if we thought age affected the outcome. The reason is that the coding would restrict the effect of being in the second age group to be twice the effect of being in the first, and, similarly, the effect of being in the third to be three times the first. That is, if we fit the model,
\begin{equation}
y = \beta_0 + \beta_1 \text{agegrp} + X\beta_2
\end{equation}
the effect of being in the first age group is \( \beta_1 \), the second \( 2\beta_1 \), and the third \( 3\beta_1 \). If the coding 1, 2, and 3 is arbitrary, we could just as well have coded the age groups 1, 4, and 9, making the effects \( \beta_1, 4\beta_1, \) and \( 9\beta_1 \).

The solution is to convert the categorical variable \( \text{agegrp} \) to a set of indicator variables, \( a_1, a_2, \) and \( a_3 \), where \( a_i \) is 1 if the individual is a member of the \( i \)th age group and 0 otherwise. We can then fit the model

\[
y = \beta_0 + \beta_{11}a_1 + \beta_{12}a_2 + \beta_{13}a_3 + X\beta_2
\]

The effect of being in age group 1 is now \( \beta_{11} \); 2, \( \beta_{12} \); and 3, \( \beta_{13} \); and these results are independent of our (arbitrary) coding. The only difficulty at this point is that the model is unidentified in the sense that there are an infinite number of \( (\beta_0, \beta_{11}, \beta_{12}, \beta_{13}) \) that fit the data equally well.

To see this, pretend that \( (\beta_0, \beta_{11}, \beta_{12}, \beta_{13}) = (1, 1, 3, 4) \). The predicted values of \( y \) for the various age groups are

\[
y = \begin{cases} 
1 + 1 + X\beta_2 = 2 + X\beta_2 & \text{(age group 1)} \\
1 + 3 + X\beta_2 = 4 + X\beta_2 & \text{(age group 2)} \\
1 + 4 + X\beta_2 = 5 + X\beta_2 & \text{(age group 3)}
\end{cases}
\]

Now pretend that \( (\beta_0, \beta_{11}, \beta_{12}, \beta_{13}) = (2, 0, 2, 3) \). The predicted values of \( y \) are

\[
y = \begin{cases} 
2 + 0 + X\beta_2 = 2 + X\beta_2 & \text{(age group 1)} \\
2 + 2 + X\beta_2 = 4 + X\beta_2 & \text{(age group 2)} \\
2 + 3 + X\beta_2 = 5 + X\beta_2 & \text{(age group 3)}
\end{cases}
\]

These two sets of predictions are indistinguishable: for age group 1, \( y = 2 + X\beta_2 \) regardless of the coefficient vector used, and similarly for age groups 2 and 3. This arises because we have three equations and four unknowns. Any solution is as good as any other, and, for our purposes, we merely need to choose one of them. The popular selection method is to set the coefficient on the first indicator variable to 0 (as we have done in our second coefficient vector). This is equivalent to fitting the model

\[
y = \beta_0 + \beta_{12}a_2 + \beta_{13}a_3 + X\beta_2
\]

How we select a particular coefficient vector (identifies the model) does not matter. It does, however, affect the interpretation of the coefficients.

For instance, we could just as well choose to omit the second group. In our artificial example, this would yield \( (\beta_0, \beta_{11}, \beta_{12}, \beta_{13}) = (4, -2, 0, 1) \) instead of \( (2, 0, 2, 3) \). These coefficient vectors are the same in the sense that

\[
y = \begin{cases} 
2 + 0 + X\beta_2 = 2 + X\beta_2 & \text{(age group 1)} \\
2 + 2 + X\beta_2 = 4 + X\beta_2 & \text{(age group 2)} \\
2 + 3 + X\beta_2 = 5 + X\beta_2 & \text{(age group 3)}
\end{cases}
\]

But what does it mean that \( \beta_{13} \) can just as well be 3 or 1? We obtain \( \beta_{13} = 3 \) when we set \( \beta_{11} = 0 \), so \( \beta_{13} = \beta_{13} - \beta_{11} \) and \( \beta_{13} \) measures the difference between age groups 3 and 1.

In the second case, we obtain \( \beta_{13} = 1 \) when we set \( \beta_{12} = 0 \), so \( \beta_{13} - \beta_{12} = 1 \) and \( \beta_{13} \) measures the difference between age groups 3 and 2. There is no inconsistency. According to our \( \beta_{12} = 0 \) model, the difference between age groups 3 and 1 is \( \beta_{13} - \beta_{11} = 1 - (-2) = 3 \), the same result we got in the \( \beta_{11} = 0 \) model.
Example 2

The issue of interpretation is important because it can affect the way we discuss results. Imagine that we are studying recovery after a coronary bypass operation. Assume that the age groups are children under 13 (we have two of them), young adults under 25 (we have a handful of them), adults under 46 (of which we have even more), mature adults under 56, older adults under 65, and elderly adults. We follow the prescription of omitting the first group, so all our results are reported relative to children under 13. While there is nothing statistically wrong with this, readers will be suspicious when we make statements like “compared with young children, older and elder adults . . .”. Moreover, we will probably have to end each statement with “although results are not statistically significant” because we have only two children in our comparison group. Of course, even with results reported in this way, we can do reasonable comparisons (say, with mature adults), but we will have to do extra work to perform the appropriate linear hypothesis test using Stata’s test command.

Here it would be better to force the omitted group to be more reasonable, such as mature adults. There is, however, a generic rule for automatic comparison group selection that, although less popular, tends to work better than the omit-the-first-group rule. That rule is to omit the most prevalent group. The most prevalent is usually a reasonable baseline.

In any case, the prescription for categorical variables is

1. Convert each $k$-valued categorical variable to $k$ indicator variables.
2. Drop one of the $k$ indicator variables; any one will do, but dropping the first is popular, dropping the most prevalent is probably better in terms of having the computer guess at a reasonable interpretation, and dropping a specified one often eases interpretation the most.
3. Fit the model on the remaining $k - 1$ indicator variables.

xi automates this procedure.

We will now consider each of xi’s features in detail.

Indicator variables for simple effects

When you type i.varname, xi internally tabulates varname (which may be a string or a numeric variable) and creates indicator (dummy) variables for each observed value, omitting the indicator for the smallest value. For instance, say that agegrp takes on the values 1, 2, 3, and 4. Typing

```
xi: logistic outcome i.agegrp
```

creates indicator variables named _Iagegrp_2, _Iagegrp_3, and _Iagegrp_4. (xi chooses the names and tries to make them readable; xi guarantees that the names are unique.) The expanded logistic model is

```
.logistic outcome _Iagegrp_2 _Iagegrp_3 _Iagegrp_4
```

Afterward, you can drop the new variables xi leaves behind by typing ‘drop _I*’ (note the capitalization).

xi provides the following features when you type i.varname:

- varname may be string or numeric.
- Dummy variables are created automatically.
• By default, the dummy-variable set is identified by dropping the dummy corresponding to the smallest value of the variable (how to specify otherwise is discussed below).

• The new dummy variables are left in your dataset. By default, the names of the new dummy variables start with _I; therefore, you can drop them by typing `drop _I*'. You do not have to do this; each time you use xi, any automatically generated dummies with the same prefix as the one specified in the prefix(string) option, or _I by default, are dropped and new ones are created.

• The new dummy variables have variable labels so that you can determine what they correspond to by typing `describe'.

• xi may be used with any Stata command (not just logistic).

Controlling the omitted dummy

By default, i.varname omits the dummy corresponding to the smallest value of varname; for a string variable, this is interpreted as dropping the first in an alphabetical, case-sensitive sort. xi provides two alternatives to dropping the first: xi will drop the dummy corresponding to the most prevalent value of varname, or xi will let you choose the particular dummy to be dropped.

To change xi’s behavior to dropping the most prevalent dummy, type

```
. char _dta[omit] prevalent
```

although whether you type “prevalent” or “yes” or anything else does not matter. Setting this characteristic affects the expansion of all categorical variables in the dataset. If you resave your dataset, the prevalent preference will be remembered. If you want to change the behavior back to the default drop-the-first rule, type

```
. char _dta[omit]
```

to clear the characteristic.

Once you set _dta[omit], i.varname omits the dummy corresponding to the most prevalent value of varname. Thus the coefficients on the dummies have the interpretation of change from the most prevalent group. For example,

```
. char _dta[omit] prevalent
. xi: regress y i.agegrp
```

might create _Iagegrp_1 through _Iagegrp_4, resulting in _Iagegrp_2 being omitted if agegrp = 2 is most common (as opposed to the default dropping of _Iagegrp_1). The model is then

\[
y = b_0 + b_1 \_Iagegrp_1 + b_3 \_Iagegrp_3 + b_4 \_Iagegrp_4 + u
\]

Then

\[
\begin{align*}
\text{Predicted } y \text{ for agegrp } 1 &= b_0 + b_1 \\
\text{Predicted } y \text{ for agegrp } 2 &= b_0 \\
\text{Predicted } y \text{ for agegrp } 3 &= b_0 + b_3 \\
\text{Predicted } y \text{ for agegrp } 4 &= b_0 + b_4
\end{align*}
\]

Thus the model’s reported \( t \) or \( Z \) statistics are for a test of whether each group is different from the most prevalent group.

Perhaps you wish to omit the dummy for agegrp 3 instead. You do this by setting the variable’s omit characteristic:

```
. char agegrp[omit] 3
```
This overrides _dta[omit] if you have set it. Now when you type

```
   . xi: regress y i.agegrp
```

_Iagegrp_3 will be omitted, and you will fit the model

\[
y = b_0 + b_1 Iagegrp_1 + b_2 Iagegrp_2 + b_4 Iagegrp_4 + u
\]

Later if you want to return to the default omission, type

```
   . char agegrp[omit]
```

to clear the characteristic.

In summary, _i.varname_ omits the first group by default, but if you define

```
   . char _dta[omit] prevalent
```

the default behavior changes to dropping the most prevalent group. Either way, if you define a characteristic of the form

```
   . char varname[omit] #
```
or, if _varname_ is a string,

```
   . char varname[omit] string-literal
```

the specified value will be omitted.

Examples:

```
   . char agegrp[omit] 1
   . char race[omit] White       (for race, a string variable)
   . char agegrp[omit]           (to restore default for agegrp)
```

### Categorical variable interactions

_i.varname_1*i.varname_2 creates the dummy variables associated with the interaction of the categorical variables _varname_1 and _varname_2. The identification rules—which categories are omitted—are the same as those for _i.varname_. For instance, assume that _agegrp_ takes on four values and _race_ takes on three values. Typing

```
   . xi: regress y i.agegrp*i.race
```

results in

model:

\[
y = a + b_2 Iagegrp_2 + b_3 Iagegrp_3 + b_4 Iagegrp_4 + c_2 Irace_2 + c_3 Irace_3 + d_{22} IageXrac_2_2 + d_{23} IageXrac_2_3 + d_{32} IageXrac_3_2 + d_{33} IageXrac_3_3 + d_{42} IageXrac_4_2 + d_{43} IageXrac_4_3 + u
\]

dummies for:

- _agegrp_
- _race_
- _agegrp*race_
That is, typing

```
  . xi: regress y i.agegrp*i.race
```

is the same as typing

```
  . xi: regress y i.agegrp i.race i.agegrp*i.race
```

Although there are many other ways the interaction could have been parameterized, this method has
the advantage that you can test the joint significance of the interactions by typing

```
  . testparm _IageXrac*
```

When you perform the estimation step, whether you specify `i.agegrp*i.race` or `i.race*i.agegrp`
makes no difference (other than in the names given to the interaction terms; in the first case, the
names will begin with _IageXrac; in the second, _IracXage). Thus

```
  . xi: regress y i.race*i.agegrp
```

fits the same model.

You may also include multiple interactions simultaneously:

```
  . xi: regress y i.agegrp*i.race i.agegrp*i.sex
```

The model fit is

```
model:

\[
y = a + b_2 \_Iagegrp\_2 + b_3 \_Iagegrp\_3 + b_4 \_Iagegrp\_4 + c_2 \_Irace\_2 + c_3 \_Irace\_3 + d_{22} \_IageXrac\_2\_2 + d_{23} \_IageXrac\_2\_3 + d_{32} \_IageXrac\_3\_2 + d_{33} \_IageXrac\_3\_3 + d_{42} \_IageXrac\_4\_2 + d_{43} \_IageXrac\_4\_3 + e_2 \_Isex\_2 + f_{22} \_IageXsex\_2\_2 + f_{23} \_IageXsex\_2\_3 + f_{24} \_IageXsex\_2\_4 + u
\]
```

dummies for:

- `agegrp`
- `race`
- `agegrp*race`
- `sex`
- `agegrp*sex`

The `agegrp` dummies are (correctly) included only once.

**Interactions with continuous variables**

`i.varname1*varname2` (as distinguished from `i.varname1*i.varname2`—note the second `i`.)
specifies an interaction of a categorical variable with a continuous variable. For instance,

```
  . xi: regress y i.agegr*wgt
```

results in the model

```
\[
y = a + b_2 \_Iagegrp\_2 + b_3 \_Iagegrp\_3 + b_4 \_Iagegrp\_4 + c \_wgt + d_{22} \_IageXwgt\_2\_2 + d_{23} \_IageXwgt\_2\_3 + d_{32} \_IageXwgt\_3\_2 + d_{33} \_IageXwgt\_3\_3 + d_{42} \_IageXwgt\_4\_2 + d_{43} \_IageXwgt\_4\_3 + u
\]
```

- `agegrp` dummies
- Continuous `wgt` effect
- `agegrp*wgt` interactions
A variation on this notation, using | rather than *, omits the `agegrp` dummies. Typing

```
.xi: regress y i.agegrp|wgt
```

fits the model

$$y = a' + c' \text{ wgt}$$  \hspace{1cm} \text{ (continuous wgt effect)}

$$+d_2'IageXwgt \_2 + d_3'IageXwgt \_3 + d'_4'IageXwgt \_4$$  \hspace{1cm} \text{ (agegrp*wgt interactions)}

$$+u'$$

The predicted values of \( y \) are

| agegrp*wgt model | agegrp|wgt model |
|------------------|-----------|
| \( y = a + c \text{ wgt} \) | \( a' + c' \text{ wgt} \) |
| \( a + c \text{ wgt} + b_2 + d_2 \text{ wgt} \) | \( a' + c' \text{ wgt} + d_2 \text{ wgt} \) |
| \( a + c \text{ wgt} + b_3 + d_3 \text{ wgt} \) | \( a' + c' \text{ wgt} + d_3 \text{ wgt} \) |
| \( a + c \text{ wgt} + b_4 + d_4 \text{ wgt} \) | \( a' + c' \text{ wgt} + d_4 \text{ wgt} \) |

That is, typing

```
.xi: regress y i.agegrp*wgt
```

is equivalent to typing

```
.xi: regress y i.agegrp i.agegrp|wgt
```

In either case, you do not need to specify separately the continuous variable `wgt`; it is included automatically.

### Using xi: Interpreting output

```
.xi: regress mpg i.rep78
i.rep78  _Irep78\_1-5  (naturally coded; _Irep78\_1 omitted)
(output from regress appears)
```

Interpretation: \( i\text{.rep78} \) expanded to the dummies \( _Irep78\_1, \_Irep78\_2, \ldots, _Irep78\_5 \). The numbers on the end are “natural” in the sense that \( _Irep78\_1 \) corresponds to \( \text{rep78} = 1 \),\( _Irep78\_2 \) to \( \text{rep78} = 2 \), and so on. Finally, the dummy for \( \text{rep78} = 1 \) was omitted.

```
.xi: regress mpg i.make
i.make  _Imake\_1-74  (_Imake\_1 for make==AMC Concord omitted)
(output from regress appears)
```

Interpretation: \( i\text{.make} \) expanded to \( _Imake\_1, _Imake\_2, \ldots, _Imake\_74 \). The coding is not natural because `make` is a string variable. \( _Imake\_1 \) corresponds to one make, \( _Imake\_2 \) to another, and so on. You can find out the coding by typing `describe _Imake\_1` for the AMC Concord was omitted.
How xi names variables

By default, xi assigns to the dummy variables it creates names having the form

\[ \_Istub\_groupid \]

You may subsequently refer to the entire set of variables by typing ‘Istub*’. For example,

<table>
<thead>
<tr>
<th>name</th>
<th>= _I + stub + _ + groupid</th>
<th>Entire set</th>
</tr>
</thead>
<tbody>
<tr>
<td>_Iagegrp_1</td>
<td>_I agegrp _ 1</td>
<td>_Iagegrp*</td>
</tr>
<tr>
<td>_Iagegrp_2</td>
<td>_I agegrp _ 2</td>
<td>_Iagegrp*</td>
</tr>
<tr>
<td>_IageXwgt_1</td>
<td>_I ageXwgt _ 1</td>
<td>_IageXwgt*</td>
</tr>
<tr>
<td>_IageXrac_1_2</td>
<td>_I ageXrac _ 1_2</td>
<td>_IageXrac*</td>
</tr>
<tr>
<td>_IageXrac_2_1</td>
<td>_I ageXrac _ 2_1</td>
<td>_IageXrac*</td>
</tr>
</tbody>
</table>

If you specify a prefix in the prefix(string) option, say, _S, then xi will name the variables starting with the prefix

\[ \_Sstub\_groupid \]

**xi as a command rather than a command prefix**

xi can be used as a command prefix or as a command by itself. In the latter form, xi merely creates the indicator and interaction variables. Typing

```
.xi: regress y i.agegrp*wgt
```

is equivalent to typing

```
.xi i.agegrp*wgt
```

**Warnings**

1. xi creates new variables in your dataset; most are bytes, but interactions with continuous variables will have the storage type of the underlying continuous variable. You may get the error message “no room to add more variables” or “insufficient memory”. You may need to adjust the maxvar setting or reset max_memory if it has been set too low; see [U] 6 Managing memory.

2. When using xi with an estimation command, you may get the error message “unable to allocate matrix”. This usually occurs because you attempted to create a matrix that is too large; see [R] Limits.
Stored results

\texttt{xi} stores the following characteristics:

- \texttt{dta[\_\_xi\_\_Vars\_\_Prefix\_\_]} prefix names
- \texttt{dta[\_\_xi\_\_Vars\_\_To\_\_Drop\_\_] } variables created

Also see

[U] 11.1.10 Prefix commands
[U] 20 Estimation and postestimation commands
**Description**

`zinb` fits a zero-inflated negative binomial (ZINB) model to overdispersed count data with excess zero counts. The ZINB model assumes that the excess zero counts come from a logit or probit model and the remaining counts come from a negative binomial model.

**Quick start**

Zero-inflated negative binomial model of `y` on `x1` and `x2` with inflation modeled using `x3`

```
zinb y x1 x2, inflate(x3)
```

And conduct likelihood-ratio test against ZIP model

```
zinb y x1 x2, inflate(x3) zip
```

Use a probit model instead of a logit model to predict excess zeros

```
zinb y x1 x2, inflate(x3) probit
```

**Menu**

Statistics > Count outcomes > Zero-inflated negative binomial regression
Syntax

```
zinb depvar [ indepvars ] [ if ] [ in ] [ weight ],

    inflate(varlist, offset(varname) | _cons) [ options ]
```

**options**

**Description**

**Model**

* `inflate()`
  - equation that determines whether the count is zero
* `noconstant`
  - suppress constant term
* `exposure(varname_o)`
  - include ln(varname_o) in model with coefficient constrained to 1
* `offset(varname_o)`
  - include varname_o in model with coefficient constrained to 1
* `constraints(constraints)`
  - apply specified linear constraints
* `probit`
  - use probit model to characterize excess zeros; default is logit

**SE/Robust**

`vce(vcetype)`

- vcetype may be oim, robust, cluster clustvar, opg, bootstrap, or jackknife

**Reporting**

`level(#)`

- set confidence level; default is level(95)
* `irr`
  - report incidence-rate ratios
* `zip`
  - perform ZIP likelihood-ratio test
* `nocnsreport`
  - do not display constraints

**display_options**

- control columns and column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling

**Maximization**

`maximize_options`

- control the maximization process; seldom used
* `collinear`
  - keep collinear variables
* `coeflegend`
  - display legend instead of statistics

---

*`inflate(varlist, offset(varname) | _cons)` is required.

indepvars and varlist may contain factor variables; see [U] 11.4.3 Factor variables.

bayes, bootstrap, by, fp, jackknife, rolling, statsby, and svy are allowed; see [U] 11.1.10 Prefix commands.

For more details, see [BAYES] bayes: zinb.

Weights are not allowed with the bootstrap prefix; see [R] bootstrap.

vce(), zip, and weights are not allowed with the svy prefix; see [SVY] svy.

`fweights`, `iweights`, and `pweights` are allowed; see [U] 11.1.6 weight.

collinear and coeflegend do not appear in the dialog box.

See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.
Options

```
 Model
 inflate(varlist[, offset(varname)] | _cons) specifies the equation that determines whether the
 observed count is zero. Conceptually, omitting inflate() would be equivalent to fitting the model
 with nbreg.

 inflate(varlist[, offset(varname)]) specifies the variables in the equation. You may optionally
 include an offset for this varlist.

 inflate(_cons) specifies that the equation determining whether the count is zero contains only
 an intercept. To run a zero-inflated model of depvar with only an intercept in both equations, type
 zinb depvar, inflate(_cons).

 noconstant, exposure(varname_e), offset(varname_o), constraints(constraints); see [R] Estimation options.

 probit requests that a probit, instead of logit, model be used to characterize the excess zeros in the
 data.

 SE/Robust
 vce(vcetype) specifies the type of standard error reported, which includes types that are derived from
 asymptotic theory (oim, opg), that are robust to some kinds of misspecification (robust), that
 allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods
 (bootstrap, jackknife); see [R] vce_option.

 Reporting
 level(#) ; see [R] Estimation options.

 irr reports estimated coefficients transformed to incidence-rate ratios, that is, $e^{\beta_i}$ rather than $\beta_i$.
 Standard errors and confidence intervals are similarly transformed. This option affects how results
 are displayed, not how they are estimated or stored. irr may be specified at estimation or when
 replaying previously estimated results.

 zip requests that a likelihood-ratio test comparing the ZINB model with the zero-inflated Poisson
 model be included in the output.

 nocnsreport; see [R] Estimation options.

 display_options: noci, nopvalues, noomitted, vsquish, noemptycells, baselevels,
 allbaselevels, nolabel, fvwrap(#), fvwrapon(style), cformat(%fmt), pformat(%fmt),
 sformat(%fmt), and nolstretch; see [R] Estimation options.

 Maximization
 maximize_options: difficult, technique(algorithm_spec), iterate(#), [no]log, trace,
 gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#),
 nrtolerance(#), nonrtolerance, and from(init_specs); see [R] Maximize. These options are
 seldom used.

 Setting the optimization type to technique(bhhh) resets the default vcetype to vce(opg).

 The following options are available with zinb but are not shown in the dialog box:
 collinear, coeflegend; see [R] Estimation options.
```
Remarks and examples

Zero-inflated negative binomial (ZINB) models are used to model count data that have a higher fraction of zeros than is likely to be generated by a standard negative binomial model. To account for excess zeros, ZINB models assume that these excess zeros come from a model other than the negative binomial model. A zero that comes from this other model is known as a “degenerate zero”.

The negative binomial overdispersion parameter, $\alpha$, differentiates the ZINB model from the zero-inflated Poisson (ZIP) model (see \texttt{R zip}). Here, overdispersion refers to the fact that the negative binomial variance is greater than its mean, whereas the Poisson variance is equal to its mean. Thus, values of $\alpha > 1$ indicate overdispersion. The larger the $\alpha$, the greater the negative binomial variance. See Methods and formulas in \texttt{R nbreg} for further discussion of negative binomial overdispersion.

The \texttt{zinb} command fits ZINB models and provides two choices for modeling the excess zeros: the default logit function or, when the \texttt{probit} option is specified, the probit function. Both functions are symmetric about zero, but the logistic function has more area under the tails.

Example 1: Fitting a ZINB model

In example 1 of \texttt{R zip}, we fit a zero-inflated Poisson model using the \texttt{zip} command to the fictional data on the number of fish caught by visitors to a national park. Let’s fit a ZINB model to these data.

Just like with \texttt{zip}, we use the required option \texttt{inflate()} to model whether a visitor fishes as a function of the number of accompanying children (\texttt{child}) and whether the visitor is camping (\texttt{camper}). Next, we assume the response variable, \texttt{count}, depends on whether the visitor used a live bait (\texttt{livebait}) and the number of persons in the party (\texttt{persons}), which includes the visitor plus other adults and children.
. use https://www.stata-press.com/data/r16/fish
   (Fictional fishing data)
. zinb count persons livebait, inflate(child camper)

Fitting constant-only model:
Iteration 0:  log likelihood = -519.33992
Iteration 1:  log likelihood = -451.38662
Iteration 2:  log likelihood = -444.49118
Iteration 3:  log likelihood = -442.96272
Iteration 4:  log likelihood = -442.71065
Iteration 5:  log likelihood = -442.66718
Iteration 6:  log likelihood = -442.6631
Iteration 7:  log likelihood = -442.66299
Iteration 8:  log likelihood = -442.66299

Fitting full model:
Iteration 0:  log likelihood = -442.66299 (not concave)
Iteration 1:  log likelihood = -432.83107 (not concave)
Iteration 2:  log likelihood = -426.32934
Iteration 3:  log likelihood = -413.75019
Iteration 4:  log likelihood = -403.09586
Iteration 5:  log likelihood = -401.56013
Iteration 6:  log likelihood = -401.54781
Iteration 7:  log likelihood = -401.54776
Iteration 8:  log likelihood = -401.54776

Zero-inflated negative binomial regression
Number of obs = 250
Nonzero obs = 108
Zero obs = 142
Inflation model = logit
LR chi2(2) = 82.23
Log likelihood = -401.5478
Prob > chi2 = 0.0000

| count          | Coef.  | Std. Err. | z   | P>|z|   | [95% Conf. Interval] |

| /lnalpha       | Coef.  | Std. Err. | z   | P>|z|   | [95% Conf. Interval] |
|----------------|--------|-----------|-----|-------|---------------------|
|                | 0.5110429 | 0.1816816 | 2.81 | 0.005 | 0.1549535 - 0.8671323 |

| alpha          | Coef.  | Std. Err. | z   | P>|z|   | [95% Conf. Interval] |
|----------------|--------|-----------|-----|-------|---------------------|
|                | 1.667029 | 0.3028685 | 1.167604 | 2.380076 |

The coefficients in the first equation of the coefficient table, labeled count, correspond to the negative binomial model for individuals who fished. For instance, among visitors who fished, using a live bait increases the expected number of caught fish by a factor of \( \exp(1.5575) \approx 4.7 \), holding other covariates constant.

The confidence interval for alpha indicates that the ZINB model is more appropriate than the ZIP model. To confirm this, you can run zinb and specify the zip option to obtain the ZIP likelihood-ratio test.

The inflate equation models whether the visitor does not fish. We can use margins to obtain a better understanding of how the inflate equation affects the occurrence of the excess zero counts. We specify margins’s options dydx(child camper) and predict(pr). pr is predict’s option
for estimating the probability of a degenerate zero or, in our example, the probability of not fishing; see the margins section in [R] zinb postestimation.

```
. margins, dydx(child camper) predict(pr)
Average marginal effects Number of obs = 250
Model VCE : OIM
Expression : Pr(count=0), predict(pr)
dy/dx w.r.t. : child camper

|         | dy/dx | Std. Err. | z    | P>|z| | [95% Conf. Interval] |
|---------|-------|-----------|------|-----|----------------------|
| child   | 0.257531 | 0.029941 | 8.60 | 0.000 | 0.1988477 - 0.3162144 |
| camper  | -0.1633578 | 0.0503938 | -3.24 | 0.001 | -0.2621277 - 0.0645878 |
```

The margins output tells us that a visitor is less likely to be visiting the park to fish if accompanied by children and more likely to fish if camping.

You also may want to evaluate whether a standard negative binomial model is adequate to fit the data. This can be done using information criteria; see example 2 in [R] zip.

## Stored results

zinb stores the following in e():

**Scalars**
- `e(N)`: number of observations
- `e(N_zero)`: number of zero observations
- `e(k)`: number of parameters
- `e(k_eq)`: number of equations in e(b)
- `e(k_eq_model)`: number of equations in overall model test
- `e(k_aux)`: number of auxiliary parameters
- `e(k_dv)`: number of dependent variables
- `e(df_m)`: model degrees of freedom
- `e(ll)`: log likelihood
- `e(ll_0)`: log likelihood, constant-only model
- `e(df_c)`: degrees of freedom for comparison test
- `e(N_clust)`: number of clusters
- `e(chi2)`: $\chi^2$
- `e(p)`: $p$-value for model test
- `e(chi2_cp)`: $\chi^2$ for test of $\alpha = 0$
- `e(rank)`: rank of $e(V)$
- `e(ic)`: number of iterations
- `e(rc)`: return code
- `e(converged)`: 1 if converged, 0 otherwise

**Macros**
- `e(cmd)`: zinb
- `e(cmdline)`: command as typed
- `e(depvar)`: name of dependent variable
- `e(inflate)`: logit or probit
- `e(utype)`: weight type
- `e(wexp)`: weight expression
- `e(title)`: title in estimation output
- `e(clustvar)`: name of cluster variable
- `e(offset1)`: offset
- `e(offset2)`: offset for inflate()
- `e(chi2type)`: Wald or LR; type of model $\chi^2$ test
The \texttt{zinb} command maximizes a likelihood function that is a mixture of the logistic (or probit) and negative binomial distributions. The logistic distribution models the unobserved process that creates the excess zeros, and the negative binomial distribution models the counts. Define

\begin{align*}
\xi_j^\beta &= x_j \beta + \text{offset}_j^\beta \\
\xi_j^\gamma &= z_j \gamma + \text{offset}_j^\gamma \\
\mu_j &= \exp(\xi_j^\beta) \\
p_j &= 1/(1 + \alpha \mu_j) \\
m &= 1/\alpha
\end{align*}

Here, the vector $x_j$ contains the covariates specified in \texttt{indepvars} for the $j$th observation, and $z_j$ contains the covariates specified in the \texttt{inflate()} option. Similarly, estimates for $\beta$ are found in the first equation of the \texttt{zinb} coefficient table (labeled after \texttt{depvar}), and the estimates for $\gamma$ are found in the second equation of the coefficient table (labeled \texttt{inflate}). The parameter $\alpha$ is the negative binomial overdispersion parameter, and its estimate is the ancillary parameter labeled \texttt{alpha} in the coefficient table. Parameters $p_j$, $m$, and $\mu_j$ are parameters of a negative binomial distribution; see \textit{Methods and formulas} in \texttt{R nbreg} for details.

The log likelihood maximized by \texttt{zinb} is

\[
\ln L = \sum_{j \in S} w_j \ln \left\{ F_j + (1 - F_j) p_j^m \right\} + \\
\sum_{j \not\in S} w_j \left\{ \ln(1 - F_j) + \ln \Gamma(m + y_j) - \ln \Gamma(y_j + 1) \\
- \ln \Gamma(m) + m \ln p_j + y_j \ln(1 - p_j) \right\}
\]
where \( w_j \) are the weights, \( S \) is the set of observations for which the observed outcome \( y_j = 0 \), and \( F_j \) is the logistic distribution function

\[
F_j = F(\xi^*_j) = \exp(\xi^*_j)/(1 + \exp(\xi^*_j))
\]

or, if the \texttt{probit} option is specified, the standard normal distribution function

\[
F_j = F(\xi^*_j) = \Phi(\xi^*_j)
\]

From Long (1997), the variance of the mixture distribution is

\[
\text{Var}(y_j|x_i, z_i) = \mu_j(1 - F_j) \{1 + \mu_j(F_j + \alpha)\}
\]

When \( F_j \) is zero, we have the variance of the negative binomial distribution; when \( F_j > 0 \), the variance can exceed that of the negative binomial distribution.

This command supports the Huber/White/sandwich estimator of the variance and its clustered version using \texttt{vce(robust)} and \texttt{vce(cluster clustvar)}, respectively. See \texttt{[P] _robust}, particularly \texttt{Maximum likelihood estimators} and \texttt{Methods and formulas}.

\texttt{zinb} also supports estimation with survey data. For details on VCEs with survey data, see \texttt{[SVY] Variance estimation}.

</tr>
<tr>
<td>stdp</td>
</tr>
</tbody>
</table>

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

Options for predict

n, the default, calculates the predicted number of events, which is \( (1 - F_j) \exp(x_j \beta) \) if neither `offset()` nor `exposure()` was specified when the model was fit, where \( F_j \) is the predicted probability of a zero outcome; \( (1 - F_j) \exp(x_j \beta + \text{offset}_j) \) if `offset()` was specified; or \( (1 - F_j) \{ \exp(x_j \beta) \times \text{exposure}_j \} \) if `exposure()` was specified.

ir calculates the incidence rate, which is the predicted number of events when exposure is 1. This is equivalent to specifying both the n and the `nooffset` options.

pr calculates the probability of a degenerate zero, predicted from the fitted degenerate distribution \( F_j = F(z_j \gamma) \). If `offset()` was specified within the `inflate()` option, then \( F_j = F(z_j \gamma + \text{offset}_j) \) is calculated.

pr(n) calculates the probability \( Pr(y_j = n) \), where \( n \) is a nonnegative integer that may be specified as a number or a variable. Note that pr is not equivalent to pr(0).
pr(a, b) calculates the probability Pr(a ≤ y_j ≤ b), where a and b are nonnegative integers that may be specified as numbers or variables;

b missing (b ≥ .) means +∞;
pr(20, .) calculates Pr(y_j ≥ 20);
pr(20, b) calculates Pr(y_j ≥ 20) in observations for which b ≥ . and calculates Pr(20 ≤ y_j ≤ b) elsewhere.

pr(. , b) produces a syntax error. A missing value in an observation of the variable a causes a missing value in that observation for pr(a , b).

xb calculates the linear prediction, which is x_j β if neither offset() nor exposure() was specified; 
x_j β + offset_j β if offset() was specified; or x_j β + ln(exposure_j) if exposure() was specified; see nooffset below.

stdp calculates the standard error of the linear prediction.

nooffset is relevant only if you specified offset() or exposure() when you fit the model. It modifies the calculations made by predict so that they ignore the offset or exposure variable; the linear prediction is treated as x_j β rather than as x_j β + offset_j β or x_j β + ln(exposure_j). Specifying predict ..., nooffset is equivalent to specifying predict ..., ir.

scores calculates equation-level score variables.

The first new variable will contain ∂ln L/∂(x_j β).

The second new variable will contain ∂ln L/∂(z_j γ).

The third new variable will contain ∂ln L/∂ lnα.
margins

Description for margins

margins estimates margins of response for number of events, incidence rates, probabilities, and linear predictions.

Menu for margins

Statistics  >  Postestimation

Syntax for margins

margins [marginlist] [ , options ]
margins [marginlist], predict(statistic ...) [predict(statistic ...)] [ options ]

</tr>
<tr>
<td>stdp</td>
<td>not allowed with margins</td>
</tr>
</tbody>
</table>

Statistics not allowed with margins are functions of stochastic quantities other than $e(b)$.

For the full syntax, see [R] margins.

Methods and formulas

See Methods and formulas in [R] zinb for the model definition and notation.

The probabilities calculated using the $pr(n)$ option are the probability $\Pr(y_j = n)$. These are calculated using

$$
\Pr(y_j = 0|x_j, z_j) = F_j + (1 - F_j) p_2(0|x_j)
$$

$$
\Pr(y_j = n|x_j, z_j) = (1 - F_j) p_2(n|x_j) \quad \text{for } n = 1, 2, \ldots
$$

where $F_j$ is the probability of obtaining an observation from the degenerate distribution whose mass is concentrated at zero, and $p_2(n|x_j)$ is the probability of $y_j = n$ from the nondegenerate, negative binomial distribution. $F_j$ can be obtained by using the $pr$ option.

See Cameron and Trivedi (2013, sec. 4.6) for further details.

[R] zinb — Zero-inflated negative binomial regression

[U] 20 Estimation and postestimation commands
**Title**

| zioprobit — Zero-inflated ordered probit regression |

**Description**

`zioprobit` fits a model for a discrete ordered outcome with a high fraction of zeros, called zero inflation. This model is known as a zero-inflated ordered probit (ZIOP) model. In the context of ZIOP models, zero is an actual 0 value or the lowest outcome category. The ZIOP model accounts for the zero inflation by assuming that the zero-valued outcomes come from both a probit model and an ordered probit model, allowing potentially different sets of covariates for each model.

**Quick start**

Zero-inflated ordered probit model of `y` on `x1` and categorical variable `a` with excess zeros modeled using `x2`

```
    zioprobit y x1 i.a, inflate(x2)
```

Add offset `x3` to the model

```
    zioprobit y x1 i.a, inflate(x2) offset(x3)
```

Model excess zeros using only a constant

```
    zioprobit y x1 i.a, inflate(_cons)
```

Model excess zeros with `x2`, and offset `x5` while suppressing the constant term

```
    zioprobit y x1 i.a, inflate(x2, offset(x5) noconstant)
```

Account for complex sampling design using `svyset` data

```
    svy: zioprobit y x1 i.a, inflate(x2)
```

**Menu**

Statistics > Ordinal outcomes > Zero-inflated ordered probit regression
### Syntax

*`inflate(varlist[, noconstant offset(varname)] | _cons)` is required.

`indepvars` and `varlist` may contain factor variables; see [U 11.4.3 Factor variables].

`bayes`, `bootstrap`, `by`, `fp`, `jackknife`, `rolling`, `statsby`, and `svy` are allowed; see [U 11.1.10 Prefix commands].
For more details, see [BAYES] `bayes: zioprobit`.

Weights are not allowed with the `bootstrap` prefix; see [R] `bootstrap`.

`vce()` and weights are not allowed with the `svy` prefix; see [SVY] `svy`.

`fweights`, `iweights`, and `pweights` are allowed; see [U 11.1.6 weight].

`collinear` and `coeflegend` do not appear in the dialog box.

See [U 20 Estimation and postestimation commands] for more capabilities of estimation commands.

### Options

```
inflate(varlist[, noconstant offset(varname)] | _cons) specifies the equation that determines the excess zero values; this option is required. Conceptually, omitting `inflate()` would be equivalent to fitting the model with `oprobit`; see [R] `oprobit`.

inflate(varlist[, noconstant offset(varname)]) specifies the variables in the equation that determines the excess zeros. To suppress the constant in this equation, specify the `noconstant` suboption. You may optionally include an offset for this `varlist`.
```
inflated(_cons) specifies that the equation determining the excess zero values contains only an intercept. To run a zero-inflated model of depvar with only an intercept in both equations, type ziprobit depvar, inflated(_cons).

offset(varname), constraints(constraints); see [R] Estimation options.

vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim, opg), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.

level(#); see [R] Estimation options.

cno; see [R] Estimation options.

display_options: noci, nopvalues, noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(#), fvwrapon(style), cformat(%,fmt), pformat(%,fmt), sformat(%,fmt), and nolstretch; see [R] Estimation options.

maximize_options: difficult, technique(algorithm_spec), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(init_specs); see [R] Maximize. These options are seldom used.

Setting the optimization type to technique(bhhh) resets the default vcetype to vce(opg).

The following options are available with ziprobit but are not shown in the dialog box:
collinear, coeflegend; see [R] Estimation options.

Remarks and examples

ZIOP models are used when the outcome of interest is an ordered response variable and the data exhibit a high fraction of observations in the lowest category or what we will refer to from now on as “zero” but without quotes. Like the ordered probit model, the actual values taken by the ordered response variable are irrelevant. While the outcome is typically coded as 0, 1, 2, ..., H, ziprobit interprets the lowest value present in the dataset as 0 to be consistent with the original derivation of the model and subsequent applications.

Like all zero-inflated models, the ZIOP model is an alternative when the data exhibit a higher fraction of zero-valued outcomes than is likely compatible with an ordered probit model. This concentration of zeros is referred to as zero inflation. Inflation is assumed to occur in the lowest value to ensure that shifting the levels of the ordered response variable by a constant will not affect the estimated parameters in the model. This is common in ordered probit models; see [R] oprobit.

Without loss of generality, we consider an ordered response variable with levels 0, 1, 2, ..., H. Traditional ordered probit models treat all observations with zero-valued outcomes as a homogeneous group. By contrast, ZIOP models assume that zeros could occur in the data as members of two latent (unobservable) groups. Individuals in the “always-zero” group have outcome 0 as the only possible value. This first group is often called the nonparticipation group. The second group, in addition to 0,
may also assume any of the other values, 1, 2, ..., $H$. This group is often called the participation group. Some disciplines, such as public health and medicine, refer to the process that determines the zeros rather than the groups. In this case, there is an incidence or occurrence process that determines whether an observation belongs to the always-zero group and a severity or intensity process that determines the level in the second group. The result of having two groups or processes is an inflation in the proportion of zero-valued observations in the data.

The ZIOP model has been used in studies of international and domestic conflicts (Bagozzi et al. 2015), sports participation (Downward, Lera-Lopez, and Rasciute 2011), and the adoption of new building technologies (Ganguly, Koebel, and Cantrell 2010), to name a few. See Kelley and Anderson (2008) for a discussion of zero-inflated ordinal models in the context of health.

The classic application of the ZIOP model is the study of tobacco use by Harris and Zhao (2007). Like the zero-inflated Poisson models in the count-data literature (Lambert 1992), Harris and Zhao derived the ZIOP model using a two-stage decision process. An individual must decide whether to participate in an activity (for example, smoking or drug consumption) and, conditional on participating, must decide on the level of participation, which also includes zero participation. The first decision is a binary choice and is modeled using a probit model, while the second is an ordered choice and is modeled using an ordered probit model. In other terms, to account for the excess of zeros, Harris and Zhao allowed for zero observations to occur in two ways: as a realization of the probit model (nonparticipants) and as a realization of the ordered probit model when the binary random variable in the probit model is 1 (participant with zero activity). See Methods and formulas for more details.

For a Bayesian derivation of the ZIOP model, see Gurmu and Dagne (2012).

You may want to check whether a standard ordered probit model is adequate to fit the data. You can do this, for instance, using information criteria; see example 2 in \texttt{R} zip.

Example 1: Zero-inflated ordered probit model

We have fictional data on cigarette consumption per day for 15,000 subjects between ages 14 and 84. The outcome of interest, tobacco, is an ordered discrete response with four levels coded as 0 for “no cigarettes”, 1 for “up to 8 cigarettes/day”, 2 for “8 to 12 cigarettes/day”, and 3 for “more than 12 cigarettes/day”. The exact number of daily consumed cigarettes is unknown.

About 63% of the respondents identified themselves as current nonsmokers. We suspect that these self-identified current nonsmokers belong to one of two groups. Individuals in the first group are genuine nonsmokers (always-zero group) who have never smoked and will never smoke. Individuals in the second group are smokers with no smoking activity who could be the corner solution of a standard consumer demand problem and who may smoke, say, if the price of tobacco falls or their income increases. It is likely that these two types of zeros are driven by different patterns of consumer behavior and a ZIOP model is a good candidate in this case.

We model tobacco consumption levels for subjects who choose to smoke as a function of years of education (education), annual income in tens of thousands of dollars (income), age in tens of years (age), and whether the respondent is a female (female). In addition to education, income, age, and female, the decision to smoke is modeled as a function of whether either of the respondent’s parents smoked (parent) and whether the respondent’s religion discourages smoking (religion). We list all the covariates in the required inflate() option.

In the output table, the first set of coefficients, labeled tobacco, corresponds to the participation (smoking) levels. These coefficients are interpreted in the same way as coefficients from an ordered probit model. The second set of coefficients, labeled inflate, corresponds to the equation for the participation decision. These are interpreted in the same way as coefficients from a binary probit model. ZIOP models do not require the variables to be the same in the participation level and decision equations. However, the same variables can appear in both. If the same variables are included, it is not uncommon for the coefficients to have opposite signs. For example, income and education in the model above have positive signs in the level equation and negative signs in the decision equation.

The estimated coefficients are not particularly informative, and as with all discrete choice models, marginal effects are better to interpret. We use margins to estimate the average marginal effect of
having a smoking parent on the probability of being a genuine nonsmoker. Specifying `pnpar` within the `predict()` option means that we are requesting the predicted probability of nonparticipation, which in our example is equivalent to being a genuine nonsmoker.

```
. margins, predict(pnpar) dydx(parent)
Average marginal effects Number of obs = 15,000
Model VCE : OIM
Expression : Pr(nonparticipation), predict(pnpar)
dy/dx w.r.t. : 1.parent
```

```
Note: dy/dx for factor levels is the discrete change from the base level.
```

On average, individuals whose parents are smokers are about 18% less likely to be nonsmokers themselves than individuals whose parents did not use tobacco. See [R] `zioprobit postestimation` for more information and examples.

### Stored results

`zioprobit` stores the following in `e()`:

**Scalars**
- `e(N)`: number of observations
- `e(N_zero)`: number of zeros or lowest-category observations
- `e(k_cat)`: number of categories
- `e(k)`: number of parameters
- `e(k_eq)`: number of equations in `e(b)`
- `e(k_eq_model)`: number of equations in overall model test
- `e(k_aux)`: number of auxiliary parameters
- `e(k_dv)`: number of dependent variables
- `e(df_m)`: model degrees of freedom
- `e(ll)`: log likelihood
- `e(N_clust)`: number of clusters
- `e(chi2)`: $\chi^2$
- `e(p)`: $p$-value for model test
- `e(rank)`: rank of `e(V)`
- `e(ic)`: number of iterations
- `e(rc)`: return code
- `e(converged)`: 1 if converged, 0 otherwise
Methods and formulas

Consider a discrete ordered response variable \( Y \) with levels coded as 0, 1, 2, \ldots, \( H \). For notational simplicity, we assume that the zeros are inflated, but the following derivation may be adapted to accommodate inflation in the lowest outcome category. Harris and Zhao (2007) derived the ZIOP model in two steps. First, the group membership (participants versus nonparticipants) can be modeled using a probit model. Let \( s_j = 1 \) if the \( j \)th individual belongs to the participation group or let \( s_j = 0 \) otherwise. With the probit model, the probability of participation is given by

\[
\text{Pr}(s_j = 1|z_j) = \Phi(z_j \gamma)
\]

(1)

\( z_j \) is a vector of covariates that determines group membership, \( \gamma \) is a vector of coefficients that have to be estimated, and \( \Phi(\cdot) \) is the standard normal distribution function. Next, conditioning on \( s_j = 1 \), participation levels \( \tilde{y}_j \) are modeled using an ordered probit model; these levels may also include 0. The corresponding probabilities are given by

\[
\text{Pr}(\tilde{y}_j = h|x_j, s_j = 1) = \Phi(\kappa_h - x_j \beta) - \Phi(\kappa_{h-1} - x_j \beta) \quad h = 0, 1, \ldots, H
\]

(2)

where \( \kappa_{-1} = -\infty, \kappa_H = +\infty \), and \( x_j \) is a vector of covariates that could be different from \( z_j \). \( \kappa_h \) are boundary parameters that need to be estimated in addition to the coefficients vector \( \beta \).
The intercept \( \beta_0 \) is set equal to 0 in (2) for identification. Note that \( s_j \) and \( \tilde{y}_j \) are both unobservable in terms of the zeros. The observed response variable is \( y_j = s_j \tilde{y}_j \). Thus, the zero outcome occurs when \( s_j = 0 \) (the individual is not a participant) or occurs when \( s_j = 1 \) and \( \tilde{y}_j = 0 \) (the individual is a participant with zero activity). To observe a positive \( y_j \), it is a joint requirement that \( s_j = 1 \) and \( \tilde{y}_j > 0 \).

The distribution of \( Y \) is given by

\[
\Pr(Y) = \begin{cases} 
\Pr(y_j = 0|z_j, x_j) & h = 1, 2, \ldots, H \\
\Pr(y_j = h|z_j, x_j) & h = 1, 2, \ldots, H - 1 \\
\Pr(y_j = H|z_j, x_j) & h = 1, 2, \ldots, H - 1
\end{cases}
\]

Substituting (1) and (2) in (3), we get

\[
\Pr(Y) = \begin{cases} 
\{1 - \Phi(z_j \gamma)\} + \Phi(z_j \gamma) \Phi(\kappa_0 - x_j \beta) & h = 1, 2, \ldots, H - 1 \\
\Phi(z_j \gamma) \left\{\Phi(\kappa_h - x_j \beta) - \Phi(\kappa_{h-1} - x_j \beta)\right\} & h = 1, 2, \ldots, H - 1
\end{cases}
\]

If the respective offset() option is specified, \( x_j \beta \) and \( z_j \gamma \) are replaced with \( x_j \beta + \text{offset}_j^\beta \) and \( z_j \gamma + \text{offset}_j^\gamma \), respectively.

The log-likelihood function is

\[
\ln L = \sum_{j=1}^{N} w_j \sum_{h=0}^{H} I(y_j = h) \ln \{\Pr(y_j = h|z_j, x_j)\}
\]

where \( w_j \) is an optional weight for the \( j \)th observation and

\[
I(y_j = h) = \begin{cases} 
1 & \text{if } y_j = h \\
0 & \text{otherwise}
\end{cases}
\]

The choice between the ZIOP model and the ordered probit model cannot be made using a likelihood-ratio test because the two hypotheses are not nested in the usual sense of parameter restrictions. The restriction \( \gamma = 0 \) does not eliminate the inflation effect; it makes the group membership probabilities both equal to 0.5 [see (1)]. What is needed to remove the inflation effect is \( z_j \gamma \to \infty \), which cannot be imposed. Because ZIOP and ordered probit models are not nested, you can compare the fits of the two models using information criteria.

zioprobit supports the Huber/White/sandwich estimator of the variance and its clustered version with vce(robust) and vce(cluster clustvar), respectively. See [P] _robust, particularly Maximum likelihood estimators and Methods and formulas.

zioprobit also supports estimation with survey data. For details on VCEs with survey data, see [SVY] Variance estimation.

If you do not specify outcome(), *pmargin* (with one new variable specified) assumes outcome(#1).
You specify one or k new variables with *pmargin*, *pjoint1*, and *pcond1*, where k is the number of outcomes.
You specify one new variable with *ppar*, *pnpar*, *xb*, *xbinfl*, *stdp*, and *stdpinfl*.
These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

Options for predict

<table>
<thead>
<tr>
<th>Main</th>
</tr>
</thead>
<tbody>
<tr>
<td><code>pmargin</code>, the default, calculates the predicted marginal probabilities, Pr(yj = h).</td>
</tr>
<tr>
<td><code>pjoint1</code> calculates the predicted joint probabilities of outcome levels and participation, Pr(yj = h, sj = 1).</td>
</tr>
</tbody>
</table>
pcond1 calculates the predicted probabilities of outcome levels conditional on participation, \( Pr(y_j = h | s_j = 1) \).

With pmargin, pjoint1, and pcond1, you can compute predicted probabilities for one or for all outcome levels. When you specify one new variable, predict computes probabilities for the first outcome level. You can specify the outcome(#k) option to obtain probabilities for the \( k \)th level. When you specify multiple new variables or a stub, predict computes probabilities for all outcome levels. The behavior of predict with one new variable is equivalent to specifying outcome(#1).

ppar calculates the predicted marginal probability of participation, \( Pr(s_j = 1) \).

pnpar calculates the predicted marginal probability of nonparticipation, \( Pr(s_j = 0) \).

xb calculates the linear prediction for the regression equation, which is \( x_j \beta \) if offset() was not specified with zioprobit and is \( x_j \beta + \text{offset}_j \beta \) if offset() was specified.

xbinfl calculates the linear prediction for the inflation equation, which is \( z_j \gamma \) if offset() was not specified in inflate() and is \( z_j \gamma + \text{offset}_j \gamma \) if offset() was specified in inflate().

stdp calculates the standard error of the linear prediction for the regression equation.

stdpfinfl calculates the standard error of the linear prediction for the inflation equation.

outcome(outcome) specifies the outcome for which predicted probabilities are to be calculated. outcome() should contain either one value of the dependent variable or one of \#1, \#2, ..., with \#1 meaning the first category of the dependent variable, \#2 meaning the second category, etc.

outcome() is allowed only with pmargin, pjoint1, and pcond1.

nooffset is relevant only if you specified offset(varname) with zioprobit or within the inflate() option. It modifies the calculations made by predict so that they ignore the offset variable; for example, the linear prediction for the regression equation is treated as \( x_j \beta \) rather than as \( x_j \beta + \text{offset}_j \beta \).

scores calculates equation-level score variables.

The first new variable, newvar_{reg}, will contain \( \partial \ln L / \partial (x_j \beta) \).

The second new variable, newvar_{infl}, will contain \( \partial \ln L / \partial (z_j \gamma) \).

When the dependent variable takes \( k \) different values, the third new variable through new variable \( k + 1 \) will contain \( \partial \ln L / \partial (\kappa_h) \) for \( h = 0, 1, \ldots, k - 2 \).
margins

Description for margins

margins estimates margins of response for probabilities and linear predictions.

Menu for margins

Statistics  >  Postestimation

Syntax for margins

margins [marginlist] [ , options ]
margins [marginlist] , predict(statistic ...) [predict(statistic ...) ...] [options ]

<table>
<thead>
<tr>

<td>not allowed with margins</td>
</tr>
</tbody>
</table>

pmargin, pjoint1, and pcond1 default to the first outcome.

Statistics not allowed with margins are functions of stochastic quantities other than e(b).

For the full syntax, see [R] margins.
Remarks and examples

Various sets of predictions and marginal effects may be of interest for the ZIOP model. For instance, we may want to investigate the marginal effects of a covariate on the probability of participation, or on the probabilities for levels of consumption conditional on participation, or on the overall probabilities for different consumption levels. We explore these options in greater detail in the following examples.

Example 1: Average marginal effects on probability of nonparticipation

In example 1 of [R] zioprobit, we fit a model for level of cigarette consumption.

```
. use https://www.stata-press.com/data/r16/tobacco
  (Fictional tobacco consumption data)
. zioprobit tobacco education income i.female age,
   inflate(education income i.parent age i.female i.religion)
  (output omitted)
```

We can use margins to estimate the expected marginal effect of gender for individuals with a college degree (17 years of education) and a smoking parent on the probability of nonparticipation (being a genuine nonsmoker). To do this, we specify predict(pnpar) with margins as follows:

```
. margins, predict(pnpar) dydx(female) at(education = 17 parent = 1)
```

Average marginal effects

```
Model VCE : OIM
Expression : Pr(nonparticipation), predict(pnpar)
dy/dx w.r.t. : 1.female
at : education = 17
     parent = 1
```

<table>
<thead>
<tr>
<th></th>
<th>Delta-method</th>
<th></th>
<th></th>
<th></th>
<th></th>
</tr>
</thead>
<tbody>
<tr>
<td></td>
<td>dy/dx</td>
<td>Std. Err.</td>
<td>z</td>
<td>P&gt;</td>
<td>z</td>
</tr>
<tr>
<td>female</td>
<td>.0855995</td>
<td>.0100239</td>
<td>8.54</td>
<td>.000</td>
<td>.0659531</td>
</tr>
</tbody>
</table>

Women with a college degree and a smoking parent are expected to have about an 8.5% higher chance of being genuine nonsmokers than do men.

Example 2: Predicted probabilities of zero-valued outcomes

In example 1 of [R] zioprobit, we found that the coefficient on income was positive in the level equation but negative in the participation equation. In the case of our tobacco consumption example, economic theory offers a reasonable interpretation for this. Higher income may act as an indicator for health awareness, which accounts for its association with an increased probability of being a genuine nonsmoker. However, if cigarettes are a normal good—that is, something for which demand increases when income increases—then smokers with higher income should have a lower probability of having zero consumption at the time of the survey.

We first consider the effect of income at six prespecified values ranging from $10,000 to $60,000 on the probability of being a genuine nonsmoker (nonparticipation). Because we know the values 1 to 6 correspond to income in tens of thousands, we conserve space and suppress the default legend by using the noatlegend option.
. margins, predict(pnpar) at(income = (1/6)) noatlegend

Predictive margins
Number of obs = 15,000

</tr>
</tbody>
</table>

The probability of being a genuine nonsmoker increases with income. For instance, for individuals who earn $10,000 a year, the expected increase in the probability of being a genuine nonsmoker is about \((0.1945 - 0.1728) \times 100\% = 2.17\%\) if they earn an additional $10,000.

We next investigate the effect of income on the joint probability of being a smoker (participation equals 1) with zero consumption. We do this by specifying `predict(pjoint1 outcome(0))` with `margins`:

. margins, predict(pjoint1 outcome(0)) at(income = (1/6)) noatlegend

Predictive margins
Number of obs = 15,000
Model VCE : OIM
Expression : Pr(tobacco=0, participation=1), predict(pjoint1 outcome(0))

<td>.2929155</td>
<td>.00317</td>
<td>92.40</td>
<td>0.000</td>
<td>.2867023</td>
</tr>
</tbody>
</table>

For individuals who are smokers, the probability of zero consumption decreases as income increases, suggesting that tobacco is like a normal good for smokers. For example, for individuals who earn $10,000 a year, earning an additional $10,000 will decrease their probability of being a smoker with zero consumption by about \((0.5595 - 0.5080) \times 100\% = 5.15\%\).

If we wanted to compute the effect of income on the overall probability of zero consumption instead of the probability of zero consumption among smokers, we would omit `pjoint1` from within the `predict` option.

. margins, predict(outcome(0)) at(income = (1/6)) noatlegend

(output omitted)

This version of the `margins` command gives the sum of the probability of nonparticipation and the joint probability of participation with zero consumption.
Methods and formulas

The participation equation is

\[ s_j = I(z_j \gamma + u_{1j} > 0) \quad j = 1, 2, \ldots, n \]

where \( s_j \) is 1 if the \( j \)th subject belongs to the participation group (for example, smokers) and is 0 if the subject belongs to the nonparticipation group (for example, genuine nonsmokers), \( z_j \) are the covariates used to model the group membership, \( \gamma \) is a vector of coefficients, and \( u_{1j} \) is a random-error term following a standard normal distribution.

The ordinal outcome equation is

\[ \tilde{y}_j = \sum_{h=0}^{H} h I(\kappa_{h-1} < x_j \beta + u_{2j} \leq \kappa_h) \]

where \( \tilde{y}_j \) is the ordinal outcome conditional on participation, \( x_j \) are the outcome covariates, \( \beta \) are the coefficients, and \( u_{2j} \) is a random-error term following a standard normal distribution. The observed outcome values are \( 0, 1, \ldots, H \). \( \kappa_0, \kappa_1, \ldots, \kappa_{H-1} \) are real numbers such that \( \kappa_i < \kappa_m \) for \( i < m \). \( \kappa_{-1} \) is taken as \(-\infty\) and \( \kappa_H \) is taken as \(+\infty\). We assume that the error terms \( u_{1j} \) and \( u_{2j} \) are independent. We observe \( y_j = s_j \tilde{y}_j \).

The probability of participation is

\[ \Pr(s_j = 1|z_j) = \Phi(z_j \gamma) \tag{1} \]

where \( \Phi(\cdot) \) is the standard normal distribution function.

The probability of nonparticipation is

\[ \Pr(s_j = 0|z_j) = 1 - \Phi(z_j \gamma) \tag{2} \]

The probability of outcome \( y_j = h \) given that the \( j \)th subject belongs to the participation group is

\[ \Pr(y_j = h|s_j = 1, x_j) = \Pr(\tilde{y}_j = h|x_j) = \Phi(\kappa_h - x_j \beta) - \Phi(\kappa_{h-1} - x_j \beta) \tag{3} \]

for \( h = 0, 1, \ldots, H \), where \( \Phi(\kappa_{-1} - x_j \beta) = 0 \) and \( \Phi(\kappa_H - x_j \beta) = 1 \).

The joint probability of outcome \( y_j = h \) and participation can be expressed as

\[ \Pr(y_j = h, s_j = 1|z_j, x_j) = \Pr(s_j = 1|z_j) \Pr(y_j = h|s_j = 1, x_j) \]

for \( h = 0, 1, \ldots, H \), and computed using (1) and (3).

The marginal probabilities of the outcome \( y_j \) are

\[ \Pr(y_j = 0|z_j, x_j) = \Pr(s_j = 0|z_j) + \Pr(s_j = 1|z_j) \Pr(\tilde{y}_j = 0|x_j) \]

\[ \Pr(y_j = h|z_j, x_j) = \Pr(s_j = 1|z_j) \Pr(\tilde{y}_j = h|x_j) \quad h = 1, 2, \ldots, H - 1 \]

\[ \Pr(y_j = H|z_j, x_j) = \Pr(s_j = 1|z_j) \Pr(\tilde{y}_j = H|x_j) \]

and can be computed using (1), (2), and (3).

If the \texttt{offset()} option is specified with \texttt{zioprobit}, \( x_j \beta \) is replaced with \( x_j \beta + \text{offset}_j^\beta \). If the \texttt{offset()} option is specified within the \texttt{inflate()} option, \( z_j \gamma \) is replaced with \( z_j \gamma + \text{offset}_j^\gamma \).

Also see

[R] \texttt{zioprobit} — Zero-inflated ordered probit regression

[U] 20 Estimation and postestimation commands
Description

zip fits a zero-inflated Poisson (ZIP) model to count data with excess zero counts. The ZIP model assumes that the excess zero counts come from a logit or probit model and the remaining counts come from a Poisson model.

Quick start

Zero-inflated Poisson model of \( y \) on \( x_1 \) and \( x_2 \) with inflation modeled using \( x_3 \)

\[
\text{zip } y \ x_1 \ x_2, \text{ inflate}(x_3)
\]

Use a probit model instead of a logit model to predict excess zeros

\[
\text{zip } y \ x_1 \ x_2, \text{ inflate}(x_3) \text{ probit}
\]

Menu

Statistics > Count outcomes > Zero-inflated Poisson regression

`zip depvar [ indepvars ] [ if ] [ in ] [ weight ] ,

    inflate(varlist[, offset(varname) ]|_cons) [ options ]

options                  Description

Model

* `inflate()`                     equation that determines whether the count is zero
  `noconstant`                   suppress constant term
  `exposure(varname_e)`          include ln(varname_e) in model with coefficient constrained to 1
  `offset(varname_o)`            include varname_o in model with coefficient constrained to 1
  `constraints(constraints)`     apply specified linear constraints
  `probit`                       use probit model to characterize excess zeros; default is logit

SE/Robust

`vce(vcetype)`               vcetype may be oim, robust, cluster clustvar, opg, bootstrap, or jackknife

Reporting

`level(#)`                   set confidence level; default is level(95)
`irr`                        report incidence-rate ratios
`nocsnsreport`               do not display constraints
`display_options`           control columns and column formats, row spacing, line width, display of omitted variables and base and empty cells, and factor-variable labeling

Maximization

`maximize_options`           control the maximization process; seldom used

`collinear`                   keep collinear variables
`coeflegend`                 display legend instead of statistics

*`inflate(varlist[, offset(varname) ]|_cons)` is required.

indepvars and varlist may contain factor variables; see [U] 11.4.3 Factor variables.
bayes, bootstrap, by, fp, jackknife, rolling, statsby, and svy are allowed; see [U] 11.1.10 Prefix commands.
For more details, see [BAYES] bayes: zip.

Weights are not allowed with the bootstrap prefix; see [R] bootstrap.
vce() and weights are not allowed with the svy prefix; see [SVY] svy.
fweight, iweight, and pweight are allowed; see [U] 11.1.6 weight.
collinear and coeflegend do not appear in the dialog box.
See [U] 20 Estimation and postestimation commands for more capabilities of estimation commands.

Options

`inflate(varlist[, offset(varname) ]|_cons)` specifies the equation that determines whether the observed count is zero. Conceptually, omitting `inflate()` would be equivalent to fitting the model with poisson; see [R] poisson.
inflatable(varlist[, offset(varname)]) specifies the variables in the equation. You may optionally include an offset for this varlist.

inflatable(_cons) specifies that the equation determining whether the count is zero contains only an intercept. To run a zero-inflated model of depvar with only an intercept in both equations, type zip depvar, inflate(_cons).

noconstant, exposure(varname_e), offset(varname_o), constraints(constraints); see [R] Estimation options.

probit requests that a probit, instead of logit, model be used to characterize the excess zeros in the data.

vce(vcetype) specifies the type of standard error reported, which includes types that are derived from asymptotic theory (oim, opg), that are robust to some kinds of misspecification (robust), that allow for intragroup correlation (cluster clustvar), and that use bootstrap or jackknife methods (bootstrap, jackknife); see [R] vce_option.

level(#); see [R] Estimation options.

irr reports estimated coefficients transformed to incidence-rate ratios, that is, \(e^b\) rather than \(b\). Standard errors and confidence intervals are similarly transformed. This option affects how results are displayed, not how they are estimated or stored. irr may be specified at estimation or when replaying previously estimated results.

nocnsreport; see [R] Estimation options.

display_options: noci, nopvalues, noomitted, vsquish, noemptycells, baselevels, allbaselevels, nofvlabel, fvwrap(#), fvwrapon(style), cformat(%fmt), pformat(%fmt), sformat(%fmt), and nolstretch; see [R] Estimation options.

maximize_options: difficult, technique(algorithm_spec), iterate(#), [no]log, trace, gradient, showstep, hessian, showtolerance, tolerance(#), ltolerance(#), nrtolerance(#), nonrtolerance, and from(init_specs); see [R] Maximize. These options are seldom used.

Setting the optimization type to technique(bhhh) resets the default vcetype to vce(opg).

The following options are available with zip but are not shown in the dialog box:
collinear, coeflegend; see [R] Estimation options.

Remarks and examples

Zero-inflated Poisson (ZIP) models address the case when the data contain a higher fraction of zeros than is likely to be generated from a Poisson model. Having a large proportion of zero observations, in itself, does not necessarily mean that we have the excess zeros problem. For instance, a Poisson model with a mean value of 0.2 predicts that \(P(Y = 0) = \exp(-0.2) \approx 0.82\). However, the range of possible outcomes is restricted because of the small variance, 0.2 (mean and variance are equal for a Poisson model), as shown by \(P(Y > 3) \approx 0.00006\). Unlike Poisson models, ZIP models allow us to have a large fraction of zeros without restricting the range of outcomes.
ZIP models assume that an observation is 0 with a probability $p$ or is a realization of a Poisson random variable, which can also be 0, with a probability $1 - p$. For instance, you might count how many fish each visitor to a park catches. Many visitors may catch zero, because they do not fish (as opposed to being unsuccessful). Using a logit or probit model, you may model the probability $p$ of whether a person does not fish depending on several covariates related to fishing. Using a Poisson distribution, you may model how many fish a person catches depending on several covariates having to do with the success of catching fish (type of lure or bait, time of day, temperature, season, etc.). This is the type of data for which the `zip` command is useful.

### Example 1: Fitting a ZIP model

We have fictional data on the number of fish caught (`count`) by visitors to a national park on a particular day. Some of the visitors do not fish, but we do not have the data on whether a person fished; we merely have data on how many fish were caught together with several covariates.

Variable `count` exhibits an excess of zero observations (142 of 250 observations), beyond what would be expected from a Poisson model. We suspect that the number of zeros may be inflated because many visitors are not fishing. That is, a zero observation may be the result of a visitor who was unfortunate and caught no fish but may also be because the visitor did not fish. A standard Poisson model (see `[R] poisson`) treats these two types of zero observations as a homogeneous group, which typically leads to biased statistical results. We would like to distinguish between the two types of zeros and possibly draw inference for them separately (see example 1 in `[R] zip postestimation`).

The `zip` command allows us to model the two types of zeros. First, using the required option `inflate()`, we model whether a visitor fishes as a function of the number of children accompanying him or her (`child`) and whether he or she is camping (`camper`). Next, we assume the response variable, `count`, depends on whether the visitor used a live bait (`livebait`) and the number of persons (`persons`), which includes the visitor and any adults or children accompanying him. Note that `persons` is always greater than `child`. 
. use https://www.stata-press.com/data/r16/fish
(Fictional fishing data)
. zip count persons livebait, inflate(child camper)

Fitting constant-only model:
Iteration 0:  log likelihood =  -1347.807
Iteration 1:  log likelihood =  -1305.3245
Iteration 2:  log likelihood =  -1104.3005
Iteration 3:  log likelihood =  -1103.9426
Iteration 4:  log likelihood =  -1103.9425

Fitting full model:
Iteration 0:  log likelihood =  -1103.9425
Iteration 1:  log likelihood =  -896.2346
Iteration 2:  log likelihood =  -851.61723
Iteration 3:  log likelihood =  -850.70435
Iteration 4:  log likelihood =  -850.70142
Iteration 5:  log likelihood =  -850.70142

Zero-inflated Poisson regression
Number of obs = 250
Nonzero obs = 108
Zero obs = 142

Inflation model = logit
LR chi2(2) = 506.48
Log likelihood = -850.7014 Prob > chi2 = 0.0000

| count                      | Coef.  | Std. Err. | z     | P>|z| | [95% Conf. Interval] |
|----------------------------|--------|-----------|-------|-----|----------------------|
| persons                   | .8068853 | .0453288  | 17.80 | 0.000 | .7180424 - .8957281  |
| livebait                  | 1.757289 | .2446082  | 7.18  | 0.000 | 1.277866 - 2.236713  |
| _cons                     | -2.178472 | .2860289  | -7.62 | 0.000 | -2.739078 - -1.617865 |

| inflate                   | Coef.  | Std. Err. | z     | P>|z| | [95% Conf. Interval] |
|----------------------------|--------|-----------|-------|-----|----------------------|
| child                     | 1.602571 | .2797719  | 5.73  | 0.000 | 1.054228 - 2.150913  |
| camper                    | -1.015698 | .365259   | -2.78 | 0.005 | -1.731593 - -0.2998038 |
| _cons                     | -.4922872 | .3114562  | -1.58 | 0.114 | -1.10273 - 0.1181558 |

Coefficients in the upper half of the table correspond to the Poisson model for individuals who fished. For instance, among visitors who fished, using a live bait increases the expected number of caught fish by a factor of $\exp(1.7572) \approx 5.8$, holding other covariates constant.

Example 2: Comparing model fit

When you have count data, you may want to test whether a conventional count data model or a zero-inflated count data model is preferable. The classical likelihood-ratio test cannot be used here because the models are not nested. But we can use information criteria such as the AIC and BIC to check whether the standard or zero-inflated model is more appropriate.

Continuing with our fishing example, let’s check whether the standard Poisson or ZIP model is more appropriate for our data. First, we store the estimation results from the previous ZIP model by typing

. estimates store zip
Next, we fit the Poisson model corresponding to the main equation of the ZIP model and store its results as `pois`:

```
. poisson count persons livebait
(output omitted)
. estimates store pois
```

We use `estimates stats` to display the AIC and BIC values for the two models.

```
. estimates stats pois zip
```

### Akaike’s information criterion and Bayesian information criterion

<table>
<thead>
<tr>
<th>Model</th>
<th>N</th>
<th>ll(null)</th>
<th>ll(model)</th>
<th>df</th>
<th>AIC</th>
<th>BIC</th>
</tr>
</thead>
<tbody>
<tr>
<td>pois</td>
<td>250</td>
<td>-1647.716</td>
<td>-1312.178</td>
<td>3</td>
<td>2630.356</td>
<td>2640.92</td>
</tr>
<tr>
<td>zip</td>
<td>250</td>
<td>-1103.942</td>
<td>-850.7014</td>
<td>6</td>
<td>1713.403</td>
<td>1734.532</td>
</tr>
</tbody>
</table>

Note: BIC uses N = number of observations. See [R] BIC note.

The ZIP model has smaller AIC and BIC values; we thus conclude that it fits our data better than the standard Poisson model.

### Stored results

`zip` stores the following in `e()`:

**Scalars**

- `e(N)`: number of observations
- `e(N_zero)`: number of zero observations
- `e(k)`: number of parameters
- `e(k_eq)`: number of equations in `e(b)`
- `e(k_eq_model)`: number of equations in overall model test
- `e(k_dv)`: number of dependent variables
- `e(df_m)`: model degrees of freedom
- `e(ll)`: log likelihood
- `e(ll_0)`: log likelihood, constant-only model
- `e(N_clust)`: number of clusters
- `e(chi2)`: \( \chi^2 \) test
- `e(p)`: \( p \)-value for model test
- `e(rank)`: rank of `e(V)`
- `e(ic)`: number of iterations
- `e(rc)`: return code
- `e(converged)`: 1 if converged, 0 otherwise

**Macros**

- `e(cmd)`: `zip`
- `e(cmdline)`: command as typed
- `e(depvar)`: name of dependent variable
- `e(inflate)`: logit or probit
- `e(wtype)`: weight type
- `e(wexp)`: weight expression
- `e(title)`: title in estimation output
- `e(clustvar)`: name of cluster variable
- `e(offset1)`: offset
- `e(offset2)`: offset for `inflate()`
- `e(chi2type)`: Wald or LR; type of model \( \chi^2 \) test
- `e(vce)`: vcetype specified in `vce()`
- `e(vcetype)`: title used to label Std. Err.
- `e(opt)`: type of optimization
Methods and formulas

Consider the formulation of a zero-inflated model as presented in Lambert (1992). Define

$$
\xi_j^\beta = x_j \beta + \text{offset}_j^\beta \\
\xi_j^\gamma = z_j \gamma + \text{offset}_j^\gamma \\
\lambda_j = \exp \left( \xi_j^\beta \right) \\
F_j = F \left( \xi_j^\gamma \right)
$$

where $F(\cdot)$ is the inverse of the logit function or, if the `probit` option was specified, the inverse of the probit function (or the standard normal cumulative distribution function). All subjects are assumed to be independent with the $j$th response determined as follows:

$$
Y_j = 0 \quad \text{with probability } F_j \\
Y_j \sim \text{Poisson} \left( \lambda_j \right) \quad \text{with probability } 1 - F_j
$$

In other words,

$$
\Pr(Y_j = 0|x_j, z_j) = F_j + (1 - F_j) \exp(-\lambda_j) \\
\Pr(Y_j = n|x_j, z_j) = (1 - F_j) \exp(-\lambda_j) \frac{\lambda_j^n}{n!} \quad \text{for } n = 1, 2, \ldots
$$

The `zip` command maximizes the log-likelihood $\ln L$, defined by

$$
\ln L = \sum_{j \in S} w_j \ln \left\{ F_j + (1 - F_j) \exp(-\lambda_j) \right\} \\
+ \sum_{j \not\in S} w_j \left\{ \ln(1 - F_j) - \lambda_j + \xi_j y_j - \ln(y_j!) \right\}
$$

where $w_j$ are the weights and $S$ is the set of observations for which the observed outcome $y_j = 0$. 
This command supports the Huber/White/sandwich estimator of the variance and its clustered version using \texttt{vce(robust)} and \texttt{vce(cluster clustvar)}, respectively. See \texttt{[P] \_robust}, particularly \textit{Maximum likelihood estimators} and \textit{Methods and formulas}.

\texttt{zip} also supports estimation with survey data. For details on VCEs with survey data, see \texttt{[SVY] Variance estimation}.

</tbody>
</table>

* `forecast`, `hausman`, and `lrtest` are not appropriate with `svy` estimation results.
predict

Description for predict

predict creates a new variable containing predictions such as numbers of events, incidence rates, probabilities, linear predictions, and standard errors.

Menu for predict

Statistics  >  Postestimation

Syntax for predict

```
predict [type] newvar [if] [in] [, statistic nooffset]
```

```
predict [type] { stub* | newvar_reg newvar_inflate } [if] [in] , scores
```

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Main</strong></td>
<td></td>
</tr>
<tr>
<td>n</td>
<td>number of events; the default</td>
</tr>
<tr>
<td>ir</td>
<td>incidence rate</td>
</tr>
<tr>
<td>pr</td>
<td>probability of a degenerate zero</td>
</tr>
<tr>
<td>pr(n)</td>
<td>probability $Pr(y_j = n)$</td>
</tr>
<tr>
<td>pr(a,b)</td>
<td>probability $Pr(a \leq y_j \leq b)$</td>
</tr>
<tr>
<td>xb</td>
<td>linear prediction</td>
</tr>
<tr>
<td>stdp</td>
<td>standard error of the linear prediction</td>
</tr>
</tbody>
</table>

These statistics are available both in and out of sample; type `predict ... if e(sample) ...` if wanted only for the estimation sample.

Options for predict

| n, the default, calculates the predicted number of events, which is $(1 - F_j)\exp(x_j\beta)$ if neither `offset()` nor `exposure()` was specified when the model was fit, where $F_j$ is the predicted probability of a zero outcome; $(1 - F_j)\exp(x_j\beta + \text{offset}_j\gamma)$ if `offset()` was specified; or $(1 - F_j)\{\exp(x_j\beta) \times \text{exposure}_j\}$ if `exposure()` was specified. |
| --- | --- |
| ir calculates the incidence rate, which is the predicted number of events when exposure is 1. This is equivalent to specifying both the n and the nooffset options. |
| pr calculates the probability of a degenerate zero, predicted from the fitted degenerate distribution $F_j = F(z_j\gamma)$. If `offset()` was specified within the inflate() option, then $F_j = F(z_j\gamma + \text{offset}_j\gamma)$ is calculated. |
| pr(n) calculates the probability $Pr(y_j = n)$, where n is a nonnegative integer that may be specified as a number or a variable. Note that pr is not equivalent to pr(0). |
| pr(a,b) calculates the probability $Pr(a \leq y_j \leq b)$, where a and b are nonnegative integers that may be specified as numbers or variables; |
$b$ missing ($b \geq .$) means $+\infty$;
$\text{pr}(20,.)$ calculates $\Pr(y_j \geq 20)$;
$\text{pr}(20,b)$ calculates $\Pr(y_j \geq 20)$ in observations for which $b \geq .$ and calculates $\Pr(20 \leq y_j \leq b)$ elsewhere.
$\text{pr}(.,b)$ produces a syntax error. A missing value in an observation of the variable $a$ causes a missing value in that observation for $\text{pr}(a,b)$.

$\text{xb}$ calculates the linear prediction, which is $x_j \beta$ if neither $\text{offset()}$ nor $\text{exposure()}$ was specified;
$x_j \beta + \text{offset}_j \beta$ if $\text{offset()}$ was specified; or $x_j \beta + \ln(\text{exposure}_j)$ if $\text{exposure()}$ was specified; see \text{nooffset} below.

$\text{stdp}$ calculates the standard error of the linear prediction.
$\text{nooffset}$ is relevant only if you specified $\text{offset()}$ or $\text{exposure()}$ when you fit the model. It modifies the calculations made by $\text{predict}$ so that they ignore the offset or exposure variable; the linear prediction is treated as $x_j \beta$ rather than as $x_j \beta + \text{offset}_j \beta$ or $x_j \beta + \ln(\text{exposure}_j)$. Specifying $\text{predict ... nooffset}$ is equivalent to specifying $\text{predict ... ir}$.

$\text{scores}$ calculates equation-level score variables.

The first new variable will contain $\partial \ln L / \partial (x_j \beta)$.

The second new variable will contain $\partial \ln L / \partial (z_j \gamma)$. 
margins

Description for margins

margins estimates margins of response for the numbers of events, incidence rates, probabilities, and linear predictions.

Menu for margins

Statistics > Postestimation

Syntax for margins

margins [marginlist] [ , options ]

margins [marginlist] , predict(statistic ...) [predict(statistic ...) ...] [options]

<table>
<thead>
<tr>
<th>statistic</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>n</td>
<td>number of events; the default</td>
</tr>
<tr>
<td>ir</td>
<td>incidence rate</td>
</tr>
<tr>
<td>pr</td>
<td>probability of a degenerate zero</td>
</tr>
<tr>
<td>pr(n)</td>
<td>probability Pr(yj = n)</td>
</tr>
<tr>
<td>pr(a,b)</td>
<td>probability Pr(a ≤ yj ≤ b)</td>
</tr>
<tr>
<td>xb</td>
<td>linear prediction</td>
</tr>
<tr>
<td>stdp</td>
<td>not allowed with margins</td>
</tr>
</tbody>
</table>

Statistics not allowed with margins are functions of stochastic quantities other than e(b).

For the full syntax, see [R] margins.

Remarks and examples

Example 1: Obtaining predicted counts

Continuing with example 1 from [R] zip, we will use predict to compute the predicted number of fish captured by each individual.

. use https://www.stata-press.com/data/r16/fish
. zip count persons livebait, inflate(child camper)
(output omitted)
. predict numfish, n
(option n assumed; predicted number of events)
. summarize numfish

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Dev.</th>
<th>Min</th>
<th>Max</th>
</tr>
</thead>
<tbody>
<tr>
<td>numfish</td>
<td>250</td>
<td>2.770999</td>
<td>3.269588</td>
<td>.079269</td>
<td>13.55015</td>
</tr>
</tbody>
</table>
The average predicted number of fish caught by all visitors, regardless of whether or not they fished, is 2.77 fish.

Example 2: Obtaining predicted probabilities

```
predict with the pr option computes the probability that an individual does not fish.
.predict pr, pr
```

On the other hand, `predict` with the `pr(n)` option computes the probability of catching \( n \) fish; particularly, the probability of catching zero fish will be

```
.predict pr0, pr(0)
.list pr pr0 in 1
```

<table>
<thead>
<tr>
<th>pr</th>
<th>pr0</th>
</tr>
</thead>
<tbody>
<tr>
<td>.3793549</td>
<td>.8609267</td>
</tr>
</tbody>
</table>

Notice that \( pr0 \) is always equal to or greater than \( pr \). For example, for the first individual, the probability of not fishing is 0.38; on the other hand, the probability of catching zero fish (0.86) is equal to the sum of the probability of not fishing and the probability of fishing but not catching any fish. \( pr0 \) can be also computed as one minus the probability of catching at least one fish, that is:

```
.predict pr_catch, pr(1,.)
gen pr0b = 1-pr_catch
```

Methods and formulas

See Methods and formulas in [R] zip for the model definition and notation.

The probabilities calculated using the `pr(n)` option are the probability \( \Pr(y_{ij} = n) \). These are calculated using

\[
\Pr(y_{ij} = 0|x_j, z_j) = F_j + (1 - F_j) \exp(-\lambda_j)
\]

\[
\Pr(y_{ij} = n|x_j, z_j) = (1 - F_j) \frac{\lambda_j^n \exp(-\lambda_j)}{n!}
\]

for \( n = 1, 2, \ldots \)

where \( F_j \) is the probability of obtaining an observation from the degenerate distribution whose mass is concentrated at zero. \( F_j \) can be obtained by using the `pr` option.

See Cameron and Trivedi (2013, sec. 4.6) for further details.

References

[R] zip — Zero-inflated Poisson regression

[U] 20 Estimation and postestimation commands
**Description**

`ztest` performs z tests on the equality of means, assuming known variances. The test can be performed for one sample against a hypothesized population value or for no difference in population means estimated from two samples. Two-sample tests can be conducted for paired and unpaired data. Clustered data are also supported.

`ztesti` is the immediate form of `ztest`; see [U] 19 Immediate commands.

For the comparison of means when variances are unknown, use `ttest`; see [R] ttest.

**Quick start**

One-sample test that the mean of v1 is 3 at the 90% confidence level

```
ztest v1 == 3, level(90)
```

As above, and adjust for clustering with clusters defined by `cvar` and an intraclass correlation of 0.5

```
ztest v1 == 3, level(90) cluster(cvar) rho(0.5)
```

Unpaired z test that the mean of v1 is equal between two groups defined by `catvar`

```
ztest v1, by(catvar)
```

As above, and adjust for clustering with clusters defined by `cvar` and an intraclass correlation of 0.5 in the two groups

```
ztest v1, by(catvar) cluster(cvar) rho(0.5)
```

Unpaired test of equality of the means of v2 and v3

```
ztest v2 == v3, unpaired
```

Paired test of equality of the means of v2 and v3 with standard deviation of the differences between paired observations of 2.4

```
ztest v2 == v3, sddiff(2.4)
```

As above, specified using a common standard deviation of 2 and correlation between observations of 0.28

```
ztest v2 == v3, sd(2) corr(0.28)
```

Immediate form unpaired test of $\mu_1 = \mu_2$ if $\bar{x}_1 = 3.2$, $sd_1 = 0.1$, $\bar{x}_2 = 3.4$, and $sd_2 = 0.15$ with $n_1 = n_2 = 120$

```
ztesti 120 3.2 0.1 120 3.4 0.15
```

`twosamplegropts` | Description
--- | ---

**Main**

* by(*`groupvar`*) | variable defining the groups
unpaired | unpaired test; implied when by() is specified
sd(#) | two-population common standard deviation; default is `sd(1)`
sd1(#) | standard deviation of the first population; requires `sd2()` and may not be combined with `sd()`
sd2(#) | standard deviation of the second population; requires `sd1()` and may not be combined with `sd()`
level(#) | confidence level; default is `level(95)`
cluster(*`varname`*) | variable defining the clusters
rho(#) | common intraclass correlation
rho1(#) | intraclass correlation for group 1
rho2(#) | intraclass correlation for group 2

*by(*`groupvar`*) is required.

| `twosamplevaropts` | Description |
--- | --- |

**Main**

* unpaired | unpaired test
sd(#) | two-population common standard deviation; default is `sd(1)`
sd1(#) | standard deviation of the first population; requires `sd2()` and may not be combined with `sd()`
sd2(#) | standard deviation of the second population; requires `sd1()` and may not be combined with `sd()`
level(#) | confidence level; default is `level(95)`

*unpaired is required.

| `pairedopts` | Description |
--- | --- |

**Main**

* corr(#) | correlation between paired observations
sd(#) | two-population common standard deviation; default is `sd(1)`; may not be combined with `sd1()`, `sd2()`, or `sddiff()`
sd1(#) | standard deviation of the first population; requires `corr()` and `sd2()` and may not be combined with `sd()` or `sddiff()`
sd2(#) | standard deviation of the second population; requires `corr()` and `sd1()` and may not be combined with `sd()` or `sddiff()`
level(#) | confidence level; default is `level(95)`

*corr(#) is required.

by is allowed with ztest; see [D] by.
by\( (\text{groupvar}) \) specifies the groupvar that defines the two groups that \texttt{ztest} will use to test the hypothesis that their means are equal. Specifying by\( (\text{groupvar}) \) implies an unpaired (two-sample) \( z \) test. Do not confuse the by() option with the by prefix; you can specify both.

unpaired specifies that the data be treated as unpaired. The unpaired option is used when the two sets of values to be compared are in different variables.

\texttt{sddiff(\#)} specifies the population standard deviation of the differences between paired observations for a paired \( z \) test. For this kind of test, either sddiff() or corr() must be specified.

\texttt{corr(\#)} specifies the correlation between paired observations for a paired \( z \) test. This option along with sd1() and sd2() or with sd() is used to compute the standard deviation of the differences between paired observations unless that standard deviation is supplied directly in the sddiff() option. For a paired \( z \) test, either sddiff() or corr() must be specified.

\texttt{sd(\#)} specifies the population standard deviation for a one-sample \( z \) test or the common population standard deviation for a two-sample \( z \) test. The default is \texttt{sd(1)}. \texttt{sd()} may not be combined with sd1(), sd2(), or sddiff().

\texttt{sd1(\#)} specifies the standard deviation of the first population or group. When \texttt{sd1()} is specified with by\( (\text{groupvar}) \), the first group is defined by the first category of the sorted groupvar. \texttt{sd1()} requires \texttt{sd2()} and may not be combined with \texttt{sd()} or sddiff().

\texttt{sd2(\#)} specifies the standard deviation of the second population or group. When \texttt{sd2()} is specified with by\( (\text{groupvar}) \), the second group is defined by the second category of the sorted groupvar. \texttt{sd2()} requires \texttt{sd1()} and may not be combined with \texttt{sd()} or sddiff().

\texttt{level(\#)} specifies the confidence level, as a percentage, for confidence intervals. The default is \texttt{level(95)} or as set by \texttt{set level}; see [U] 20.8 Specifying the width of confidence intervals.

\texttt{cluster(\texttt{varname})} specifies the variable that identifies clusters. The \texttt{cluster()} option is required to adjust the computation for clustering.

\texttt{rho(\#)} specifies the intraclass correlation for a one-sample test or the common intraclass correlation for a two-sample test. The \texttt{rho()} option is required to adjust the computation for clustering for a one-sample test.

\texttt{rho1(\#)} specifies the intraclass correlation of the first group for a two-sample test using groups. The \texttt{rho()} option or both \texttt{rho1()} and \texttt{rho2()} options are required to adjust the computation for clustering.

\texttt{rho2(\#)} specifies the intraclass correlation of the second group for a two-sample test using groups. The \texttt{rho()} option or both \texttt{rho1()} and \texttt{rho2()} options are required to adjust the computation for clustering.

When by() is used, sd1() and sd2() or sd() is used to specify the population standard deviations of the two groups defined by \texttt{groupvar} for an unpaired two-sample \( z \) test (using groups). By default, a common standard deviation of one, \texttt{sd(1)}, is assumed.

When unpaired is used, sd1() and sd2() or sd() is used to specify the population standard deviations of \texttt{varname1} and \texttt{varname2} for an unpaired two-sample \( z \) test (using variables). By default, a common standard deviation of one, \texttt{sd(1)}, is assumed.

Options corr(), sd1(), and sd2() or corr() and sd() are used for a paired \( z \) test to compute the standard deviation of the differences between paired observations. By default, a common standard
deviation of one, \( sd(1) \), is assumed for both populations. Alternatively, the standard deviation of the differences between paired observations may be supplied directly with the \texttt{sddiff()} option.

### Remarks and examples

Remarks are presented under the following headings:

- **One-sample z test**
- **Two-sample z test**
- **Paired z test**
- **Adjust for clustering**
- **Immediate form**

For the purpose of illustration, we assume that variances are known in all the examples below.

### One-sample z test

#### Example 1

In the first form, \texttt{ztest} tests whether the mean of the sample is equal to a known constant under the assumption of known variance. Assume that we have a sample of 74 automobiles. We know each automobile’s average mileage rating and wish to test whether the overall average for the sample is 20 miles per gallon. We also assume that the population standard deviation is 6.

```stata
use https://www.stata-press.com/data/r16/auto
(1978 Automobile Data)
.ztest mpg==20, sd(6)
```

**One-sample z test**

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>Std. Dev.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>mpg</td>
<td>74</td>
<td>21.2973</td>
<td>.6974858</td>
<td>6</td>
<td>19.93025 22.66434</td>
</tr>
</tbody>
</table>

\[ mean = \text{mean}(mpg) \]
\[ z = 1.8600 \]
\[ \text{Ho: mean} = 20 \]
\[ \text{Ha: mean} < 20 \]
\[ \text{Ha: mean} \neq 20 \]
\[ \text{Ha: mean} > 20 \]
\[ \text{Pr}(Z < z) = 0.9686 \]
\[ \text{Pr}(|Z| > |z|) = 0.0629 \]
\[ \text{Pr}(Z > z) = 0.0314 \]

The \( p \)-value for the two-sided test is 0.0629, so we do not have statistical evidence to reject the null hypothesis that the mean equals 20 at a 5% significance level, but we would reject the null hypothesis at a 10% level.
Two-sample $z$ test

Example 2: Two-sample $z$ test using groups

We are testing the effectiveness of a new fuel additive. We run an experiment in which 12 cars are given the fuel treatment and 12 cars are not. The results of the experiment are as follows:

<table>
<thead>
<tr>
<th>treated</th>
<th>mpg</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>20</td>
</tr>
<tr>
<td>0</td>
<td>23</td>
</tr>
<tr>
<td>0</td>
<td>21</td>
</tr>
<tr>
<td>0</td>
<td>25</td>
</tr>
<tr>
<td>0</td>
<td>18</td>
</tr>
<tr>
<td>0</td>
<td>17</td>
</tr>
<tr>
<td>0</td>
<td>18</td>
</tr>
<tr>
<td>0</td>
<td>24</td>
</tr>
<tr>
<td>0</td>
<td>20</td>
</tr>
<tr>
<td>0</td>
<td>24</td>
</tr>
<tr>
<td>0</td>
<td>23</td>
</tr>
<tr>
<td>0</td>
<td>19</td>
</tr>
<tr>
<td>1</td>
<td>24</td>
</tr>
<tr>
<td>1</td>
<td>25</td>
</tr>
<tr>
<td>1</td>
<td>21</td>
</tr>
<tr>
<td>1</td>
<td>22</td>
</tr>
<tr>
<td>1</td>
<td>23</td>
</tr>
<tr>
<td>1</td>
<td>18</td>
</tr>
<tr>
<td>1</td>
<td>17</td>
</tr>
<tr>
<td>1</td>
<td>28</td>
</tr>
<tr>
<td>1</td>
<td>24</td>
</tr>
<tr>
<td>1</td>
<td>27</td>
</tr>
<tr>
<td>1</td>
<td>21</td>
</tr>
<tr>
<td>1</td>
<td>23</td>
</tr>
</tbody>
</table>

The treated variable is coded as 1 if the car received the fuel treatment and 0 otherwise.

We can test the equality of means of the treated and untreated group by typing

```
use https://www.stata-press.com/data/r16/fuel3
ztest mpg, by(treated) sd(3)
```

<table>
<thead>
<tr>
<th>Group</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>Std. Dev.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>12</td>
<td>21</td>
<td>0.8660254</td>
<td>3</td>
<td>19.30262 22.69738</td>
</tr>
<tr>
<td>1</td>
<td>12</td>
<td>22.75</td>
<td>0.8660254</td>
<td>3</td>
<td>21.05262 24.44738</td>
</tr>
<tr>
<td>diff</td>
<td>12</td>
<td>-1.75</td>
<td>1.224745</td>
<td>3</td>
<td>-4.150456 .6504558</td>
</tr>
</tbody>
</table>

diff = mean(0) - mean(1)  \[ z = -1.4289 \]
Ho: \[ \text{diff} = 0 \]
Ha: \[ \text{diff} < 0 \]  \[ \text{Ha: diff} \neq 0 \]  \[ \text{Ha: diff} > 0 \]
Pr(Z < z) = 0.0765  \[ \text{Pr(|Z|} > |z|\) = 0.1530 \]  \[ \text{Pr(Z} > z)\) = 0.9235 \]

We do not have evidence to reject the null hypothesis that the means of the two groups are equal at a 5% significance level.

In the above, we assumed that the two groups have the same standard deviation of 3. If the standard deviations for the two groups are different, we can specify group-specific standard deviations in options `sd1()` and `sd2()`:
. ztest mpg, by(treated) sd1(2.7) sd2(3.2)

Two-sample z test

<table>
<thead>
<tr>
<th>Group</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>Std. Dev.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>0</td>
<td>12</td>
<td>21</td>
<td>.7794229</td>
<td>2.7</td>
<td>19.47236 22.52764</td>
</tr>
<tr>
<td>1</td>
<td>12</td>
<td>22.75</td>
<td>.9237604</td>
<td>3.2</td>
<td>20.93946 24.56054</td>
</tr>
<tr>
<td>diff</td>
<td>12</td>
<td>-1.75</td>
<td>1.208649</td>
<td>-4.118909</td>
<td>.6189093</td>
</tr>
</tbody>
</table>

\[ \text{diff} = \text{mean}(0) - \text{mean}(1) \quad z = -1.4479 \]

Ho: \( \text{diff} = 0 \)

\begin{align*}
\text{Ha: diff < 0} & \quad \text{Pr}(Z < z) = 0.0738 \\
\text{Ha: diff} & \neq 0 \quad \text{Pr}(|Z| > |z|) = 0.1476 \\
\text{Ha: diff > 0} & \quad \text{Pr}(Z > z) = 0.9262
\end{align*}

Technical note

In two-sample randomized designs, subjects will sometimes refuse the assigned treatment but still be measured for an outcome. In this case, take care to specify the group properly. You might be tempted to let `varname` contain missing where the subject refused and thus let `ztest` drop such observations from the analysis. Zelen (1979) argues that it would be better to specify that the subject belongs to the group in which he or she was randomized, even though such inclusion will dilute the measured effect.

Example 3: Two-sample \( z \) test using variables

There is a second, inferior way to organize the data in the preceding example. We ran a test on 24 cars, 12 without the additive and 12 with. We now create two new variables, `mpg1` and `mpg2`.

\begin{verbatim}
mpg1  mpg2
20    24
23    25
21    21
25    22
18    23
17    18
18    17
24    28
20    24
24    27
23    21
19    23
\end{verbatim}

This method is inferior because it suggests a connection that is not there. There is no link between the car with 20 mpg and the car with 24 mpg in the first row of the data. Each column of data could be arranged in any order. Nevertheless, if our data are organized like this, `ztest` can accommodate us.
Two-sample z test

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>Std. Dev.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>mpg1</td>
<td>12</td>
<td>21</td>
<td>0.8660254</td>
<td>3</td>
<td>19.30262 22.69738</td>
</tr>
<tr>
<td>mpg2</td>
<td>12</td>
<td>22.75</td>
<td>0.8660254</td>
<td>3</td>
<td>21.05262 24.44738</td>
</tr>
<tr>
<td>diff</td>
<td>-1.75</td>
<td>1.224745</td>
<td>-4.150456</td>
<td>0.6504558</td>
<td></td>
</tr>
</tbody>
</table>

\[ \text{diff} = \text{mean(mpg1)} - \text{mean(mpg2)} \]
\[ z = -1.4289 \]

Ho: \( \text{diff} = 0 \)

Ha: \( \text{diff} < 0 \) Ha: \( \text{diff} \neq 0 \) Ha: \( \text{diff} > 0 \)

\[ \text{Pr}(Z < z) = 0.0765 \quad \text{Pr}(|Z| > |z|) = 0.1530 \quad \text{Pr}(Z > z) = 0.9235 \]

---

Paired z test

Example 4

Suppose that the preceding data were actually collected by running a test on 12 cars. Each car was run once with the fuel additive and once without. Our data are stored in the same manner as in example 3, but this time, there is most certainly a connection between the mpg values that appear in the same row. These come from the same car. The variables mpg1 and mpg2 represent mileage without and with the treatment, respectively. Suppose that the two variables have a common standard deviation of 2 and the correlation between them is 0.4.

```
. use https://www.stata-press.com/data/r16/fuel
. ztest mpg1==mpg2, sd(2) corr(0.4)
```

Paired z test

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>Std. Dev.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>mpg1</td>
<td>12</td>
<td>21</td>
<td>0.5773503</td>
<td>2</td>
<td>19.86841 22.13159</td>
</tr>
<tr>
<td>mpg2</td>
<td>12</td>
<td>22.75</td>
<td>0.5773503</td>
<td>2</td>
<td>21.61841 23.88159</td>
</tr>
<tr>
<td>diff</td>
<td>-1.75</td>
<td>0.6324555</td>
<td>2.19089</td>
<td>-2.98959 -0.5104099</td>
<td></td>
</tr>
</tbody>
</table>

\[ \text{mean(diff)} = \text{mean(mpg1)} - \text{mean(mpg2)} \]
\[ z = -2.7670 \]

Ho: \( \text{mean(diff)} = 0 \)

Ha: \( \text{mean(diff)} < 0 \) Ha: \( \text{mean(diff)} \neq 0 \) Ha: \( \text{mean(diff)} > 0 \)

\[ \text{Pr}(Z < z) = 0.0028 \quad \text{Pr}(|Z| > |z|) = 0.0057 \quad \text{Pr}(Z > z) = 0.9972 \]

The \( p \)-value for the two-sided test is 0.0057, so we reject, for example, the null hypothesis that the two means are equal at a 5% significance level.

Equivalently, we could specify directly the standard deviation of the differences between paired observations with the \text{sddiff()} option:
. ztest mpg1==mpg2, sdiff(2.191)

Paired z test

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>Std. Dev.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>diff</td>
<td>12</td>
<td>-1.75</td>
<td>.6324872</td>
<td>2.191</td>
<td>-2.989652 -.5103478</td>
</tr>
</tbody>
</table>

mean(diff) = mean(mpg1 - mpg2)

Ho: mean(diff) = 0
Ha: mean(diff) < 0 Ha: mean(diff) != 0 Ha: mean(diff) > 0
Pr(Z < z) = 0.0028 Pr(|Z| > |z|) = 0.0057 Pr(Z > z) = 0.9972

Adjust for clustering

When observations are not independent and can be grouped into clusters, we need to adjust for clustering in a \( z \) test. For example, in a cluster randomized design, groups of individuals are randomized instead of individuals. To adjust for clustering, we need to specify the cluster identifier variable in the `cluster()` option. In the case of a one-sample \( z \) test, we need to also specify the intraclass correlation in the `rho()` option. In the case of a two-sample \( z \) test, we need to also specify the common population intraclass correlation in the `rho()` option or group-specific population intraclass correlations in the `rho1()` and `rho2()` options.

Example 5: One-sample \( z \) test, adjusting for clusters

Consider data on the SAT score of 75 students from 15 classes, with 5 students in each class. We want to test whether the mean verbal SAT score is different from 600. We assume a known standard deviation of 132 and a known intraclass correlation of 0.7. To perform the test, we specify the options `cluster(class)`, `rho(0.7)`, and `sd(132)`:

. use https://www.stata-press.com/data/r16/sat
    (Fictional SAT data)
. ztest score == 600, cluster(class) rho(0.7) sd(132)

One-sample \( z \) test
    Number of clusters =   15
    Cluster variable: class
    Cluster size =     5
    Intraclass corr. = 0.7000

<table>
<thead>
<tr>
<th>Variable</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>Std. Dev.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>score</td>
<td>75</td>
<td>504.8</td>
<td>29.71222</td>
<td>132</td>
<td>446.5651 563.0349</td>
</tr>
</tbody>
</table>

mean = mean(score)

Ho: mean = 600

Ha: mean < 600 Ha: mean != 600 Ha: mean > 600
Pr(Z < z) = 0.0028 Pr(|Z| > |z|) = 0.0057 Pr(Z > z) = 0.9972

We find statistical evidence to reject the null hypothesis of \( H_0: \mu_{SAT} = 600 \) versus a two-sided alternative \( H_a: \mu_{SAT} \neq 600 \) at the 5% significance level; the \( p \)-value = 0.0014 < 0.05.
Example 6: Two-sample z test using groups, adjusting for clusters

Consider a cluster randomized control trial that studies the effect of additional training of nurses and general practitioners in patient-centered care on the well-being and future disease risk of patients with type 2 diabetes (Kinmonth et al. [1998] and Campbell and Walters [2014]). Practices (practice) are randomly allocated to two groups—one trained to give patient-centered care (intervention group) and another trained to give routine care (comparison or control group). In our analysis, we transform the original bmi using the formula \( \ln(bmi - 14.67355) \) to obtain a variable that is approximately normally distributed, \( \ln\text{bmi} \). We want to test the equality of the means of \( \ln\text{bmi} \) for the two groups. We assume a known common standard deviation of 0.35 and a known common intraclass correlation of 0.028.

To perform the test, we need to specify the \( \text{rho}(0.028) \) and \( \text{sd}(0.35) \) options. We also need to specify the cluster identifier practice in the cluster() option and the group identifier group in the by() option.

```
. use https://www.stata-press.com/data/r16/dcfd_trial
   (BMI data from Diabetes Care from Diagnosis trial (Kinmonth et al., 1998))
. ztest lbmi, by(group) cluster(practice) rho(0.028) sd(0.35)
```

Two-sample z test
Cluster variable: practice

<table>
<thead>
<tr>
<th>Group</th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>Std. Dev.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>Control</td>
<td>102</td>
<td>2.62954</td>
<td>0.0372502</td>
<td>0.35</td>
<td>2.556531 2.702549</td>
</tr>
<tr>
<td>Interv.</td>
<td>138</td>
<td>2.749023</td>
<td>0.0332182</td>
<td>0.35</td>
<td>2.683916 2.81413</td>
</tr>
</tbody>
</table>

\[ \text{diff} = \text{mean(Control)} - \text{mean(Interv.)} \]
\[ z = -2.3940 \]

Ho: \( \text{diff} = 0 \)
Ha: \( \text{diff} < 0 \)
Pr(\(Z < z\)) = 0.0083

We find statistical evidence to reject the null hypothesis of \( H_0: \mu_{\text{diff}} = 0 \) versus a two-sided alternative \( H_a: \mu_{\text{diff}} \neq 0 \) at the 5% significance level; the \( p \)-value = 0.0167 < 0.05.

Immediate form

Example 7: One-sample z test

```
ztesti
```

\( z \)test is like \( z \)test, except that we specify summary statistics rather than variables as arguments. For instance, we are reading an article that reports the mean number of sunspots per month as 62.6 with a standard deviation of 15.8. We assume this standard deviation is the population standard deviation. There are 24 months of data. We wish to test whether the mean is 75:
. ztesti 24 62.6 15.8 75

One-sample z test

<table>
<thead>
<tr>
<th></th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>Std. Dev.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>x</td>
<td>24</td>
<td>62.6</td>
<td>3.225161</td>
<td>15.8</td>
<td>56.2788 68.9212</td>
</tr>
</tbody>
</table>

mean = mean(x)  
Ho: mean = 75
Ha: mean < 75  Ha: mean != 75  Ha: mean > 75
Pr(Z < z) = 0.0001  Pr(|Z| > |z|) = 0.0001  Pr(Z > z) = 0.9999

Example 8: Two-sample z test

There is no immediate form of ztest with paired data because the test is also a function of the covariance, a number unlikely to be reported in any published source. For unpaired data, however, we might type

. ztesti 20 20 5 32 15 4

Two-sample z test

<table>
<thead>
<tr>
<th></th>
<th>Obs</th>
<th>Mean</th>
<th>Std. Err.</th>
<th>Std. Dev.</th>
<th>[95% Conf. Interval]</th>
</tr>
</thead>
<tbody>
<tr>
<td>x</td>
<td>20</td>
<td>20</td>
<td>1.118034</td>
<td>5</td>
<td>17.80869 22.19131</td>
</tr>
<tr>
<td>y</td>
<td>32</td>
<td>15</td>
<td>0.7071068</td>
<td>4</td>
<td>13.6141 16.3859</td>
</tr>
<tr>
<td>diff</td>
<td>5</td>
<td>5</td>
<td>1.322876</td>
<td>2.407211</td>
<td>7.592789</td>
</tr>
</tbody>
</table>

diff = mean(x) - mean(y)  
Ho: diff = 0
Ha: diff < 0  Ha: diff != 0  Ha: diff > 0
Pr(Z < z) = 0.9999  Pr(|Z| > |z|) = 0.0002  Pr(Z > z) = 0.0001

Stored results

One-sample ztest and ztesti store the following in r():

Scalars

- r(N): sample size
- r(mu): sample mean
- r(sd): standard deviation
- r(se): standard error
- r(lb): lower confidence bound of one-sample mean
- r(ub): upper confidence bound of one-sample mean
- r(z): z statistic
- r(p_l): lower one-sided p-value
- r(p): two-sided p-value
- r(p_u): upper one-sided p-value
- r(level): confidence level
Cluster-adjusted one-sample \texttt{ztest} also stores the following in \texttt{r()}:

Scalars
\begin{itemize}
\item[] \texttt{r(K)} \quad \text{number of clusters } K
\item[] \texttt{r(M)} \quad \text{cluster size } M
\item[] \texttt{r(rho)} \quad \text{intraclass correlation}
\item[] \texttt{r(CV\_cluster)} \quad \text{coefficient of variation for cluster sizes}
\end{itemize}

Two-sample \texttt{ztest} and \texttt{ztesti} store the following in \texttt{r()}: 

Scalars
\begin{itemize}
\item[] \texttt{r(N1)} \quad \text{sample size of population one}
\item[] \texttt{r(N2)} \quad \text{sample size of population two}
\item[] \texttt{r(mu1)} \quad \text{sample mean for population one}
\item[] \texttt{r(mu2)} \quad \text{sample mean for population two}
\item[] \texttt{r(mu\_diff)} \quad \text{difference of means}
\item[] \texttt{r(corr)} \quad \text{correlation between paired observations; if the \texttt{corr()} option is specified}
\item[] \texttt{r(sd)} \quad \text{common standard deviation}
\item[] \texttt{r(sd1)} \quad \text{standard deviation for population one}
\item[] \texttt{r(sd2)} \quad \text{standard deviation for population two}
\item[] \texttt{r(sd\_diff)} \quad \text{standard deviation of the differences between paired observations}
\item[] \texttt{r(se1)} \quad \text{standard error of population-one sample mean}
\item[] \texttt{r(se2)} \quad \text{standard error of population-two sample mean}
\item[] \texttt{r(se\_diff)} \quad \text{standard error of the difference of means}
\item[] \texttt{r(lb1)} \quad \text{lower confidence bound of population-one sample mean}
\item[] \texttt{r(ub1)} \quad \text{upper confidence bound of population-one sample mean}
\item[] \texttt{r(lb2)} \quad \text{lower confidence bound of population-two sample mean}
\item[] \texttt{r(ub2)} \quad \text{upper confidence bound of population-two sample mean}
\item[] \texttt{r(lb\_diff)} \quad \text{lower confidence bound of the difference of means}
\item[] \texttt{r(ub\_diff)} \quad \text{upper confidence bound of the difference of means}
\item[] \texttt{r(z)} \quad \text{z statistic}
\item[] \texttt{r(p\_l)} \quad \text{lower one-sided } p\text{-value}
\item[] \texttt{r(p)} \quad \text{two-sided } p\text{-value}
\item[] \texttt{r(p\_u)} \quad \text{upper one-sided } p\text{-value}
\item[] \texttt{r(level)} \quad \text{confidence level}
\end{itemize}

Cluster-adjusted two-sample \texttt{ztest} using the \texttt{by()} option also stores the following in \texttt{r()}:

Scalars
\begin{itemize}
\item[] \texttt{r(K1)} \quad \text{population-one number of clusters } K_1
\item[] \texttt{r(K2)} \quad \text{population-two number of clusters } K_2
\item[] \texttt{r(M1)} \quad \text{population-one cluster size } M_1
\item[] \texttt{r(M2)} \quad \text{population-two cluster size } M_2
\item[] \texttt{r(rho)} \quad \text{common intraclass correlation}
\item[] \texttt{r(rho1)} \quad \text{population-one intraclass correlation}
\item[] \texttt{r(rho2)} \quad \text{population-two intraclass correlation}
\item[] \texttt{r(CV\_cluster1)} \quad \text{population-one coefficient of variation for cluster sizes}
\item[] \texttt{r(CV\_cluster2)} \quad \text{population-two coefficient of variation for cluster sizes}
\end{itemize}

\section*{Methods and formulas}

Methods and formulas are presented under the following headings:

- \textit{One-sample z test}
- \textit{Two-sample unpaired z test}
- \textit{Paired z test}
For all the tests below, the test statistic $z$ is distributed as standard normal, and the $p$-value is computed as

$$p = \begin{cases} 
1 - \Phi(z) & \text{for an upper one-sided test} \\
\Phi(z) & \text{for a lower one-sided test} \\
2 \{1 - \Phi(|z|)\} & \text{for a two-sided test}
\end{cases}$$

where $\Phi(\cdot)$ is the cdf of a standard normal distribution and $|z|$ is an absolute value of $z$.

Also see, for instance, Hoel (1984, 140–161), Dixon and Massey (1983, 100–130), and Tamhane and Dunlop (2000, 237–290) for more information about $z$ tests.

One-sample $z$ test

Suppose that we observe a random sample $x_1, x_2, \ldots, x_n$ of size $n$, which follows a normal distribution with mean $\mu$ and standard deviation $\sigma$. We are interested in testing the null hypothesis $H_0: \mu = \mu_0$ versus the two-sided alternative hypothesis $H_a: \mu \neq \mu_0$, the upper one-sided alternative $H_a: \mu > \mu_0$, or the lower one-sided alternative $H_a: \mu < \mu_0$. Assuming a known standard deviation $\sigma$, we use the following test statistic,

$$z = \frac{\bar{x} - \mu_0}{s}$$

where $\bar{x} = (\sum_{i=1}^{n} x_i)/n$ is the sample mean and $s = \sigma/\sqrt{n}$ is the standard error of $\bar{x}$.

The $100(1 - \alpha)%$ confidence interval for $\bar{x}$ is given by

$$\bar{x} \pm z_{1-\alpha/2}s$$

where $z_{1-\alpha/2}$ is the $(1 - \alpha/2)$th quantile of the standard normal distribution.

With clustered data, suppose that there are $K$ clusters. The $i$th cluster of size $M_i$ contains the observations $x_{i1}, x_{i2}, \ldots, x_{iM_i}$, such that $n = \sum_{i=1}^{K} M_i$ and $\bar{x} = \frac{1}{n} \sum_{i=1}^{K} \sum_{j=1}^{M_i} x_{ij}$. Let $\rho$ be the intraclass correlation. Following Ahn, Heo, and Zhang (2015), we assume that the cluster sizes $M_i$ are independent and identically distributed. Let $C_{adj}$ be the adjustment to the standard error for clustered data,

$$C_{adj} = \sqrt{\sum_{i=1}^{K} M_i \{1 + \rho(M_i - 1)\}/n}$$

such that $s_{cl} = C_{adj}s$.

$C_{adj}$ can be equivalently written as

$$C_{adj} = \sqrt{1 + \rho(\bar{M} - 1) + \rho \bar{M} CV_{cl}^2}$$

where $\bar{M} = \sum_{i=1}^{K} M_i/K$ is the average cluster size and $CV_{cl}$ is the coefficient of variation for cluster sizes:

$$CV_{cl} = \sqrt{\frac{\sum_{i=1}^{K} (M_i - \bar{M})^2/K}{\bar{M}}}$$
To adjust the test statistic $z$ and the confidence interval for clustering, replace $s$ with $s_{cl}$ in the corresponding formulas. In the presence of clustering, the test statistic $z$ is asymptotically normally distributed conditional on the empirical distribution of $M_i$'s.

### Two-sample unpaired z test

Suppose that we observe a random sample $x_{11}, x_{12}, \ldots, x_{1n_1}$ of size $n_1$, which follows a normal distribution with mean $\mu_1$ and standard deviation $\sigma_1$, and another random sample $x_{21}, x_{22}, \ldots, x_{2n_2}$ of size $n_2$, which follows a normal distribution with mean $\mu_2$ and standard deviation $\sigma_2$. We are interested in testing the null hypothesis $H_0: \mu_2 = \mu_1$ versus the two-sided alternative hypothesis $H_a: \mu_2 \neq \mu_1$, the upper one-sided alternative $H_a': \mu_2 > \mu_1$, or the lower one-sided alternative $H_a: \mu_2 < \mu_1$. Assuming known standard deviations $\sigma_1$ and $\sigma_2$, we use the following test statistic,

$$z = \frac{\bar{x}_2 - \bar{x}_1}{\sqrt{s_1^2 + s_2^2}}$$

where $\bar{x}_1 = (\sum_{i=1}^{n_1} x_{1i})/n_1$ and $\bar{x}_2 = (\sum_{i=1}^{n_2} x_{2i})/n_2$ are the two sample means and $s_1 = \sigma_1/\sqrt{n_1}$ and $s_2 = \sigma_2/\sqrt{n_2}$ are the corresponding two standard errors.

The 100$(1 - \alpha)%$ confidence intervals for $\bar{x}_1$ and $\bar{x}_2$ are given by

$$\bar{x}_1 \pm z_{1-\alpha/2}s_1$$
$$\bar{x}_2 \pm z_{1-\alpha/2}s_2$$

where $z_{1-\alpha/2}$ is the $(1 - \alpha/2)$th quantile of the standard normal distribution.

The 100$(1 - \alpha)%$ confidence interval for $\bar{x}_1 - \bar{x}_2$ is given by

$$\bar{x}_1 - \bar{x}_2 \pm z_{1-\alpha/2}\sqrt{s_1^2 + s_2^2}$$

With clustered data, similar to the discussion for the one-sample test, suppose that population one has $K_1$ clusters and population two has $K_2$ clusters. Let $\rho_1$ and $\rho_2$ be the intraclass correlations, $\bar{M}_1$ and $\bar{M}_2$ be the average cluster sizes, $\bar{x}_1 = (1/n_1) \sum_{i=1}^{K_1} \sum_{j=1}^{M_{1i}} x_{1ij}$ and $\bar{x}_2 = (1/n_2) \sum_{i=1}^{K_2} \sum_{j=1}^{M_{2i}} x_{2ij}$ be the sample means, and $\text{CV}_{cl,1}$ and $\text{CV}_{cl,2}$ be the coefficients of variation for cluster sizes for population one and population two. Let $s_{1,cl} = C_{adj,1} s_1$ and $s_{2,cl} = C_{adj,2} s_2$ be the standard errors of the population-specific sample means adjusted for clustered data, where the population-specific adjustment factors are defined as described for the one-sample test. To adjust the two-sample test statistic and the confidence intervals for clustering, replace $s_1$ with $s_{1,cl}$ and $s_2$ with $s_{2,cl}$ in the corresponding formulas.

### Paired z test

Some experiments have paired observations (also known as matched observations, correlated pairs, or permanent components). Consider a sequence of $n$ paired observations denoted by $x_{ij}$ for subjects $i = 1, 2, \ldots, n$ and groups $j = 1, 2$. An individual observation corresponds to the pair $(x_{i1}, x_{i2})$, and inference is made on the differences within the pairs. Let $\mu_d = \mu_2 - \mu_1$ denote the mean difference, where $\mu_j$ is the population mean of group $j$, and let $D_i = x_{i2} - x_{i1}$ denote the difference between individual observations. $D_i$ follows a normal distribution with mean $\mu_d$ and standard deviation $\sigma_d$, where $\sigma_d = \sqrt{\sigma_1^2 + \sigma_2^2 - 2\rho_{pair}\sigma_1\sigma_2}$, $\sigma_j$ is the population standard deviation of group $j$ and $\rho_{pair}$ is the correlation between paired observations.
We are interested in testing the null hypothesis $H_0: \mu_2 = \mu_1$ versus the two-sided alternative hypothesis $H_a: \mu_2 \neq \mu_1$, the upper one-sided alternative $H_a: \mu_2 > \mu_1$, or the lower one-sided alternative $H_a: \mu_2 < \mu_1$. Assuming the standard deviation of the differences $\sigma_d$ is known, we use the following test statistic,

$$z = \frac{\bar{d}}{s_d}$$

where $\bar{d} = (\sum_{i=1}^{n} D_i)/n$ is the sample mean of the differences between paired observations and $s_d = \sigma_d/\sqrt{n}$ is the standard error of $\bar{d}$.

The $100(1 - \alpha)\%$ confidence interval for $\bar{d}$ is given by

$$\bar{d} \pm z_{1-\alpha/2} s_d$$
